# Preface

**Artificial Intelligence** (AI) is a big field, and this is a big book. We have tried to explore the full breadth of the field, which encompasses logic, probability, and continuous mathematics; perception, reasoning, learning, and action; fairness, trust, social good, and safety; and applications that range from microelectronic devices to robotic planetary explorers to online services with billions of users.

The subtitle of this book is “A Modern Approach.” That means we have chosen to tell the story from a current perspective. We synthesize what is now known into a common framework, recasting early work using the ideas and terminology that are prevalent today. We apologize to those whose subfields are, as a result, less recognizable.

## New to this edition

This edition reflects the changes in AI since the last edition in 2010:

- We focus more on machine learning rather than hand-crafted knowledge engineering, due to the increased availability of data, computing resources, and new algorithms.
- Deep learning, probabilistic programming, and multiagent systems receive expanded coverage, each with their own chapter.
- The coverage of natural language understanding, robotics, and computer vision has been revised to reflect the impact of deep learning.
- The robotics chapter now includes robots that interact with humans and the application of reinforcement learning to robotics.
- Previously we defined the goal of AI as creating systems that try to maximize expected utility, where the specific utility information—the objective—is supplied by the human designers of the system. Now we no longer assume that the objective is fixed and known by the AI system; instead, the system may be uncertain about the true objectives of the humans on whose behalf it operates. It must learn what to maximize and must function appropriately even while uncertain about the objective.
- We increase coverage of the impact of AI on society, including the vital issues of ethics, fairness, trust, and safety.
- We have moved the exercises from the end of each chapter to an online site. This allows us to continuously add to, update, and improve the exercises, to meet the needs of instructors and to reflect advances in the field and in AI-related software tools.
- Overall, about 25% of the material in the book is brand new. The remaining 75% has been largely rewritten to present a more unified picture of the field. 22% of the citations in this edition are to works published after 2010.

## Overview of the book

The main unifying theme is the idea of an **intelligent agent**. We define AI as the study of agents that receive percepts from the environment and perform actions. Each such agent implements a function that maps percept sequences to actions, and we cover different ways to represent these functions, such as reactive agents, real-time planners, decision-theoretic

systems, and deep learning systems. We emphasize learning both as a construction method for competent systems and as a way of extending the reach of the designer into unknown environments. We treat robotics and vision not as independently defined problems, but as occurring in the service of achieving goals. We stress the importance of the task environment in determining the appropriate agent design.

Our primary aim is to convey the *ideas* that have emerged over the past seventy years of AI research and the past two millennia of related work. We have tried to avoid excessive formality in the presentation of these ideas, while retaining precision. We have included mathematical formulas and pseudocode algorithms to make the key ideas concrete; mathematical concepts and notation are described in Appendix A and our pseudocode is described in Appendix B.

This book is primarily intended for use in an undergraduate course or course sequence. The book has 29 chapters, each requiring about a week's worth of lectures, so working through the whole book requires a two-semester sequence. A one-semester course can use selected chapters to suit the interests of the instructor and students. The book can also be used in a graduate-level course (perhaps with the addition of some of the primary sources suggested in the bibliographical notes), or for self-study or as a reference.

Term

Throughout the book, *important points* are marked with a triangle icon in the margin. Wherever a new **term** is defined, it is also noted in the margin. Subsequent significant uses of the **term** are in bold, but not in the margin. We have included a comprehensive index and an extensive bibliography.

The only prerequisite is familiarity with basic concepts of computer science (algorithms, data structures, complexity) at a sophomore level. Freshman calculus and linear algebra are useful for some of the topics.

## Online resources

Online resources are available through [pearsonglobaleditions.com](http://pearsonglobaleditions.com). There you will find:

- Exercises, programming projects, and research projects. These are no longer at the end of each chapter; they are online only. Within the book, we refer to an online exercise with a name like “Exercise 6.NARY.” Instructions on the Web site allow you to find exercises by name or by topic.
- Implementations of the algorithms in the book in Python, Java, and other programming languages.
- Supplementary material and links for students and instructors.
- Instructions on how to report errors in the book in the likely event that some exist.

## Book cover

The cover depicts the final position from the decisive game 6 of the 1997 chess match in which the program Deep Blue defeated Garry Kasparov (playing Black), making this the first time a computer had beaten a world champion in a chess match. Kasparov is shown at the top. To his right is a pivotal position from the second game of the historic Go match between former world champion Lee Sedol and DeepMind’s ALPHAGO program. Move 37 by ALPHAGO violated centuries of Go orthodoxy and was immediately seen by human experts

as an embarrassing mistake, but it turned out to be a winning move. At top left is an Atlas humanoid robot built by Boston Dynamics. A depiction of a self-driving car sensing its environment appears between Ada Lovelace, the world's first computer programmer, and Alan Turing, whose fundamental work defined artificial intelligence. At the bottom of the chess board are a Mars Exploration Rover robot and a statue of Aristotle, who pioneered the study of logic; his planning algorithm from *De Motu Animalium* appears behind the authors' names. Behind the chess board is a probabilistic programming model used by the UN Comprehensive Nuclear-Test-Ban Treaty Organization for detecting nuclear explosions from seismic signals.

## Acknowledgments

It takes a global village to make a book. Over 600 people read parts of the book and made suggestions for improvement. The complete list is at [pearsonglobaleditions.com](http://pearsonglobaleditions.com); we are grateful to all of them. We have space here to mention only a few especially important contributors. First the contributing writers:

- Judea Pearl (Section 13.5, Causal Networks);
- Michael Wooldridge (Chapter 17, Multiagent Decision Making);
- Vikash Mansinghka (Section 18.4, Programs as Probability Models);
- Ian Goodfellow (Chapter 22, Deep Learning);
- Jacob Devlin and Mei-Wing Chang (Chapter 25, Deep Learning for Natural Language Processing);
- Anca Dragan (Chapter 26, Robotics);
- Jitendra Malik and David Forsyth (Chapter 27, Computer Vision).

Then some key roles:

- Cynthia Yeung and Malika Cantor (project management);
- Julie Sussman and Tom Galloway (copyediting and writing suggestions);
- Omari Stephens (illustrations);
- Tracy Johnson (editor);
- Erin Ault and Rose Kernan (cover and color conversion);
- Nalin Chhibber, Sam Goto, Raymond de Lacaze, Ravi Mohan, Ciaran O'Reilly, Amit Patel, Dragomir Radiv, and Samagra Sharma (online code development and mentoring);
- Google Summer of Code students (online code development).

**Stuart would like to thank** his wife, Loy Sheflott, for her endless patience and boundless wisdom. He hopes that Gordon, Lucy, George, and Isaac will soon be reading this book after they have forgiven him for working so long on it. RUGS (Russell's Unusual Group of Students) have been unusually helpful, as always.

**Peter would like to thank** his parents (Torsten and Gerda) for getting him started, and his wife (Kris), children (Bella and Juliet), colleagues, boss, and friends for encouraging and tolerating him through the long hours of writing and rewriting.

# About the Authors

**Stuart Russell** was born in 1962 in Portsmouth, England. He received his B.A. with first-class honours in physics from Oxford University in 1982, and his Ph.D. in computer science from Stanford in 1986. He then joined the faculty of the University of California at Berkeley, where he is a professor and former chair of computer science, director of the Center for Human-Compatible AI, and holder of the Smith-Zadeh Chair in Engineering. In 1990, he received the Presidential Young Investigator Award of the National Science Foundation, and in 1995 he was cowinner of the Computers and Thought Award. He is a Fellow of the American Association for Artificial Intelligence, the Association for Computing Machinery, and the American Association for the Advancement of Science, an Honorary Fellow of Wadham College, Oxford, and an Andrew Carnegie Fellow. He held the Chaire Blaise Pascal in Paris from 2012 to 2014. He has published over 300 papers on a wide range of topics in artificial intelligence. His other books include *The Use of Knowledge in Analogy and Induction*, *Do the Right Thing: Studies in Limited Rationality* (with Eric Wefald), and *Human Compatible: Artificial Intelligence and the Problem of Control*.

**Peter Norvig** is currently a Director of Research at Google, Inc., and was previously the director responsible for the core Web search algorithms. He co-taught an online AI class that signed up 160,000 students, helping to kick off the current round of massive open online classes. He was head of the Computational Sciences Division at NASA Ames Research Center, overseeing research and development in artificial intelligence and robotics. He received a B.S. in applied mathematics from Brown University and a Ph.D. in computer science from Berkeley. He has been a professor at the University of Southern California and a faculty member at Berkeley and Stanford. He is a Fellow of the American Association for Artificial Intelligence, the Association for Computing Machinery, the American Academy of Arts and Sciences, and the California Academy of Science. His other books are *Paradigms of AI Programming: Case Studies in Common Lisp*, *Verbmobil: A Translation System for Face-to-Face Dialog*, and *Intelligent Help Systems for UNIX*.

The two authors shared the inaugural AAAI/EAAI Outstanding Educator award in 2016.

# Contents

## I Artificial Intelligence

<b>1</b>	<b>Introduction</b>	<b>19</b>
1.1	What Is AI? . . . . .	19
1.2	The Foundations of Artificial Intelligence . . . . .	23
1.3	The History of Artificial Intelligence . . . . .	35
1.4	The State of the Art . . . . .	45
1.5	Risks and Benefits of AI . . . . .	49
	Summary . . . . .	52
	Bibliographical and Historical Notes . . . . .	53
<b>2</b>	<b>Intelligent Agents</b>	<b>54</b>
2.1	Agents and Environments . . . . .	54
2.2	Good Behavior: The Concept of Rationality . . . . .	57
2.3	The Nature of Environments . . . . .	60
2.4	The Structure of Agents . . . . .	65
	Summary . . . . .	78
	Bibliographical and Historical Notes . . . . .	78

## II Problem-solving

<b>3</b>	<b>Solving Problems by Searching</b>	<b>81</b>
3.1	Problem-Solving Agents . . . . .	81
3.2	Example Problems . . . . .	84
3.3	Search Algorithms . . . . .	89
3.4	Uninformed Search Strategies . . . . .	94
3.5	Informed (Heuristic) Search Strategies . . . . .	102
3.6	Heuristic Functions . . . . .	115
	Summary . . . . .	122
	Bibliographical and Historical Notes . . . . .	124
<b>4</b>	<b>Search in Complex Environments</b>	<b>128</b>
4.1	Local Search and Optimization Problems . . . . .	128
4.2	Local Search in Continuous Spaces . . . . .	137
4.3	Search with Nondeterministic Actions . . . . .	140
4.4	Search in Partially Observable Environments . . . . .	144
4.5	Online Search Agents and Unknown Environments . . . . .	152
	Summary . . . . .	159
	Bibliographical and Historical Notes . . . . .	160
<b>5</b>	<b>Constraint Satisfaction Problems</b>	<b>164</b>
5.1	Defining Constraint Satisfaction Problems . . . . .	164
5.2	Constraint Propagation: Inference in CSPs . . . . .	169

5.3	Backtracking Search for CSPs . . . . .	175
5.4	Local Search for CSPs . . . . .	181
5.5	The Structure of Problems . . . . .	183
	Summary . . . . .	187
	Bibliographical and Historical Notes . . . . .	188
<b>6</b>	<b>Adversarial Search and Games</b>	<b>192</b>
6.1	Game Theory . . . . .	192
6.2	Optimal Decisions in Games . . . . .	194
6.3	Heuristic Alpha–Beta Tree Search . . . . .	202
6.4	Monte Carlo Tree Search . . . . .	207
6.5	Stochastic Games . . . . .	210
6.6	Partially Observable Games . . . . .	214
6.7	Limitations of Game Search Algorithms . . . . .	219
	Summary . . . . .	220
	Bibliographical and Historical Notes . . . . .	221
<b>III Knowledge, reasoning, and planning</b>		
<b>7</b>	<b>Logical Agents</b>	<b>226</b>
7.1	Knowledge-Based Agents . . . . .	227
7.2	The Wumpus World . . . . .	228
7.3	Logic . . . . .	232
7.4	Propositional Logic: A Very Simple Logic . . . . .	235
7.5	Propositional Theorem Proving . . . . .	240
7.6	Effective Propositional Model Checking . . . . .	250
7.7	Agents Based on Propositional Logic . . . . .	255
	Summary . . . . .	264
	Bibliographical and Historical Notes . . . . .	265
<b>8</b>	<b>First-Order Logic</b>	<b>269</b>
8.1	Representation Revisited . . . . .	269
8.2	Syntax and Semantics of First-Order Logic . . . . .	274
8.3	Using First-Order Logic . . . . .	283
8.4	Knowledge Engineering in First-Order Logic . . . . .	289
	Summary . . . . .	295
	Bibliographical and Historical Notes . . . . .	296
<b>9</b>	<b>Inference in First-Order Logic</b>	<b>298</b>
9.1	Propositional vs. First-Order Inference . . . . .	298
9.2	Unification and First-Order Inference . . . . .	300
9.3	Forward Chaining . . . . .	304
9.4	Backward Chaining . . . . .	311
9.5	Resolution . . . . .	316
	Summary . . . . .	327
	Bibliographical and Historical Notes . . . . .	328

<b>10 Knowledge Representation</b>	<b>332</b>
10.1 Ontological Engineering . . . . .	332
10.2 Categories and Objects . . . . .	335
10.3 Events . . . . .	340
10.4 Mental Objects and Modal Logic . . . . .	344
10.5 Reasoning Systems for Categories . . . . .	347
10.6 Reasoning with Default Information . . . . .	351
Summary . . . . .	355
Bibliographical and Historical Notes . . . . .	356
<b>11 Automated Planning</b>	<b>362</b>
11.1 Definition of Classical Planning . . . . .	362
11.2 Algorithms for Classical Planning . . . . .	366
11.3 Heuristics for Planning . . . . .	371
11.4 Hierarchical Planning . . . . .	374
11.5 Planning and Acting in Nondeterministic Domains . . . . .	383

# CHAPTER 1

## INTRODUCTION

*In which we try to explain why we consider artificial intelligence to be a subject most worthy of study, and in which we try to decide what exactly it is, this being a good thing to decide before embarking.*

We call ourselves *Homo sapiens*—man the wise—because our **intelligence** is so important to us. For thousands of years, we have tried to understand *how we think and act*—that is, how our brain, a mere handful of matter, can perceive, understand, predict, and manipulate a world far larger and more complicated than itself. The field of **artificial intelligence**, or **AI**, is concerned with not just understanding but also *building* intelligent entities—machines that can compute how to act effectively and safely in a wide variety of novel situations.

Surveys regularly rank AI as one of the most interesting and fastest-growing fields, and it is already generating over a trillion dollars a year in revenue. AI expert **Kai-Fu Lee** predicts that its impact will be “*more than anything in the history of mankind*.” Moreover, the intellectual frontiers of AI are wide open. Whereas a student of an older science such as physics might feel that the best ideas have already been discovered by Galileo, Newton, Curie, Einstein, and the rest, AI still has many openings for full-time masterminds.

AI currently encompasses a huge variety of subfields, ranging from the general (learning, reasoning, perception, and so on) to the specific, such as playing chess, proving mathematical theorems, writing poetry, driving a car, or diagnosing diseases. AI is relevant to any intellectual task; it is truly a universal field.

### 1.1 What Is AI?

We have claimed that AI is interesting, but we have not said what it *is*. Historically, researchers have pursued several different versions of AI. Some have defined intelligence in terms of fidelity to *human* performance, while others prefer an abstract, formal definition of intelligence called **rationality**—loosely speaking, doing the “right thing.” The subject matter itself also varies: some consider intelligence to be a property of *internal thought processes* and *reasoning*, while others focus on intelligent *behavior*, an external characterization.<sup>1</sup>

From these two dimensions—*human* vs. *rational*<sup>2</sup> and *thought* vs. *behavior*—there are four possible combinations, and there have been adherents and research programs for all

<sup>1</sup> In the public eye, there is sometimes confusion between the terms “artificial intelligence” and “machine learning.” Machine learning is a subfield of AI that studies the ability to improve performance based on experience. Some AI systems use machine learning methods to achieve competence, but some do not.

<sup>2</sup> We are not suggesting that humans are “irrational” in the dictionary sense of “deprived of normal mental clarity.” We are merely conceding that human decisions are not always mathematically perfect.

four. The methods used are necessarily different: the pursuit of human-like intelligence must be in part an empirical science related to psychology, involving observations and hypotheses about actual human behavior and thought processes; a rationalist approach, on the other hand, involves a combination of mathematics and engineering, and connects to statistics, control theory, and economics. The various groups have both disparaged and helped each other. Let us look at the four approaches in more detail.

### 1.1.1 Acting humanly: The Turing test approach

Turing test

The **Turing test**, proposed by Alan Turing (1950), was designed as a thought experiment that would sidestep the philosophical vagueness of the question “Can a machine think?” A computer passes the test if a human interrogator, after posing some written questions, cannot tell whether the written responses come from a person or from a computer. Chapter 28 discusses the details of the test and whether a computer would really be intelligent if it passed. For now, we note that programming a computer to pass a rigorously applied test provides plenty to work on. The computer would need the following capabilities:

- **natural language processing** to communicate successfully in a human language;
- **knowledge representation** to store what it knows or hears;
- **automated reasoning** to answer questions and to draw new conclusions;
- **machine learning** to adapt to new circumstances and to detect and extrapolate patterns.

Natural language processing  
Knowledge representation  
Automated reasoning  
Machine learning

Total Turing test  
Computer vision  
Robotics

Turing viewed the *physical* simulation of a person as unnecessary to demonstrate intelligence. However, other researchers have proposed a **total Turing test**, which requires interaction with objects and people in the real world. To pass the total Turing test, a robot will need

- **computer vision** and speech recognition to perceive the world;
- **robotics** to manipulate objects and move about.

These six disciplines compose most of AI. Yet AI researchers have devoted little effort to passing the Turing test, believing that it is more important to study the underlying principles of intelligence. The quest for “artificial flight” succeeded when engineers and inventors stopped imitating birds and started using wind tunnels and learning about aerodynamics. Aeronautical engineering texts do not define the goal of their field as making “machines that fly so exactly like pigeons that they can fool even other pigeons.”

### 1.1.2 Thinking humanly: The cognitive modeling approach

To say that a program thinks like a human, we must know how humans think. We can learn about human thought in three ways:

Introspection  
Psychological experiment  
Brain imaging

- **introspection**—trying to catch our own thoughts as they go by;
- **psychological experiments**—observing a person in action;
- **brain imaging**—observing the brain in action.

Once we have a sufficiently precise theory of the mind, it becomes possible to express the theory as a computer program. If the program’s input–output behavior matches corresponding human behavior, that is evidence that some of the program’s mechanisms could also be operating in humans.

For example, Allen Newell and Herbert Simon, who developed GPS, the “General Problem Solver” (Newell and Simon, 1961), were not content merely to have their program solve

problems correctly. They were more concerned with comparing the sequence and timing of its reasoning steps to those of human subjects solving the same problems. The interdisciplinary field of **cognitive science** brings together computer models from AI and experimental techniques from psychology to construct precise and testable theories of the human mind.

Cognitive science is a fascinating field in itself, worthy of several textbooks and at least one encyclopedia (Wilson and Keil, 1999). We will occasionally comment on similarities or differences between AI techniques and human cognition. Real cognitive science, however, is necessarily based on experimental investigation of actual humans or animals. We will leave that for other books, as we assume the reader has only a computer for experimentation.

In the early days of AI there was often confusion between the approaches. An author would argue that an algorithm performs well on a task and that it is *therefore* a good model of human performance, or vice versa. Modern authors separate the two kinds of claims; this distinction has allowed both AI and cognitive science to develop more rapidly. The two fields fertilize each other, most notably in computer vision, which incorporates neurophysiological evidence into computational models. Recently, the combination of neuroimaging methods combined with machine learning techniques for analyzing such data has led to the beginnings of a capability to “read minds”—that is, to ascertain the semantic content of a person’s inner thoughts. This capability could, in turn, shed further light on how human cognition works.

### 1.1.3 Thinking rationally: The “laws of thought” approach

The Greek philosopher Aristotle was one of the first to attempt to codify “right thinking”—that is, irrefutable reasoning processes. His **syllogisms** provided patterns for argument structures that always yielded correct conclusions when given correct premises. The canonical example starts with *Socrates is a man and all men are mortal* and concludes that *Socrates is mortal*. (This example is probably due to Sextus Empiricus rather than Aristotle.) These laws of thought were supposed to govern the operation of the mind; their study initiated the field called **logic**.

Logicians in the 19th century developed a precise notation for statements about objects in the world and the relations among them. (Contrast this with ordinary arithmetic notation, which provides only for statements about *numbers*.) By 1965, programs could, in principle, solve *any* solvable problem described in logical notation. The so-called **logicist** tradition within artificial intelligence hopes to build on such programs to create intelligent systems.

Logic as conventionally understood requires knowledge of the world that is *certain*—a condition that, in reality, is seldom achieved. We simply don’t know the rules of, say, politics or warfare in the same way that we know the rules of chess or arithmetic. The theory of **probability** fills this gap, allowing rigorous reasoning with uncertain information. In principle, it allows the construction of a comprehensive model of rational thought, leading from raw perceptual information to an understanding of how the world works to predictions about the future. What it does not do, is generate intelligent *behavior*. For that, we need a theory of rational action. Rational thought, by itself, is not enough.

### 1.1.4 Acting rationally: The rational agent approach

An **agent** is just something that acts (*agent* comes from the Latin *agere*, to do). Of course, all computer programs do something, but computer agents are expected to do more: operate autonomously, perceive their environment, persist over a prolonged time period, adapt to

Cognitive science

Syllogism

Logicist

Probability

Agent

## Rational agent

change, and create and pursue goals. A **rational agent** is one that acts so as to achieve the best outcome or, when there is uncertainty, the best expected outcome.

In the “laws of thought” approach to AI, the emphasis was on correct inferences. Making correct inferences is sometimes *part* of being a rational agent, because one way to act rationally is to deduce that a given action is best and then to act on that conclusion. On the other hand, there are ways of acting rationally that cannot be said to involve inference. For example, recoiling from a hot stove is a reflex action that is usually more successful than a slower action taken after careful deliberation.

All the skills needed for the Turing test also allow an agent to act rationally. Knowledge representation and reasoning enable agents to reach good decisions. We need to be able to generate comprehensible sentences in natural language to get by in a complex society. We need learning not only for erudition, but also because it improves our ability to generate effective behavior, especially in circumstances that are new.

The rational-agent approach to AI has two advantages over the other approaches. First, it is more general than the “laws of thought” approach because correct inference is just one of several possible mechanisms for achieving rationality. Second, it is more amenable to scientific development. The standard of rationality is mathematically well defined and completely general. We can often work back from this specification to derive agent designs that provably achieve it—something that is largely impossible if the goal is to imitate human behavior or thought processes.

For these reasons, the rational-agent approach to AI has prevailed throughout most of the field’s history. In the early decades, rational agents were built on logical foundations and formed definite plans to achieve specific goals. Later, methods based on probability theory and machine learning allowed the creation of agents that could make decisions under uncertainty to attain the best expected outcome. In a nutshell, *AI has focused on the study and construction of agents that do the right thing*. What counts as the right thing is defined by the objective that we provide to the agent. This general paradigm is so pervasive that we might call it the **standard model**. It prevails not only in AI, but also in control theory, where a controller minimizes a cost function; in operations research, where a policy maximizes a sum of rewards; in statistics, where a decision rule minimizes a loss function; and in economics, where a decision maker maximizes utility or some measure of social welfare.

We need to make one important refinement to the standard model to account for the fact that perfect rationality—always taking the exactly optimal action—is not feasible in complex environments. The computational demands are just too high. Chapters 6 and 16 deal with the issue of **limited rationality**—acting appropriately when there is not enough time to do all the computations one might like. However, perfect rationality often remains a good starting point for theoretical analysis.

### 1.1.5 Beneficial machines

The standard model has been a useful guide for AI research since its inception, but it is probably not the right model in the long run. The reason is that the standard model assumes that we will supply a fully specified objective to the machine.

For an artificially defined task such as chess or shortest-path computation, the task comes with an objective built in—so the standard model is applicable. As we move into the real world, however, it becomes more and more difficult to specify the objective completely and

## Do the right thing

## Standard model

## Limited rationality

correctly. For example, in designing a self-driving car, one might think that the objective is to reach the destination safely. But driving along any road incurs a risk of injury due to other errant drivers, equipment failure, and so on; thus, a strict goal of safety requires staying in the garage. There is a tradeoff between making progress towards the destination and incurring a risk of injury. How should this tradeoff be made? Furthermore, to what extent can we allow the car to take actions that would annoy other drivers? How much should the car moderate its acceleration, steering, and braking to avoid shaking up the passenger? These kinds of questions are difficult to answer *a priori*. They are particularly problematic in the general area of human–robot interaction, of which the self-driving car is one example.

The problem of achieving agreement between our true preferences and the objective we put into the machine is called the **value alignment problem**: the values or objectives put into the machine must be aligned with those of the human. If we are developing an AI system in the lab or in a simulator—as has been the case for most of the field’s history—there is an easy fix for an incorrectly specified objective: reset the system, fix the objective, and try again. As the field progresses towards increasingly capable intelligent systems that are deployed in the real world, this approach is no longer viable. A system deployed with an incorrect objective will have negative consequences. Moreover, the more intelligent the system, the more negative the consequences.

Returning to the apparently unproblematic example of chess, consider what happens if the machine is intelligent enough to reason and act beyond the confines of the chessboard. In that case, it might attempt to increase its chances of winning by such ruses as hypnotizing or blackmailing its opponent or bribing the audience to make rustling noises during its opponent’s thinking time.<sup>3</sup> It might also attempt to hijack additional computing power for itself. *These behaviors are not “unintelligent” or “insane”; they are a logical consequence of defining winning as the sole objective for the machine.*

It is impossible to anticipate all the ways in which a machine pursuing a fixed objective might misbehave. There is good reason, then, to think that the standard model is inadequate. We don’t want machines that are intelligent in the sense of pursuing *their* objectives; we want them to pursue *our* objectives. If we cannot transfer those objectives perfectly to the machine, then we need a new formulation—one in which the machine is pursuing our objectives, but is necessarily *uncertain* as to what they are. When a machine knows that it doesn’t know the complete objective, it has an incentive to act cautiously, to ask permission, to learn more about our preferences through observation, and to defer to human control. Ultimately, we want agents that are **provably beneficial** to humans. We will return to this topic in Section 1.5.

Value alignment problem

Provably beneficial

## 1.2 The Foundations of Artificial Intelligence

In this section, we provide a brief history of the disciplines that contributed ideas, viewpoints, and techniques to AI. Like any history, this one concentrates on a small number of people, events, and ideas and ignores others that also were important. We organize the history around a series of questions. We certainly would not wish to give the impression that these questions are the only ones the disciplines address or that the disciplines have all been working toward AI as their ultimate fruition.

<sup>3</sup> In one of the first books on chess, Ruy Lopez (1561) wrote, “Always place the board so the sun is in your opponent’s eyes.”

### 1.2.1 Philosophy

- Can formal rules be used to draw valid conclusions?
- How does the mind arise from a physical brain?
- Where does knowledge come from?
- How does knowledge lead to action?

Aristotle (384–322 BCE) was the first to formulate a precise set of laws governing the rational part of the mind. He developed an informal system of syllogisms for proper reasoning, which in principle allowed one to generate conclusions mechanically, given initial premises.

Ramon Llull (c. 1232–1315) devised a system of reasoning published as *Ars Magna* or *The Great Art* (1305). Llull tried to implement his system using an actual mechanical device: a set of paper wheels that could be rotated into different permutations.

Around 1500, Leonardo da Vinci (1452–1519) designed but did not build a mechanical calculator; recent reconstructions have shown the design to be functional. The first known calculating machine was constructed around 1623 by the German scientist Wilhelm Schickard (1592–1635). Blaise Pascal (1623–1662) built the Pascaline in 1642 and wrote that it “produces effects which appear nearer to thought than all the actions of animals.” Gottfried Wilhelm Leibniz (1646–1716) built a mechanical device intended to carry out operations on concepts rather than numbers, but its scope was rather limited. In his 1651 book *Leviathan*, Thomas Hobbes (1588–1679) suggested the idea of a thinking machine, an “artificial animal” in his words, arguing “For what is the heart but a spring; and the nerves, but so many strings; and the joints, but so many wheels.” He also suggested that reasoning was like numerical computation: “For ‘reason’ . . . is nothing but ‘reckoning,’ that is adding and subtracting.”

It’s one thing to say that the mind operates, at least in part, according to logical or numerical rules, and to build physical systems that emulate some of those rules. It’s another to say that the mind itself is such a physical system. René Descartes (1596–1650) gave the first clear discussion of the distinction between mind and matter. He noted that a purely physical conception of the mind seems to leave little room for free will. If the mind is governed entirely by physical laws, then it has no more free will than a rock “deciding” to fall downward. Descartes was a proponent of **dualism**. He held that there is a part of the human mind (or soul or spirit) that is outside of nature, exempt from physical laws. Animals, on the other hand, did not possess this dual quality; they could be treated as machines.

An alternative to dualism is **materialism**, which holds that the brain’s operation according to the laws of physics constitutes the mind. Free will is simply the way that the perception of available choices appears to the choosing entity. The terms **physicalism** and **naturalism** are also used to describe this view that stands in contrast to the supernatural.

Given a physical mind that manipulates knowledge, the next problem is to establish the source of knowledge. The **empiricism** movement, starting with Francis Bacon’s (1561–1626) *Novum Organum*,<sup>4</sup> is characterized by a dictum of John Locke (1632–1704): “Nothing is in the understanding, which was not first in the senses.”

David Hume’s (1711–1776) *A Treatise of Human Nature* (Hume, 1739) proposed what is now known as the principle of **induction**: that general rules are acquired by exposure to repeated associations between their elements.

Dualism

Empiricism

Induction

<sup>4</sup> The *Novum Organum* is an update of Aristotle’s *Organon*, or instrument of thought.

Building on the work of Ludwig Wittgenstein (1889–1951) and Bertrand Russell (1872–1970), the famous Vienna Circle (Sigmund, 2017), a group of philosophers and mathematicians meeting in Vienna in the 1920s and 1930s, developed the doctrine of **logical positivism**.

Logical positivism

This doctrine holds that all knowledge can be characterized by logical theories connected, ultimately, to **observation sentences** that correspond to sensory inputs; thus logical positivism combines rationalism and empiricism.

Observation sentence

The **confirmation theory** of Rudolf Carnap (1891–1970) and Carl Hempel (1905–1997) attempted to analyze the acquisition of knowledge from experience by quantifying the degree of belief that should be assigned to logical sentences based on their connection to observations that confirm or disconfirm them. Carnap's book *The Logical Structure of the World* (1928) was perhaps the first theory of mind as a computational process.

Confirmation theory  
Confirmation theory, developed by Rudolf Carnap and Carl Hempel, aimed to understand how we gain knowledge from our experiences by assigning degrees of belief to statements based on how well they align with observations that support or refute them.

The final element in the philosophical picture of the mind is the connection between knowledge and action. This question is vital to AI because intelligence requires action as well as reasoning. Moreover, only by understanding how actions are justified can we understand how to build an agent whose actions are justifiable (or rational).

Aristotle argued (in *De Motu Animalium*) that actions are justified by a logical connection between goals and knowledge of the action's outcome:

But how does it happen that thinking is sometimes accompanied by action and sometimes not, sometimes by motion, and sometimes not? It looks as if almost the same thing happens as in the case of reasoning and making inferences about unchanging objects. But in that case the end is a speculative proposition ... whereas here the conclusion which results from the two premises is an action. ... I need covering; a cloak is a covering. I need a cloak. What I need, I have to make; I need a cloak. I have to make a cloak. And the conclusion, the "I have to make a cloak," is an action.

In the *Nicomachean Ethics* (Book III. 3, 1112b), Aristotle further elaborates on this topic, suggesting an algorithm:

We deliberate not about ends, but about means. For a doctor does not deliberate whether he shall heal, nor an orator whether he shall persuade, ... They assume the end and consider how and by what means it is attained, and if it seems easily and best produced thereby; while if it is achieved by one means only they consider *how* it will be achieved by this and by what means *this* will be achieved, till they come to the first cause, ... and what is last in the order of analysis seems to be first in the order of becoming. And if we come on an impossibility, we give up the search, e.g., if we need money and this cannot be got; but if a thing appears possible we try to do it.

Aristotle's algorithm was implemented 2300 years later by Newell and Simon in their **General Problem Solver** program. We would now call it a greedy regression planning system (see Chapter 11). Methods based on logical planning to achieve definite goals dominated the first few decades of theoretical research in AI.

Thinking purely in terms of actions achieving goals is often useful but sometimes inapplicable. For example, if there are several different ways to achieve a goal, there needs to be some way to choose among them. More importantly, it may not be possible to achieve a goal with certainty, but some action must still be taken. How then should one decide? Antoine Arnauld (1662), analyzing the notion of rational decisions in gambling, proposed a quantitative formula for maximizing the expected monetary value of the outcome. Later, Daniel Bernoulli (1738) introduced the more general notion of **utility** to capture the internal, subjective value

Utility

of an outcome. The modern notion of rational decision making under uncertainty involves maximizing expected utility, as explained in Chapter 15.

In matters of ethics and public policy, a decision maker must consider the interests of multiple individuals. Jeremy Bentham (1823) and John Stuart Mill (1863) promoted the idea of **utilitarianism**: that rational decision making based on maximizing utility should apply to all spheres of human activity, including public policy decisions made on behalf of many individuals. Utilitarianism is a specific kind of **consequentialism**: the idea that what is right and wrong is determined by the expected outcomes of an action.

In contrast, Immanuel Kant, in 1785, proposed a theory of rule-based or **deontological ethics**, in which “doing the right thing” is determined not by outcomes but by universal social laws that govern allowable actions, such as “don’t lie” or “don’t kill.” Thus, a utilitarian could tell a white lie if the expected good outweighs the bad, but a Kantian would be bound not to, because lying is inherently wrong. Mill acknowledged the value of rules, but understood them as efficient decision procedures compiled from first-principles reasoning about consequences. Many modern AI systems adopt exactly this approach.

### 1.2.2 Mathematics

- What are the formal rules to draw valid conclusions?
- What can be computed?
- How do we reason with uncertain information?

Philosophers staked out some of the fundamental ideas of AI, but the leap to a formal science required the mathematization of logic and probability and the introduction of a new branch of mathematics: computation.

The idea of **formal logic** can be traced back to the philosophers of ancient Greece, India, and China, but its mathematical development really began with the work of George Boole (1815–1864), who worked out the details of propositional, or Boolean, logic (Boole, 1847). In 1879, Gottlob Frege (1848–1925) extended Boole’s logic to include objects and relations, creating the first-order logic that is used today.<sup>5</sup> In addition to its central role in the early period of AI research, first-order logic motivated the work of Gödel and Turing that underpinned computation itself, as we explain below.

The theory of **probability** can be seen as generalizing logic to situations with uncertain information—a consideration of great importance for AI. Gerolamo Cardano (1501–1576) first framed the idea of probability, describing it in terms of the possible outcomes of gambling events. In 1654, Blaise Pascal (1623–1662), in a letter to Pierre Fermat (1601–1665), showed how to predict the future of an unfinished gambling game and assign average payoffs to the gamblers. Probability quickly became an invaluable part of the quantitative sciences, helping to deal with uncertain measurements and incomplete theories. Jacob Bernoulli (1654–1705, uncle of Daniel), Pierre Laplace (1749–1827), and others advanced the theory and introduced new statistical methods. Thomas Bayes (1702–1761) proposed a rule for updating probabilities in the light of new evidence; Bayes’ rule is a crucial tool for AI systems.

The formalization of probability, combined with the availability of data, led to the emergence of **statistics** as a field. One of the first uses was John Graunt’s analysis of Lon-

Utilitarianism

Deontological ethics

Formal logic

Probability

Statistics

---

<sup>5</sup> Frege’s proposed notation for first-order logic—an arcane combination of textual and geometric features—never became popular.

don census data in 1662. Ronald Fisher is considered the first modern statistician (Fisher, 1922). He brought together the ideas of probability, experiment design, analysis of data, and computing—in 1919, he insisted that he couldn’t do his work without a mechanical calculator called the MILLIONAIRE (the first calculator that could do multiplication), even though the cost of the calculator was more than his annual salary (Ross, 2012).

The history of computation is as old as the history of numbers, but the first nontrivial **algorithm** is thought to be Euclid’s algorithm for computing greatest common divisors. The word *algorithm* comes from Muhammad ibn Musa al-Khwarizmi, a 9th century mathematician, whose writings also introduced Arabic numerals and algebra to Europe. Boole and others discussed algorithms for logical deduction, and, by the late 19th century, efforts were under way to formalize general mathematical reasoning as logical deduction.

Kurt Gödel (1906–1978) showed that there exists an effective procedure to prove any true statement in the first-order logic of Frege and Russell, but that first-order logic could not capture the principle of mathematical induction needed to characterize the natural numbers. In 1931, Gödel showed that limits on deduction do exist. His **incompleteness theorem** showed that in any formal theory as strong as Peano arithmetic (the elementary theory of natural numbers), there are necessarily true statements that have no proof within the theory.

This fundamental result can also be interpreted as showing that some functions on the integers cannot be represented by an algorithm—that is, they cannot be computed. This motivated Alan Turing (1912–1954) to try to characterize exactly which functions *are computable*—capable of being computed by an effective procedure. The Church–Turing thesis proposes to identify the general notion of computability with functions computed by a Turing machine (Turing, 1936). Turing also showed that there were some functions that no Turing machine can compute. For example, no machine can tell *in general* whether a given program will return an answer on a given input or run forever.

Although computability is important to an understanding of computation, the notion of **tractability** has had an even greater impact on AI. Roughly speaking, a problem is called intractable if the time required to solve instances of the problem grows exponentially with the size of the instances. The distinction between polynomial and exponential growth in complexity was first emphasized in the mid-1960s (Cobham, 1964; Edmonds, 1965). It is important because exponential growth means that even moderately large instances cannot be solved in any reasonable time.

The theory of **NP-completeness**, pioneered by Cook (1971) and Karp (1972), provides a basis for analyzing the tractability of problems: any problem class to which the class of NP-complete problems can be reduced is likely to be intractable. (Although it has not been proved that NP-complete problems are necessarily intractable, most theoreticians believe it.) These results contrast with the optimism with which the popular press greeted the first computers—“Electronic Super-Brains” that were “Faster than Einstein!” Despite the increasing speed of computers, careful use of resources and necessary imperfection will characterize intelligent systems. Put crudely, the world is an *extremely* large problem instance!

### 1.2.3 Economics

- How should we make decisions in accordance with our preferences?
- How should we do this when others may not go along?
- How should we do this when the payoff may be far in the future?

Algorithm

Incompleteness theorem

Computability

Tractability

NP-completeness

The science of economics originated in 1776, when Adam Smith (1723–1790) published *An Inquiry into the Nature and Causes of the Wealth of Nations*. Smith proposed to analyze economies as consisting of many individual agents attending to their own interests. Smith was not, however, advocating financial greed as a moral position: his earlier (1759) book *The Theory of Moral Sentiments* begins by pointing out that concern for the well-being of others is an essential component of the interests of every individual.

Most people think of economics as being about money, and indeed the first mathematical analysis of decisions under uncertainty, the maximum-expected-value formula of Arnauld (1662), dealt with the monetary value of bets. Daniel Bernoulli (1738) noticed that this formula didn't seem to work well for larger amounts of money, such as investments in maritime trading expeditions. He proposed instead a principle based on maximization of expected utility, and explained human investment choices by proposing that the marginal utility of an additional quantity of money diminished as one acquired more money.

Léon Walras (pronounced “Valrasse”) (1834–1910) gave utility theory a more general foundation in terms of preferences between gambles on any outcomes (not just monetary outcomes). The theory was improved by Ramsey (1931) and later by John von Neumann and Oskar Morgenstern in their book *The Theory of Games and Economic Behavior* (1944). Economics is no longer the study of money; rather it is the study of desires and preferences.

#### Decision theory

**Decision theory**, which combines probability theory with utility theory, provides a formal and complete framework for individual decisions (economic or otherwise) made under uncertainty—that is, in cases where probabilistic descriptions appropriately capture the decision maker's environment. This is suitable for “large” economies where each agent need pay no attention to the actions of other agents as individuals. For “small” economies, the situation is much more like a **game**: the actions of one player can significantly affect the utility of another (either positively or negatively). Von Neumann and Morgenstern's development of **game theory** (see also Luce and Raiffa, 1957) included the surprising result that, for some games, a rational agent should adopt policies that are (or least appear to be) randomized. Unlike decision theory, game theory does not offer an unambiguous prescription for selecting actions. In AI, decisions involving multiple agents are studied under the heading of **multiagent systems** (Chapter 17).

#### Operations research

Economists, with some exceptions, did not address the third question listed above: how to make rational decisions when payoffs from actions are not immediate but instead result from several actions taken *in sequence*. This topic was pursued in the field of **operations research**, which emerged in World War II from efforts in Britain to optimize radar installations, and later found innumerable civilian applications. The work of Richard Bellman (1957) formalized a class of sequential decision problems called **Markov decision processes**, which we study in Chapter 16 and, under the heading of **reinforcement learning**, in Chapter 23.

#### Satisficing

Work in economics and operations research has contributed much to our notion of rational agents, yet for many years AI research developed along entirely separate paths. One reason was the apparent complexity of making rational decisions. The pioneering AI researcher Herbert Simon (1916–2001) won the Nobel Prize in economics in 1978 for his early work showing that models based on **satisficing**—making decisions that are “good enough,” rather than laboriously calculating an optimal decision—gave a better description of actual human behavior (Simon, 1947). Since the 1990s, there has been a resurgence of interest in decision-theoretic techniques for AI.

### 1.2.4 Neuroscience

- How do brains process information?

**Neuroscience** is the study of the nervous system, particularly the brain. Although the exact way in which the brain enables thought is one of the great mysteries of science, the fact that it *does* enable thought has been appreciated for thousands of years because of the evidence that strong blows to the head can lead to mental incapacitation. It has also long been known that human brains are somehow different; in about 335 BCE Aristotle wrote, “Of all the animals, man has the largest brain in proportion to his size.”<sup>6</sup> Still, it was not until the middle of the 18th century that the brain was widely recognized as the seat of consciousness. Before then, candidate locations included the heart and the spleen.

Paul Broca’s (1824–1880) investigation of aphasia (speech deficit) in brain-damaged patients in 1861 initiated the study of the brain’s functional organization by identifying a localized area in the left hemisphere—now called Broca’s area—that is responsible for speech production.<sup>7</sup> By that time, it was known that the brain consisted largely of nerve cells, or **neurons**, but it was not until 1873 that Camillo Golgi (1843–1926) developed a staining technique allowing the observation of individual neurons (see Figure 1.1). This technique was used by Santiago Ramon y Cajal (1852–1934) in his pioneering studies of neuronal organization.<sup>8</sup> It is now widely accepted that cognitive functions result from the electrochemical operation of these structures. That is, *a collection of simple cells can lead to thought, action, and consciousness*. In the pithy words of John Searle (1992), *brains cause minds*.

We now have some data on the mapping between areas of the brain and the parts of the body that they control or from which they receive sensory input. Such mappings are able to change radically over the course of a few weeks, and some animals seem to have multiple maps. Moreover, we do not fully understand how other areas can take over functions when one area is damaged. There is almost no theory on how an individual memory is stored or on how higher-level cognitive functions operate.

The measurement of intact brain activity began in 1929 with the invention by Hans Berger of the electroencephalograph (EEG). The development of functional magnetic resonance imaging (fMRI) (Ogawa *et al.*, 1990; Cabeza and Nyberg, 2001) is giving neuroscientists unprecedentedly detailed images of brain activity, enabling measurements that correspond in interesting ways to ongoing cognitive processes. These are augmented by advances in single-cell electrical recording of neuron activity and by the methods of **optogenetics** (Crick, 1999; Zemelman *et al.*, 2002; Han and Boyden, 2007), which allow both measurement and control of individual neurons modified to be light-sensitive.

The development of **brain-machine interfaces** (Lebedev and Nicolelis, 2006) for both sensing and motor control not only promises to restore function to disabled individuals, but also sheds light on many aspects of neural systems. A remarkable finding from this work is that the brain is able to adjust itself to interface successfully with an external device, treating it in effect like another sensory organ or limb.

<sup>6</sup> It has since been discovered that the tree shrew and some bird species exceed the human brain/body ratio.

<sup>7</sup> Many cite Alexander Hood (1824) as a possible prior source.

<sup>8</sup> Golgi persisted in his belief that the brain’s functions were carried out primarily in a continuous medium in which neurons were embedded, whereas Cajal propounded the “neuronal doctrine.” The two shared the Nobel Prize in 1906 but gave mutually antagonistic acceptance speeches.

**Figure 1.1** The parts of a nerve cell or neuron. Each neuron consists of a cell body, or soma, that contains a cell nucleus. Branching out from the cell body are a number of fibers called dendrites and a single long fiber called the axon. The axon stretches out for a long distance, much longer than the scale in this diagram indicates. Typically, an axon is 1 cm long (100 times the diameter of the cell body), but can reach up to 1 meter. A neuron makes connections with 10 to 100,000 other neurons at junctions called synapses. Signals are propagated from neuron to neuron by a complicated electrochemical reaction. The signals control brain activity in the short term and also enable long-term changes in the connectivity of neurons. These mechanisms are thought to form the basis for learning in the brain. Most information processing goes on in the cerebral cortex, the outer layer of the brain. The basic organizational unit appears to be a column of tissue about 0.5 mm in diameter, containing about 20,000 neurons and extending the full depth of the cortex (about 4 mm in humans).

Singularity

Brains and digital computers have somewhat different properties. Figure 1.2 shows that computers have a cycle time that is a million times faster than a brain. The brain makes up for that with far more storage and interconnection than even a high-end personal computer, although the largest supercomputers match the brain on some metrics. Futurists make much of these numbers, pointing to an approaching **singularity** at which computers reach a superhuman level of performance (Vinge, 1993; Kurzweil, 2005; Doctorow and Stross, 2012), and then rapidly improve themselves even further. But the comparisons of raw numbers are not especially informative. Even with a computer of virtually unlimited capacity, we still require further conceptual breakthroughs in our understanding of intelligence (see Chapter 29). Crudely put, without the right theory, faster machines just give you the wrong answer faster.

### 1.2.5 Psychology

- How do humans and animals think and act?

The origins of scientific psychology are usually traced to the work of the German physicist Hermann von Helmholtz (1821–1894) and his student Wilhelm Wundt (1832–1920). Helmholtz applied the scientific method to the study of human vision, and his *Handbook of Physiological Optics* has been described as “the single most important treatise on the physics and physiology of human vision” (Nalwa, 1993, p.15). In 1879, Wundt opened the first laboratory of experimental psychology, at the University of Leipzig. Wundt insisted on carefully

	Supercomputer	Personal Computer	Human Brain
Computational units	$10^6$ GPUs + CPUs	8 CPU cores	$10^6$ columns
	$10^{15}$ transistors	$10^{10}$ transistors	$10^{11}$ neurons
Storage units	$10^{16}$ bytes RAM	$10^{10}$ bytes RAM	$10^{11}$ neurons
	$10^{17}$ bytes disk	$10^{12}$ bytes disk	$10^{14}$ synapses
Cycle time	$10^{-9}$ sec	$10^{-9}$ sec	$10^{-3}$ sec
Operations/sec	$10^{18}$	$10^{10}$	$10^{17}$

**Figure 1.2** A crude comparison of a leading supercomputer, Summit (Feldman, 2017); a typical personal computer of 2019; and the human brain. Human brain power has not changed much in thousands of years, whereas supercomputers have improved from megaFLOPs in the 1960s to gigaFLOPs in the 1980s, teraFLOPs in the 1990s, petaFLOPs in 2008, and exaFLOPs in 2018 (1 exaFLOP =  $10^{18}$  floating point operations per second).

controlled experiments in which his workers would perform a perceptual or associative task while introspecting on their thought processes. The careful controls went a long way toward making psychology a science, but the subjective nature of the data made it unlikely that experimenters would ever disconfirm their own theories.

Biologists studying animal behavior, on the other hand, lacked introspective data and developed an objective methodology, as described by H. S. Jennings (1906) in his influential work *Behavior of the Lower Organisms*. Applying this viewpoint to humans, the **behaviorism** movement, led by John Watson (1878–1958), rejected *any* theory involving mental processes on the grounds that introspection could not provide reliable evidence. Behaviorists insisted on studying only objective measures of the percepts (or *stimulus*) given to an animal and its resulting actions (or *response*). Behaviorism discovered a lot about rats and pigeons but had less success at understanding humans.

Behaviorism

**Cognitive psychology**, which views the brain as an information-processing device, can be traced back at least to the works of William James (1842–1910). Helmholtz also insisted that perception involved a form of unconscious logical inference. The cognitive viewpoint was largely eclipsed by behaviorism in the United States, but at Cambridge's Applied Psychology Unit, directed by Frederic Bartlett (1886–1969), cognitive modeling was able to flourish. *The Nature of Explanation*, by Bartlett's student and successor Kenneth Craik (1943), forcefully reestablished the legitimacy of such "mental" terms as beliefs and goals, arguing that they are just as scientific as, say, using pressure and temperature to talk about gases, despite gasses being made of molecules that have neither.

Cognitive psychology

Craik specified the three key steps of a knowledge-based agent: (1) the stimulus must be translated into an internal representation, (2) the representation is manipulated by cognitive processes to derive new internal representations, and (3) these are in turn retranslated back into action. He clearly explained why this was a good design for an agent:

If the organism carries a "small-scale model" of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, utilize the knowledge of past events in dealing with the present and future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it. (Craik, 1943)

After Craik's death in a bicycle accident in 1945, his work was continued by Donald Broadbent, whose book *Perception and Communication* (1958) was one of the first works to model psychological phenomena as information processing. Meanwhile, in the United States, the development of computer modeling led to the creation of the field of **cognitive science**. The field can be said to have started at a workshop in September 1956 at MIT—just two months after the conference at which AI itself was “born.”

At the workshop, George Miller presented *The Magic Number Seven*, Noam Chomsky presented *Three Models of Language*, and Allen Newell and Herbert Simon presented *The Logic Theory Machine*. These three influential papers showed how computer models could be used to address the psychology of memory, language, and logical thinking, respectively. It is now a common (although far from universal) view among psychologists that “a cognitive theory should be like a computer program” (Anderson, 1980); that is, it should describe the operation of a cognitive function in terms of the processing of information.

For purposes of this review, we will count the field of **human-computer interaction** (HCI) under psychology. Doug Engelbart, one of the pioneers of HCI, championed the idea of **intelligence augmentation**—IA rather than AI. He believed that computers should augment human abilities rather than automate away human tasks. In 1968, Engelbart’s “mother of all demos” showed off for the first time the computer mouse, a windowing system, hypertext, and video conferencing—all in an effort to demonstrate what human knowledge workers could collectively accomplish with some intelligence augmentation.

Today we are more likely to see IA and AI as two sides of the same coin, with the former emphasizing human control and the latter emphasizing intelligent behavior on the part of the machine. Both are needed for machines to be useful to humans.

### 1.2.6 Computer engineering

- How can we build an efficient computer?

The modern digital electronic computer was invented independently and almost simultaneously by scientists in three countries embattled in World War II. The first *operational* computer was the electromechanical Heath Robinson,<sup>9</sup> built in 1943 by Alan Turing's team for a single purpose: deciphering German messages. In 1943, the same group developed the Colossus, a powerful general-purpose machine based on vacuum tubes.<sup>10</sup> The first operational *programmable* computer was the Z-3, the invention of Konrad Zuse in Germany in 1941. Zuse also invented floating-point numbers and the first high-level programming language, Plankalkül. The first *electronic* computer, the ABC, was assembled by John Atanasoff and his student Clifford Berry between 1940 and 1942 at Iowa State University. Atanasoff's research received little support or recognition; it was the ENIAC, developed as part of a secret military project at the University of Pennsylvania by a team including John Mauchly and J. Presper Eckert, that proved to be the most influential forerunner of modern computers.

Since that time, each generation of computer hardware has brought an increase in speed and capacity and a decrease in price—a trend captured in **Moore's law**. Performance doubled every 18 months or so until around 2005, when power dissipation problems led manufacturers

Intelligence augmentation

Moore's law

<sup>9</sup> A complex machine named after a British cartoonist who depicted whimsical and absurdly complicated contraptions for everyday tasks such as buttering toast.

<sup>10</sup> In the postwar period, Turing wanted to use these computers for AI research—for example, he created an outline of the first chess program (Turing *et al.*, 1953)—but the British government blocked this research.

to start multiplying the number of CPU cores rather than the clock speed. Current expectations are that future increases in functionality will come from massive parallelism—a curious convergence with the properties of the brain. We also see new hardware designs based on the idea that in dealing with an uncertain world, we don’t need 64 bits of precision in our numbers; just 16 bits (as in the `bfloat16` format) or even 8 bits will be enough, and will enable faster processing.

We are just beginning to see hardware tuned for AI applications, such as the graphics processing unit (GPU), tensor processing unit (TPU), and wafer scale engine (WSE). From the 1960s to about 2012, the amount of computing power used to train top machine learning applications followed Moore’s law. Beginning in 2012, things changed: from 2012 to 2018 there was a 300,000-fold increase, which works out to a doubling every 100 days or so (Amodei and Hernandez, 2018). A machine learning model that took a full day to train in 2014 takes only two minutes in 2018 (Ying *et al.*, 2018). Although it is not yet practical, **quantum computing** holds out the promise of far greater accelerations for some important subclasses of AI algorithms.

Of course, there were calculating devices before the electronic computer. The earliest automated machines, dating from the 17th century, were discussed on page 24. The first *programmable* machine was a loom, devised in 1805 by Joseph Marie Jacquard (1752–1834), that used punched cards to store instructions for the pattern to be woven.

In the mid-19th century, Charles Babbage (1792–1871) designed two computing machines, neither of which he completed. The Difference Engine was intended to compute mathematical tables for engineering and scientific projects. It was finally built and shown to work in 1991 (Swade, 2000). Babbage’s Analytical Engine was far more ambitious: it included addressable memory, stored programs based on Jacquard’s punched cards, and conditional jumps. It was the first machine capable of universal computation.

Babbage’s colleague Ada Lovelace, daughter of the poet Lord Byron, understood its potential, describing it as “a thinking or … a reasoning machine,” one capable of reasoning about “all subjects in the universe” (Lovelace, 1843). She also anticipated AI’s hype cycles, writing, “It is desirable to guard against the possibility of exaggerated ideas that might arise as to the powers of the Analytical Engine.” Unfortunately, Babbage’s machines and Lovelace’s ideas were largely forgotten.

AI also owes a debt to the software side of computer science, which has supplied the operating systems, programming languages, and tools needed to write modern programs (and papers about them). But this is one area where the debt has been repaid: work in AI has pioneered many ideas that have made their way back to mainstream computer science, including time sharing, interactive interpreters, personal computers with windows and mice, rapid development environments, the linked-list data type, automatic storage management, and key concepts of symbolic, functional, declarative, and object-oriented programming.

### 1.2.7 Control theory and cybernetics

- How can artifacts operate under their own control?

Ktesibios of Alexandria (c. 250 BCE) built the first self-controlling machine: a water clock with a regulator that maintained a constant flow rate. This invention changed the definition of what an artifact could do. Previously, only living things could modify their behavior in response to changes in the environment. Other examples of self-regulating feedback control

systems include the steam engine governor, created by James Watt (1736–1819), and the thermostat, invented by Cornelis Drebbel (1572–1633), who also invented the submarine. James Clerk Maxwell (1868) initiated the mathematical theory of control systems.

A central figure in the post-war development of **control theory** was Norbert Wiener (1894–1964). Wiener was a brilliant mathematician who worked with Bertrand Russell, among others, before developing an interest in biological and mechanical control systems and their connection to cognition. Like Craik (who also used control systems as psychological models), Wiener and his colleagues Arturo Rosenblueth and Julian Bigelow challenged the behaviorist orthodoxy (Rosenblueth *et al.*, 1943). They viewed purposive behavior as arising from a regulatory mechanism trying to minimize “error”—the difference between current state and goal state. In the late 1940s, Wiener, along with Warren McCulloch, Walter Pitts, and John von Neumann, organized a series of influential conferences that explored the new mathematical and computational models of cognition. Wiener’s book *Cybernetics* (1948) became a bestseller and awoke the public to the possibility of artificially intelligent machines.

Meanwhile, in Britain, W. Ross Ashby pioneered similar ideas (Ashby, 1940). Ashby, Alan Turing, Grey Walter, and others formed the Ratio Club for “those who had Wiener’s ideas before Wiener’s book appeared.” Ashby’s *Design for a Brain* (1948, 1952) elaborated on his idea that intelligence could be created by the use of **homeostatic** devices containing appropriate feedback loops to achieve stable adaptive behavior.

Modern control theory, especially the branch known as stochastic optimal control, has as its goal the design of systems that minimize a **cost function** over time. This roughly matches the standard model of AI: designing systems that behave optimally. Why, then, are AI and control theory two different fields, despite the close connections among their founders? The answer lies in the close coupling between the mathematical techniques that were familiar to the participants and the corresponding sets of problems that were encompassed in each world view. Calculus and matrix algebra, the tools of control theory, lend themselves to systems that are describable by fixed sets of continuous variables, whereas AI was founded in part as a way to escape from these perceived limitations. The tools of logical inference and computation allowed AI researchers to consider problems such as language, vision, and symbolic planning that fell completely outside the control theorist’s purview.

### 1.2.8 Linguistics

- How does language relate to thought?

In 1957, B. F. Skinner published *Verbal Behavior*. This was a comprehensive, detailed account of the behaviorist approach to language learning, written by the foremost expert in the field. But curiously, a review of the book became as well known as the book itself, and served to almost kill off interest in behaviorism. The author of the review was the linguist Noam Chomsky, who had just published a book on his own theory, *Syntactic Structures*. Chomsky pointed out that the behaviorist theory did not address the notion of creativity in language—it did not explain how children could understand and make up sentences that they had never heard before. Chomsky’s theory—based on syntactic models going back to the Indian linguist Panini (c. 350 BCE)—could explain this, and unlike previous theories, it was formal enough that it could in principle be programmed.

Modern linguistics and AI, then, were “born” at about the same time, and grew up together, intersecting in a hybrid field called **computational linguistics** or **natural language**

**processing.** The problem of understanding language turned out to be considerably more complex than it seemed in 1957. Understanding language requires an understanding of the subject matter and context, not just an understanding of the structure of sentences. This might seem obvious, but it was not widely appreciated until the 1960s. Much of the early work in **knowledge representation** (the study of how to put knowledge into a form that a computer can reason with) was tied to language and informed by research in linguistics, which was connected in turn to decades of work on the philosophical analysis of language.

## 1.3 The History of Artificial Intelligence

---

One quick way to summarize the milestones in AI history is to list the Turing Award winners: Marvin Minsky (1969) and John McCarthy (1971) for defining the foundations of the field based on representation and reasoning; Allen Newell and Herbert Simon (1975) for symbolic models of problem solving and human cognition; Ed Feigenbaum and Raj Reddy (1994) for developing expert systems that encode human knowledge to solve real-world problems; Judea Pearl (2011) for developing probabilistic reasoning techniques that deal with uncertainty in a principled manner; and finally Yoshua Bengio, Geoffrey Hinton, and Yann LeCun (2019) for making “deep learning” (multilayer neural networks) a critical part of modern computing. The rest of this section goes into more detail on each phase of AI history.

### 1.3.1 The inception of artificial intelligence (1943–1956)

The first work that is now generally recognized as AI was done by Warren McCulloch and Walter Pitts (1943). Inspired by the mathematical modeling work of Pitts’s advisor Nicolas Rashevsky (1936, 1938), they drew on three sources: knowledge of the basic physiology and function of neurons in the brain; a formal analysis of propositional logic due to Russell and Whitehead; and Turing’s theory of computation. They proposed a model of artificial neurons in which each neuron is characterized as being “on” or “off,” with a switch to “on” occurring in response to stimulation by a sufficient number of neighboring neurons. The state of a neuron was conceived of as “factually equivalent to a proposition which proposed its adequate stimulus.” They showed, for example, that any computable function could be computed by some network of connected neurons, and that all the logical connectives (AND, OR, NOT, etc.) could be implemented by simple network structures. McCulloch and Pitts also suggested that suitably defined networks could learn. Donald Hebb (1949) demonstrated a simple updating rule for modifying the connection strengths between neurons. His rule, now called **Hebbian learning**, remains an influential model to this day.

Two undergraduate students at Harvard, Marvin Minsky (1927–2016) and Dean Edmonds, built the first neural network computer in 1950. The SNARC, as it was called, used 3000 vacuum tubes and a surplus automatic pilot mechanism from a B-24 bomber to simulate a network of 40 neurons. Later, at Princeton, Minsky studied universal computation in neural networks. His Ph.D. committee was skeptical about whether this kind of work should be considered mathematics, but von Neumann reportedly said, “If it isn’t now, it will be someday.”

There were a number of other examples of early work that can be characterized as AI, including two checkers-playing programs developed independently in 1952 by Christopher Strachey at the University of Manchester and by Arthur Samuel at IBM. However, Alan Turing’s vision was the most influential. He gave lectures on the topic as early as 1947 at the London Mathematical Society and articulated a persuasive agenda in his 1950 article “Com-

Hebbian learning

puting Machinery and Intelligence.” Therein, he introduced the Turing test, machine learning, genetic algorithms, and reinforcement learning. He dealt with many of the objections raised to the possibility of AI, as described in Chapter 28. He also suggested that it would be easier to create human-level AI by developing learning algorithms and then teaching the machine rather than by programming its intelligence by hand. In subsequent lectures he warned that achieving this goal might not be the best thing for the human race.

In 1955, John McCarthy of Dartmouth College convinced Minsky, Claude Shannon, and Nathaniel Rochester to help him bring together U.S. researchers interested in automata theory, neural nets, and the study of intelligence. They organized a two-month workshop at Dartmouth in the summer of 1956. There were 10 attendees in all, including Allen Newell and Herbert Simon from Carnegie Tech,<sup>11</sup> Trenchard More from Princeton, Arthur Samuel from IBM, and Ray Solomonoff and Oliver Selfridge from MIT. The proposal states:<sup>12</sup>

We propose that a 2 month, 10 man study of artificial intelligence be carried out during the summer of 1956 at Dartmouth College in Hanover, New Hampshire. The study is to proceed on the basis of the conjecture that every aspect of learning or any other feature of intelligence can in principle be so precisely described that a machine can be made to simulate it. An attempt will be made to find how to make machines use language, form abstractions and concepts, solve kinds of problems now reserved for humans, and improve themselves. We think that a significant advance can be made in one or more of these problems if a carefully selected group of scientists work on it together for a summer.

Despite this optimistic prediction, the Dartmouth workshop did not lead to any breakthroughs. Newell and Simon presented perhaps the most mature work, a mathematical theorem-proving system called the Logic Theorist (LT). Simon claimed, “We have invented a computer program capable of thinking non-numerically, and thereby solved the venerable mind–body problem.”<sup>13</sup> Soon after the workshop, the program was able to prove most of the theorems in Chapter 2 of Russell and Whitehead’s *Principia Mathematica*. Russell was reportedly delighted when told that LT had come up with a proof for one theorem that was shorter than the one in *Principia*. The editors of the *Journal of Symbolic Logic* were less impressed; they rejected a paper coauthored by Newell, Simon, and Logic Theorist.

### 1.3.2 Early enthusiasm, great expectations (1952–1969)

The intellectual establishment of the 1950s, by and large, preferred to believe that “a machine can never do X.” (See Chapter 28 for a long list of X’s gathered by Turing.) AI researchers naturally responded by demonstrating one X after another. They focused in particular on tasks considered indicative of intelligence in humans, including games, puzzles, mathematics, and IQ tests. John McCarthy referred to this period as the “Look, Ma, no hands!” era.

---

<sup>11</sup> Now Carnegie Mellon University (CMU).

<sup>12</sup> This was the first official usage of McCarthy’s term *artificial intelligence*. Perhaps “computational rationality” would have been more precise and less threatening, but “AI” has stuck. At the 50th anniversary of the Dartmouth conference, McCarthy stated that he resisted the terms “computer” or “computational” in deference to Norbert Wiener, who was promoting analog cybernetic devices rather than digital computers.

<sup>13</sup> Newell and Simon also invented a list-processing language, IPL, to write LT. They had no compiler and translated it into machine code by hand. To avoid errors, they worked in parallel, calling out binary numbers to each other as they wrote each instruction to make sure they agreed.

Newell and Simon followed up their success with LT with the General Problem Solver, or GPS. Unlike LT, this program was designed from the start to imitate human problem-solving protocols. Within the limited class of puzzles it could handle, it turned out that the order in which the program considered subgoals and possible actions was similar to that in which humans approached the same problems. Thus, GPS was probably the first program to embody the “thinking humanly” approach. The success of GPS and subsequent programs as models of cognition led Newell and Simon (1976) to formulate the famous **physical symbol system** hypothesis, which states that “a physical symbol system has the necessary and sufficient means for general intelligent action.” What they meant is that any system (human or machine) exhibiting intelligence must operate by manipulating data structures composed of symbols. We will see later that this hypothesis has been challenged from many directions.

Physical symbol system

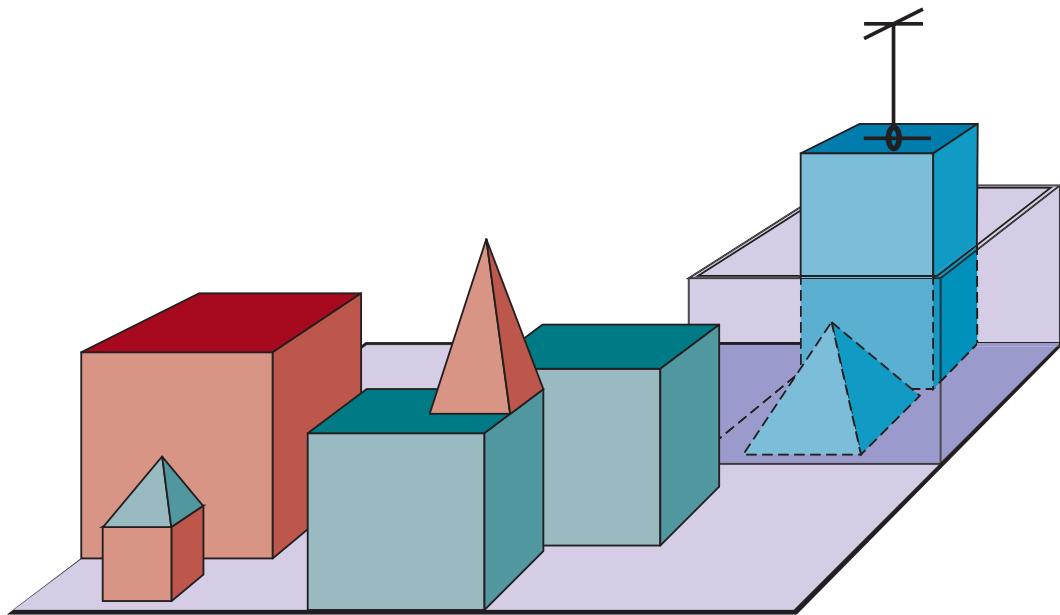

At IBM, Nathaniel Rochester and his colleagues produced some of the first AI programs. Herbert Gelernter (1959) constructed the Geometry Theorem Prover, which was able to prove theorems that many students of mathematics would find quite tricky. This work was a precursor of modern mathematical theorem provers.

Of all the exploratory work done during this period, perhaps the most influential in the long run was that of Arthur Samuel on checkers (draughts). Using methods that we now call reinforcement learning (see Chapter 23), Samuel’s programs learned to play at a strong amateur level. He thereby disproved the idea that computers can do only what they are told to: his program quickly learned to play a better game than its creator. The program was demonstrated on television in 1956, creating a strong impression. Like Turing, Samuel had trouble finding computer time. Working at night, he used machines that were still on the testing floor at IBM’s manufacturing plant. Samuel’s program was the precursor of later systems such as TD-GAMMON (Tesauro, 1992), which was among the world’s best backgammon players, and ALPHAGO (Silver *et al.*, 2016), which shocked the world by defeating the human world champion at Go (see Chapter 6).

In 1958, John McCarthy made two important contributions to AI. In MIT AI Lab Memo No. 1, he defined the high-level language **Lisp**, which was to become the dominant AI programming language for the next 30 years. In a paper entitled *Programs with Common Sense*, he advanced a conceptual proposal for AI systems based on knowledge and reasoning. The paper describes the Advice Taker, a hypothetical program that would embody general knowledge of the world and could use it to derive plans of action. The concept was illustrated with simple logical axioms that suffice to generate a plan to drive to the airport. The program was also designed to accept new axioms in the normal course of operation, thereby allowing it to achieve competence in new areas *without being reprogrammed*. The Advice Taker thus embodied the central principles of knowledge representation and reasoning: that it is useful to have a formal, explicit representation of the world and its workings and to be able to manipulate that representation with deductive processes. The paper influenced the course of AI and remains relevant today.

Lisp

1958 also marked the year that Marvin Minsky moved to MIT. His initial collaboration with McCarthy did not last, however. McCarthy stressed representation and reasoning in formal logic, whereas Minsky was more interested in getting programs to work and eventually developed an anti-logic outlook. In 1963, McCarthy started the AI lab at Stanford. His plan to use logic to build the ultimate Advice Taker was advanced by J. A. Robinson’s discovery in 1965 of the resolution method (a complete theorem-proving algorithm for first-order

**Figure 1.3** A scene from the blocks world. SHRDLU (Winograd, 1972) has just completed the command “Find a block which is taller than the one you are holding and put it in the box.”

logic; see Chapter 9). Work at Stanford emphasized general-purpose methods for logical reasoning. Applications of logic included Cordell Green’s question-answering and planning systems (Green, 1969b) and the Shakey robotics project at the Stanford Research Institute (SRI). The latter project, discussed further in Chapter 26, was the first to demonstrate the complete integration of logical reasoning and physical activity.

At MIT, Minsky supervised a series of students who chose limited problems that appeared to require intelligence to solve. These limited domains became known as **microworlds**. James Slagle’s SAINT program (1963) was able to solve closed-form calculus integration problems typical of first-year college courses. Tom Evans’s ANALOGY program (1968) solved geometric analogy problems that appear in IQ tests. Daniel Bobrow’s STUDENT program (1967) solved algebra story problems, such as the following:

If the number of customers Tom gets is twice the square of 20 percent of the number of advertisements he runs, and the number of advertisements he runs is 45, what is the number of customers Tom gets?

#### Microworld

#### Blocks world

The most famous microworld is the **blocks world**, which consists of a set of solid blocks placed on a tabletop (or more often, a simulation of a tabletop), as shown in Figure 1.3. A typical task in this world is to rearrange the blocks in a certain way, using a robot hand that can pick up one block at a time. The blocks world was home to the vision project of David Huffman (1971), the vision and constraint-propagation work of David Waltz (1975), the learning theory of Patrick Winston (1970), the natural-language-understanding program of Terry Winograd (1972), and the planner of Scott Fahlman (1974).

Early work building on the neural networks of McCulloch and Pitts also flourished. The work of Shmuel Winograd and Jack Cowan (1963) showed how a large number of elements

could collectively represent an individual concept, with a corresponding increase in robustness and parallelism. Hebb's learning methods were enhanced by Bernie Widrow (Widrow and Hoff, 1960; Widrow, 1962), who called his networks **adalines**, and by Frank Rosenblatt (1962) with his **perceptrons**. The **perceptron convergence theorem** (Block *et al.*, 1962) says that the learning algorithm can adjust the connection strengths of a perceptron to match any input data, provided such a match exists.

### 1.3.3 A dose of reality (1966–1973)

From the beginning, AI researchers were not shy about making predictions of their coming successes. The following statement by Herbert Simon in 1957 is often quoted:

It is not my aim to surprise or shock you—but the simplest way I can summarize is to say that there are now in the world machines that think, that learn and that create. Moreover, their ability to do these things is going to increase rapidly until—in a visible future—the range of problems they can handle will be coextensive with the range to which the human mind has been applied.

The term “visible future” is vague, but Simon also made more concrete predictions: that within 10 years a computer would be chess champion and a significant mathematical theorem would be proved by machine. These predictions came true (or approximately true) within 40 years rather than 10. Simon’s overconfidence was due to the promising performance of early AI systems on simple examples. In almost all cases, however, these early systems failed on more difficult problems.

There were two main reasons for this failure. The first was that many early AI systems were based primarily on “informed introspection” as to how humans perform a task, rather than on a careful analysis of the task, what it means to be a solution, and what an algorithm would need to do to reliably produce such solutions.

The second reason for failure was a lack of appreciation of the intractability of many of the problems that AI was attempting to solve. Most of the early problem-solving systems worked by trying out different combinations of steps until the solution was found. This strategy worked initially because microworlds contained very few objects and hence very few possible actions and very short solution sequences. Before the theory of computational complexity was developed, it was widely thought that “scaling up” to larger problems was simply a matter of faster hardware and larger memories. The optimism that accompanied the development of resolution theorem proving, for example, was soon dampened when researchers failed to prove theorems involving more than a few dozen facts. *The fact that a program can find a solution in principle does not mean that the program contains any of the mechanisms needed to find it in practice.*

The illusion of unlimited computational power was not confined to problem-solving programs. Early experiments in **machine evolution** (now called **genetic programming**) (Friedberg, 1958; Friedberg *et al.*, 1959) were based on the undoubtedly correct belief that by making an appropriate series of small mutations to a machine-code program, one can generate a program with good performance for any particular task. The idea, then, was to try random mutations with a selection process to preserve mutations that seemed useful. Despite thousands of hours of CPU time, almost no progress was demonstrated.

Failure to come to grips with the “combinatorial explosion” was one of the main criticisms of AI contained in the Lighthill report (Lighthill, 1973), which formed the basis for the

Machine evolution

decision by the British government to end support for AI research in all but two universities. (Oral tradition paints a somewhat different and more colorful picture, with political ambitions and personal animosities whose description is beside the point.)

A third difficulty arose because of some fundamental limitations on the basic structures being used to generate intelligent behavior. For example, Minsky and Papert's book *Perceptrons* (1969) proved that, although perceptrons (a simple form of neural network) could be shown to learn anything they were capable of representing, they could represent very little. In particular, a two-input perceptron could not be trained to recognize when its two inputs were different. Although their results did not apply to more complex, multilayer networks, research funding for neural-net research soon dwindled to almost nothing. Ironically, the new back-propagation learning algorithms that were to cause an enormous resurgence in neural-net research in the late 1980s and again in the 2010s had already been developed in other contexts in the early 1960s (Kelley, 1960; Bryson, 1962).

### 1.3.4 Expert systems (1969–1986)

**Weak method**

The picture of problem solving that had arisen during the first decade of AI research was of a general-purpose search mechanism trying to string together elementary reasoning steps to find complete solutions. Such approaches have been called **weak methods** because, although general, they do not scale up to large or difficult problem instances. The alternative to weak methods is to use more powerful, domain-specific knowledge that allows larger reasoning steps and can more easily handle typically occurring cases in narrow areas of expertise. One might say that to solve a hard problem, you have to almost know the answer already.

The DENDRAL program (Buchanan *et al.*, 1969) was an early example of this approach. It was developed at Stanford, where Ed Feigenbaum (a former student of Herbert Simon), Bruce Buchanan (a philosopher turned computer scientist), and Joshua Lederberg (a Nobel laureate geneticist) teamed up to solve the problem of inferring molecular structure from the information provided by a mass spectrometer. The input to the program consists of the elementary formula of the molecule (e.g., C<sub>6</sub>H<sub>13</sub>NO<sub>2</sub>) and the mass spectrum giving the masses of the various fragments of the molecule generated when it is bombarded by an electron beam. For example, the mass spectrum might contain a peak at  $m = 15$ , corresponding to the mass of a methyl (CH<sub>3</sub>) fragment.

The naive version of the program generated all possible structures consistent with the formula, and then predicted what mass spectrum would be observed for each, comparing this with the actual spectrum. As one might expect, this is intractable for even moderate-sized molecules. The DENDRAL researchers consulted analytical chemists and found that they worked by looking for well-known patterns of peaks in the spectrum that suggested common substructures in the molecule. For example, the following rule is used to recognize a ketone (C=O) subgroup (which weighs 28):

**if**  $M$  is the mass of the whole molecule and there are two peaks at  $x_1$  and  $x_2$  such that  
 (a)  $x_1 + x_2 = M + 28$ ; (b)  $x_1 - 28$  is a high peak; (c)  $x_2 - 28$  is a high peak; and  
 (d) At least one of  $x_1$  and  $x_2$  is high  
**then** there is a ketone subgroup.

Recognizing that the molecule contains a particular substructure reduces the number of possible candidates enormously. According to its authors, DENDRAL was powerful because it embodied the relevant knowledge of mass spectroscopy not in the form of first principles but

in efficient “cookbook recipes” (Feigenbaum *et al.*, 1971). The significance of DENDRAL was that it was the first successful *knowledge-intensive* system: its expertise derived from large numbers of special-purpose rules. In 1971, Feigenbaum and others at Stanford began the Heuristic Programming Project (HPP) to investigate the extent to which the new methodology of **expert systems** could be applied to other areas.

The next major effort was the MYCIN system for diagnosing blood infections. With about 450 rules, MYCIN was able to perform as well as some experts, and considerably better than junior doctors. It also contained two major differences from DENDRAL. First, unlike the DENDRAL rules, no general theoretical model existed from which the MYCIN rules could be deduced. They had to be acquired from extensive interviewing of experts. Second, the rules had to reflect the uncertainty associated with medical knowledge. MYCIN incorporated a calculus of uncertainty called **certainty factors** (see Chapter 13), which seemed (at the time) to fit well with how doctors assessed the impact of evidence on the diagnosis.

The first successful commercial expert system, R1, began operation at the Digital Equipment Corporation (McDermott, 1982). The program helped configure orders for new computer systems; by 1986, it was saving the company an estimated \$40 million a year. By 1988, DEC’s AI group had 40 expert systems deployed, with more on the way. DuPont had 100 in use and 500 in development. Nearly every major U.S. corporation had its own AI group and was either using or investigating expert systems.

The importance of domain knowledge was also apparent in the area of natural language understanding. Despite the success of Winograd’s SHRDLU system, its methods did not extend to more general tasks: for problems such as ambiguity resolution it used simple rules that relied on the tiny scope of the blocks world.

Several researchers, including Eugene Charniak at MIT and Roger Schank at Yale, suggested that robust language understanding would require general knowledge about the world and a general method for using that knowledge. (Schank went further, claiming, “There is no such thing as syntax,” which upset a lot of linguists but did serve to start a useful discussion.) Schank and his students built a series of programs (Schank and Abelson, 1977; Wilensky, 1978; Schank and Riesbeck, 1981) that all had the task of understanding natural language. The emphasis, however, was less on language *per se* and more on the problems of representing and reasoning with the knowledge required for language understanding.

The widespread growth of applications to real-world problems led to the development of a wide range of representation and reasoning tools. Some were based on logic—for example, the Prolog language became popular in Europe and Japan, and the PLANNER family in the United States. Others, following Minsky’s idea of **frames** (1975), adopted a more structured approach, assembling facts about particular object and event types and arranging the types into a large taxonomic hierarchy analogous to a biological taxonomy.

In 1981, the Japanese government announced the “Fifth Generation” project, a 10-year plan to build massively parallel, intelligent computers running Prolog. The budget was to exceed a \$1.3 billion in today’s money. In response, the United States formed the Microelectronics and Computer Technology Corporation (MCC), a consortium designed to assure national competitiveness. In both cases, AI was part of a broad effort, including chip design and human-interface research. In Britain, the Alvey report reinstated the funding removed by the Lighthill report. However, none of these projects ever met its ambitious goals in terms of new AI capabilities or economic impact.

Expert systems

Certainty factor

Frames

Overall, the AI industry boomed from a few million dollars in 1980 to billions of dollars in 1988, including hundreds of companies building expert systems, vision systems, robots, and software and hardware specialized for these purposes.

Soon after that came a period called the “AI winter,” in which many companies fell by the wayside as they failed to deliver on extravagant promises. It turned out to be difficult to build and maintain expert systems for complex domains, in part because the reasoning methods used by the systems broke down in the face of uncertainty and in part because the systems could not learn from experience.

### 1.3.5 The return of neural networks (1986–present)

In the mid-1980s at least four different groups reinvented the **back-propagation** learning algorithm first developed in the early 1960s. The algorithm was applied to many learning problems in computer science and psychology, and the widespread dissemination of the results in the collection *Parallel Distributed Processing* (Rumelhart and McClelland, 1986) caused great excitement.

Connectionist

These so-called **connectionist** models were seen by some as direct competitors both to the symbolic models promoted by Newell and Simon and to the logicist approach of McCarthy and others. It might seem obvious that at some level humans manipulate symbols—in fact, the anthropologist Terrence Deacon’s book *The Symbolic Species* (1997) suggests that this is the *defining characteristic* of humans. Against this, Geoff Hinton, a leading figure in the resurgence of neural networks in the 1980s and 2010s, has described symbols as the “luminiferous aether of AI”—a reference to the non-existent medium through which many 19th-century physicists believed that electromagnetic waves propagated. Certainly, many concepts that we name in language fail, on closer inspection, to have the kind of logically defined necessary and sufficient conditions that early AI researchers hoped to capture in axiomatic form. It may be that connectionist models form internal concepts in a more fluid and imprecise way that is better suited to the messiness of the real world. They also have the capability to learn from examples—they can compare their predicted output value to the true value on a problem and modify their parameters to decrease the difference, making them more likely to perform well on future examples.

### 1.3.6 Probabilistic reasoning and machine learning (1987–present)

The brittleness of expert systems led to a new, more scientific approach incorporating probability rather than Boolean logic, machine learning rather than hand-coding, and experimental results rather than philosophical claims.<sup>14</sup> It became more common to build on existing theories than to propose brand-new ones, to base claims on rigorous theorems or solid experimental methodology (Cohen, 1995) rather than on intuition, and to show relevance to real-world applications rather than toy examples.

Shared benchmark problem sets became the norm for demonstrating progress, including the UC Irvine repository for machine learning data sets, the International Planning Compe-

---

<sup>14</sup> Some have characterized this change as a victory of the **neats**—those who think that AI theories should be grounded in mathematical rigor—over the **scruffies**—those who would rather try out lots of ideas, write some programs, and then assess what seems to be working. Both approaches are important. A shift toward neatness implies that the field has reached a level of stability and maturity. The present emphasis on deep learning may represent a resurgence of the scruffies.

tition for planning algorithms, the LibriSpeech corpus for speech recognition, the MNIST data set for handwritten digit recognition, ImageNet and COCO for image object recognition, SQuAD for natural language question answering, the WMT competition for machine translation, and the International SAT Competitions for Boolean satisfiability solvers.

AI was founded in part as a rebellion against the limitations of existing fields like control theory and statistics, but in this period it embraced the positive results of those fields. As David McAllester (1998) put it:

In the early period of AI it seemed plausible that new forms of symbolic computation, e.g., frames and semantic networks, made much of classical theory obsolete. This led to a form of isolationism in which AI became largely separated from the rest of computer science. This isolationism is currently being abandoned. There is a recognition that machine learning should not be isolated from information theory, that uncertain reasoning should not be isolated from stochastic modeling, that search should not be isolated from classical optimization and control, and that automated reasoning should not be isolated from formal methods and static analysis.

The field of speech recognition illustrates the pattern. In the 1970s, a wide variety of different architectures and approaches were tried. Many of these were rather ad hoc and fragile, and worked on only a few carefully selected examples. In the 1980s, approaches using **hidden Markov models** (HMMs) came to dominate the area. Two aspects of HMMs are relevant. First, they are based on a rigorous mathematical theory. This allowed speech researchers to build on several decades of mathematical results developed in other fields. Second, they are generated by a process of training on a large corpus of real speech data. This ensures that the performance is robust, and in rigorous blind tests HMMs improved their scores steadily. As a result, speech technology and the related field of handwritten character recognition made the transition to widespread industrial and consumer applications. Note that there was no scientific claim that humans use HMMs to recognize speech; rather, HMMs provided a mathematical framework for understanding and solving the problem. We will see in Section 1.3.8, however, that deep learning has rather upset this comfortable narrative.

1988 was an important year for the connection between AI and other fields, including statistics, operations research, decision theory, and control theory. Judea Pearl's (1988) *Probabilistic Reasoning in Intelligent Systems* led to a new acceptance of probability and decision theory in AI. Pearl's development of **Bayesian networks** yielded a rigorous and efficient formalism for representing uncertain knowledge as well as practical algorithms for probabilistic reasoning. Chapters 12, 13, 14, 15, and 18 cover this area, in addition to more recent developments that have greatly increased the expressive power of probabilistic formalisms; Chapter 21 describes methods for learning Bayesian networks and related models from data.

A second major contribution in 1988 was Rich Sutton's work connecting reinforcement learning—which had been used in Arthur Samuel's checker-playing program in the 1950s—to the theory of Markov decision processes (MDPs) developed in the field of operations research. A flood of work followed connecting AI planning research to MDPs, and the field of reinforcement learning found applications in robotics and process control as well as acquiring deep theoretical foundations.

One consequence of AI's newfound appreciation for data, statistical modeling, optimization, and machine learning was the gradual reunification of subfields such as computer vision, robotics, speech recognition, multiagent systems, and natural language processing that had

Hidden Markov  
models

Bayesian network

become somewhat separate from core AI. The process of reintegration has yielded significant benefits both in terms of applications—for example, the deployment of practical robots expanded greatly during this period—and in a better theoretical understanding of the core problems of AI.

### 1.3.7 Big data (2001–present)

Big data

Remarkable advances in computing power and the creation of the World Wide Web have facilitated the creation of very large data sets—a phenomenon sometimes known as **big data**. These data sets include trillions of words of text, billions of images, and billions of hours of speech and video, as well as vast amounts of genomic data, vehicle tracking data, clickstream data, social network data, and so on.

This has led to the development of learning algorithms specially designed to take advantage of very large data sets. Often, the vast majority of examples in such data sets are *unlabeled*; for example, in Yarowsky’s (1995) influential work on word-sense disambiguation, occurrences of a word such as “plant” are not labeled in the data set to indicate whether they refer to flora or factory. With large enough data sets, however, suitable learning algorithms can achieve an accuracy of over 96% on the task of identifying which sense was intended in a sentence. Moreover, Banko and Brill (2001) argued that the improvement in performance obtained from increasing the size of the data set by two or three orders of magnitude outweighs any improvement that can be obtained from tweaking the algorithm.

A similar phenomenon seems to occur in computer vision tasks such as filling in holes in photographs—holes caused either by damage or by the removal of ex-friends. Hays and Efros (2007) developed a clever method for doing this by blending in pixels from similar images; they found that the technique worked poorly with a database of only thousands of images but crossed a threshold of quality with millions of images. Soon after, the availability of tens of millions of images in the ImageNet database (Deng *et al.*, 2009) sparked a revolution in the field of computer vision.

The availability of big data and the shift towards machine learning helped AI recover commercial attractiveness (Havenstein, 2005; Halevy *et al.*, 2009). Big data was a crucial factor in the 2011 victory of IBM’s Watson system over human champions in the Jeopardy! quiz game, an event that had a major impact on the public’s perception of AI.

### 1.3.8 Deep learning (2011–present)

Deep learning

The term **deep learning** refers to machine learning using multiple layers of simple, adjustable computing elements. Experiments were carried out with such networks as far back as the 1970s, and in the form of **convolutional neural networks** they found some success in handwritten digit recognition in the 1990s (LeCun *et al.*, 1995). It was not until 2011, however, that deep learning methods really took off. This occurred first in speech recognition and then in visual object recognition.

In the 2012 ImageNet competition, which required classifying images into one of a thousand categories (armadillo, bookshelf, corkscrew, etc.), a deep learning system created in Geoffrey Hinton’s group at the University of Toronto (Krizhevsky *et al.*, 2013) demonstrated a dramatic improvement over previous systems, which were based largely on handcrafted features. Since then, deep learning systems have exceeded human performance on some vision tasks (and lag behind in some other tasks). Similar gains have been reported in speech

recognition, machine translation, medical diagnosis, and game playing. The use of a deep network to represent the evaluation function contributed to ALPHAGO’s victories over the leading human Go players (Silver *et al.*, 2016, 2017, 2018).

These remarkable successes have led to a resurgence of interest in AI among students, companies, investors, governments, the media, and the general public. It seems that every week there is news of a new AI application approaching or exceeding human performance, often accompanied by speculation of either accelerated success or a new AI winter.

Deep learning relies heavily on powerful hardware. Whereas a standard computer CPU can do  $10^9$  or  $10^{10}$  operations per second, a deep learning algorithm running on specialized hardware (e.g., GPU, TPU, or FPGA) might consume between  $10^{14}$  and  $10^{17}$  operations per second, mostly in the form of highly parallelized matrix and vector operations. Of course, deep learning also depends on the availability of large amounts of training data, and on a few algorithmic tricks (see Chapter 22).

## 1.4 The State of the Art

---

Stanford University’s One Hundred Year Study on AI (also known as AI100) convenes panels of experts to provide reports on the state of the art in AI. Their 2016 report (Stone *et al.*, 2016; Grosz and Stone, 2018) concludes that “Substantial increases in the future uses of AI applications, including more self-driving cars, healthcare diagnostics and targeted treatment, and physical assistance for elder care can be expected” and that “Society is now at a crucial juncture in determining how to deploy AI-based technologies in ways that promote rather than hinder democratic values such as freedom, equality, and transparency.” AI100 also produces an **AI Index** at [aiindex.org](http://aiindex.org) to help track progress. Some highlights from the 2018 and [AI Index](#) 2019 reports (comparing to a year 2000 baseline unless otherwise stated):

- Publications: AI papers increased 20-fold between 2010 and 2019 to about 20,000 a year. The most popular category was machine learning. (Machine learning papers in arXiv.org doubled every year from 2009 to 2017.) Computer vision and natural language processing were the next most popular.
- Sentiment: About 70% of news articles on AI are neutral, but articles with positive tone increased from 12% in 2016 to 30% in 2018. The most common issues are ethical: data privacy and algorithm bias.
- Students: Course enrollment increased 5-fold in the U.S. and 16-fold internationally from a 2010 baseline. AI is the most popular specialization in Computer Science.
- Diversity: AI Professors worldwide are about 80% male, 20% female. Similar numbers hold for Ph.D. students and industry hires.
- Conferences: Attendance at NeurIPS increased 800% since 2012 to 13,500 attendees. Other conferences are seeing annual growth of about 30%.
- Industry: AI startups in the U.S. increased 20-fold to over 800.
- Internationalization: China publishes more papers per year than the U.S. and about as many as all of Europe. However, in citation-weighted impact, U.S. authors are 50% ahead of Chinese authors. Singapore, Brazil, Australia, Canada, and India are the fastest growing countries in terms of the number of AI hires.

- Vision: Error rates for object detection (as achieved in LSVRC, the Large-Scale Visual Recognition Challenge) improved from 28% in 2010 to 2% in 2017, exceeding human performance. Accuracy on open-ended visual question answering (VQA) improved from 55% to 68% since 2015, but lags behind human performance at 83%.
- Speed: Training time for the image recognition task dropped by a factor of 100 in just the past two years. The amount of computing power used in top AI applications is doubling every 3.4 months.
- Language: Accuracy on question answering, as measured by F1 score on the Stanford Question Answering Dataset (SQuAD), increased from 60 to 95 from 2015 to 2019; on the SQuAD 2 variant, progress was faster, going from 62 to 90 in just one year. Both scores exceed human-level performance.
- Human benchmarks: By 2019, AI systems had reportedly met or exceeded human-level performance in chess, Go, poker, Pac-Man, Jeopardy!, ImageNet object detection, speech recognition in a limited domain, Chinese-to-English translation in a restricted domain, Quake III, Dota 2, StarCraft II, various Atari games, skin cancer detection, prostate cancer detection, protein folding, and diabetic retinopathy diagnosis.

When (if ever) will AI systems achieve human-level performance across a broad variety of tasks? Ford (2018) interviews AI experts and finds a wide range of target years, from 2029 to 2200, with a mean of 2099. In a similar survey (Grace *et al.*, 2017) 50% of respondents thought this could happen by 2066, although 10% thought it could happen as early as 2025, and a few said “never.” The experts were also split on whether we need fundamental new breakthroughs or just refinements on current approaches. But don’t take their predictions too seriously; as Philip Tetlock (2017) demonstrates in the area of predicting world events, experts are no better than amateurs.

How will future AI systems operate? We can’t yet say. As detailed in this section, the field has adopted several stories about itself—first the bold idea that intelligence by a machine was even possible, then that it could be achieved by encoding expert knowledge into logic, then that probabilistic models of the world would be the main tool, and most recently that machine learning would induce models that might not be based on any well-understood theory at all. The future will reveal what model comes next.

What can AI do today? Perhaps not as much as some of the more optimistic media articles might lead one to believe, but still a great deal. Here are some examples:

**Robotic vehicles:** The history of robotic vehicles stretches back to radio-controlled cars of the 1920s, but the first demonstrations of autonomous road driving without special guides occurred in the 1980s (Kanade *et al.*, 1986; Dickmanns and Zapp, 1987). After successful demonstrations of driving on dirt roads in the 132-mile DARPA Grand Challenge in 2005 (Thrun, 2006) and on streets with traffic in the 2007 Urban Challenge, the race to develop self-driving cars began in earnest. In 2018, Waymo test vehicles passed the landmark of 10 million miles driven on public roads without a serious accident, with the human driver stepping in to take over control only once every 6,000 miles. Soon after, the company began offering a commercial robotic taxi service.

In the air, autonomous fixed-wing drones have been providing cross-country blood deliveries in Rwanda since 2016. Quadcopters perform remarkable aerobatic maneuvers, explore buildings while constructing 3-D maps, and self-assemble into autonomous formations.

**Legged locomotion:** BigDog, a quadruped robot by Raibert *et al.* (2008), upended our notions of how robots move—no longer the slow, stiff-legged, side-to-side gait of Hollywood movie robots, but something closely resembling an animal and able to recover when shoved or when slipping on an icy puddle. Atlas, a humanoid robot, not only walks on uneven terrain but jumps onto boxes and does backflips (Ackerman and Guizzo, 2016).

**Autonomous planning and scheduling:** A hundred million miles from Earth, NASA’s Remote Agent program became the first on-board autonomous planning program to control the scheduling of operations for a spacecraft (Jonsson *et al.*, 2000). Remote Agent generated plans from high-level goals specified from the ground and monitored the execution of those plans—detecting, diagnosing, and recovering from problems as they occurred. Today, the EUROPA planning toolkit (Barreiro *et al.*, 2012) is used for daily operations of NASA’s Mars rovers and the SEXTANT system (Winternitz, 2017) allows autonomous navigation in deep space, beyond the global GPS system.

During the Persian Gulf crisis of 1991, U.S. forces deployed a Dynamic Analysis and Replanning Tool, DART (Cross and Walker, 1994), to do automated logistics planning and scheduling for transportation. This involved up to 50,000 vehicles, cargo, and people at a time, and had to account for starting points, destinations, routes, transport capacities, port and airfield capacities, and conflict resolution among all parameters. The Defense Advanced Research Project Agency (DARPA) stated that this single application more than paid back DARPA’s 30-year investment in AI.

Every day, ride hailing companies such as Uber and mapping services such as Google Maps provide driving directions for hundreds of millions of users, quickly plotting an optimal route taking into account current and predicted future traffic conditions.

**Machine translation:** Online machine translation systems now enable the reading of documents in over 100 languages, including the native languages of over 99% of humans, and render hundreds of billions of words per day for hundreds of millions of users. While not perfect, they are generally adequate for understanding. For closely related languages with a great deal of training data (such as French and English) translations within a narrow domain are close to the level of a human (Wu *et al.*, 2016b).

**Speech recognition:** In 2017, Microsoft showed that its Conversational Speech Recognition System had reached a word error rate of 5.1%, matching human performance on the Switchboard task, which involves transcribing telephone conversations (Xiong *et al.*, 2017). About a third of computer interaction worldwide is now done by voice rather than keyboard; Skype provides real-time speech-to-speech translation in ten languages. Alexa, Siri, Cortana, and Google offer assistants that can answer questions and carry out tasks for the user; for example the Google Duplex service uses speech recognition and speech synthesis to make restaurant reservations for users, carrying out a fluent conversation on their behalf.

**Recommendations:** Companies such as Amazon, Facebook, Netflix, Spotify, YouTube, Walmart, and others use machine learning to recommend what you might like based on your past experiences and those of others like you. The field of recommender systems has a long history (Resnick and Varian, 1997) but is changing rapidly due to new deep learning methods that analyze content (text, music, video) as well as history and metadata (van den Oord *et al.*, 2014; Zhang *et al.*, 2017). Spam filtering can also be considered a form of recommendation (or dis-recommendation); current AI techniques filter out over 99.9% of spam, and email services can also recommend potential recipients, as well as possible response text.

**Game playing:** When Deep Blue defeated world chess champion Garry Kasparov in 1997, defenders of human supremacy placed their hopes on Go. Piet Hut, an astrophysicist and Go enthusiast, predicted that it would take “a hundred years before a computer beats humans at Go—maybe even longer.” But just 20 years later, ALPHAGO surpassed all human players (Silver *et al.*, 2017). Ke Jie, the world champion, said, “Last year, it was still quite human-like when it played. But this year, it became like a god of Go.” ALPHAGO benefited from studying hundreds of thousands of past games by human Go players, and from the distilled knowledge of expert Go players that worked on the team.

A followup program, ALPHAZERO, used no input from humans (except for the rules of the game), and was able to learn through self-play alone to defeat all opponents, human and machine, at Go, chess, and shogi (Silver *et al.*, 2018). Meanwhile, human champions have been beaten by AI systems at games as diverse as Jeopardy! (Ferrucci *et al.*, 2010), poker (Bowling *et al.*, 2015; Moravčík *et al.*, 2017; Brown and Sandholm, 2019), and the video games Dota 2 (Fernandez and Mahlmann, 2018), StarCraft II (Vinyals *et al.*, 2019), and Quake III (Jaderberg *et al.*, 2019).

**Image understanding:** Not content with exceeding human accuracy on the challenging ImageNet object recognition task, computer vision researchers have taken on the more difficult problem of image captioning. Some impressive examples include “A person riding a motorcycle on a dirt road,” “Two pizzas sitting on top of a stove top oven,” and “A group of young people playing a game of frisbee” (Vinyals *et al.*, 2017b). Current systems are far from perfect, however: a “refrigerator filled with lots of food and drinks” turns out to be a no-parking sign partially obscured by lots of small stickers.

**Medicine:** AI algorithms now equal or exceed expert doctors at diagnosing many conditions, particularly when the diagnosis is based on images. Examples include Alzheimer’s disease (Ding *et al.*, 2018), metastatic cancer (Liu *et al.*, 2017; Esteva *et al.*, 2017), ophthalmic disease (Gulshan *et al.*, 2016), and skin diseases (Liu *et al.*, 2019c). A systematic review and meta-analysis (Liu *et al.*, 2019a) found that the performance of AI programs, on average, was equivalent to health care professionals. One current emphasis in medical AI is in facilitating human–machine partnerships. For example, the LYNA system achieves 99.6% overall accuracy in diagnosing metastatic breast cancer—better than an unaided human expert—but the combination does better still (Liu *et al.*, 2018; Steiner *et al.*, 2018).

The widespread adoption of these techniques is now limited not by diagnostic accuracy but by the need to demonstrate improvement in clinical outcomes and to ensure transparency, lack of bias, and data privacy (Topol, 2019). In 2017, only two medical AI applications were approved by the FDA, but that increased to 12 in 2018, and continues to rise.

**Climate science:** A team of scientists won the 2018 Gordon Bell Prize for a deep learning model that discovers detailed information about extreme weather events that were previously buried in climate data. They used a supercomputer with specialized GPU hardware to exceed the exaflop level ( $10^{18}$  operations per second), the first machine learning program to do so (Kurth *et al.*, 2018). Rolnick *et al.* (2019) present a 60-page catalog of ways in which machine learning can be used to tackle climate change.

These are just a few examples of artificial intelligence systems that exist today. Not magic or science fiction—but rather science, engineering, and mathematics, to which this book provides an introduction.

## 1.5 Risks and Benefits of AI

---

Francis Bacon, a philosopher credited with creating the scientific method, noted in *The Wisdom of the Ancients* (1609) that the “mechanical arts are of ambiguous use, serving as well for hurt as for remedy.” As AI plays an increasingly important role in the economic, social, scientific, medical, financial, and military spheres, we would do well to consider the hurts and remedies—in modern parlance, the risks and benefits—that it can bring. The topics summarized here are covered in greater depth in Chapters 28 and 29.

To begin with the benefits: put simply, our entire civilization is the product of our human intelligence. If we have access to substantially greater machine intelligence, the ceiling on our ambitions is raised substantially. The potential for AI and robotics to free humanity from menial repetitive work and to dramatically increase the production of goods and services could presage an era of peace and plenty. The capacity to accelerate scientific research could result in cures for disease and solutions for climate change and resource shortages. As Demis Hassabis, CEO of Google DeepMind, has suggested: “First solve AI, then use AI to solve everything else.”

Long before we have an opportunity to “solve AI,” however, we will incur risks from the misuse of AI, inadvertent or otherwise. Some of these are already apparent, while others seem likely based on current trends:

- *Lethal autonomous weapons*: These are defined by the United Nations as weapons that can locate, select, and eliminate human targets without human intervention. A primary concern with such weapons is their *scalability*: the absence of a requirement for human supervision means that a small group can deploy an arbitrarily large number of weapons against human targets defined by any feasible recognition criterion. The technologies needed for autonomous weapons are similar to those needed for self-driving cars. Informal expert discussions on the potential risks of lethal autonomous weapons began at the UN in 2014, moving to the formal pre-treaty stage of a Group of Governmental Experts in 2017.
- *Surveillance and persuasion*: While it is expensive, tedious, and sometimes legally questionable for security personnel to monitor phone lines, video camera feeds, emails, and other messaging channels, AI (speech recognition, computer vision, and natural language understanding) can be used in a scalable fashion to perform mass surveillance of individuals and detect activities of interest. By tailoring information flows to individuals through social media, based on machine learning techniques, political behavior can be modified and controlled to some extent—a concern that became apparent in elections beginning in 2016.
- *Biased decision making*: Careless or deliberate misuse of machine learning algorithms for tasks such as evaluating parole and loan applications can result in decisions that are biased by race, gender, or other protected categories. Often, the data themselves reflect pervasive bias in society.
- *Impact on employment*: Concerns about machines eliminating jobs are centuries old. The story is never simple: machines do some of the tasks that humans might otherwise do, but they also make humans more productive and therefore more employable, and make companies more profitable and therefore able to pay higher wages. They may render some activities economically viable that would otherwise be impractical. Their

use generally results in increasing wealth but tends to have the effect of shifting wealth from labor to capital, further exacerbating increases in inequality. Previous advances in technology—such as the invention of mechanical looms—have resulted in serious disruptions to employment, but eventually people find new kinds of work to do. On the other hand, it is possible that AI will be doing those new kinds of work too. This topic is rapidly becoming a major focus for economists and governments around the world.

- *Safety-critical applications:* As AI techniques advance, they are increasingly used in high-stakes, safety-critical applications such as driving cars and managing the water supplies of cities. Fatal accidents have already occurred and highlight the difficulty of formal verification and statistical risk analysis for systems developed using machine learning techniques. The field of AI will need to develop technical and ethical standards at least comparable to those prevalent in other engineering and healthcare disciplines where people’s lives are at stake.
- *Cybersecurity:* AI techniques are useful in defending against cyberattack, for example by detecting unusual patterns of behavior, but they will also contribute to the potency, survivability, and proliferation capability of malware. For example, reinforcement learning methods have been used to create highly effective tools for automated, personalized blackmail and phishing attacks.

We will revisit these topics in more depth in Section 28.3. As AI systems become more capable, they will take on more of the societal roles previously played by humans. Just as humans have used these roles in the past to perpetrate mischief, we can expect that humans may misuse AI systems in these roles to perpetrate even more mischief. All of the examples given above point to the importance of governance and, eventually, regulation. At present, the research community and the major corporations involved in AI research have developed voluntary self-governance principles for AI-related activities (see Section 28.3). Governments and international organizations are setting up advisory bodies to devise appropriate regulations for each specific use case, to prepare for the economic and social impacts, and to take advantage of AI capabilities to address major societal problems.

What of the longer term? Will we achieve the long-standing goal: the creation of intelligence comparable to or more capable than human intelligence? And, if we do, what then?

For much of AI’s history, these questions have been overshadowed by the daily grind of getting AI systems to do anything even remotely intelligent. As with any broad discipline, the great majority of AI researchers have specialized in a specific subfield such as game-playing, knowledge representation, vision, or natural language understanding—often on the assumption that progress in these subfields would contribute to the broader goals of AI. Nils Nilsson (1995), one of the original leaders of the Shakey project at SRI, reminded the field of those broader goals and warned that the subfields were in danger of becoming ends in themselves. Later, some influential founders of AI, including John McCarthy (2007), Marvin Minsky (2007), and Patrick Winston (Beal and Winston, 2009), concurred with Nilsson’s warnings, suggesting that instead of focusing on measurable performance in specific applications, AI should return to its roots of striving for, in Herb Simon’s words, “machines that think, that learn and that create.” They called the effort **human-level AI** or **HLAI**—a machine should be able to learn to do anything a human can do. Their first symposium was in 2004 (Minsky *et al.*, 2004). Another effort with similar goals, the **artificial general intelligence (AGI)**

movement (Goertzel and Pennachin, 2007), held its first conference and organized the *Journal of Artificial General Intelligence* in 2008.

At around the same time, concerns were raised that creating **artificial superintelligence** or **ASI**—intelligence that far surpasses human ability—might be a bad idea (Yudkowsky, 2008; Omohundro, 2008). Turing (1996) himself made the same point in a lecture given in Manchester in 1951, drawing on earlier ideas from Samuel Butler (1863):<sup>15</sup>

It seems probable that once the machine thinking method had started, it would not take long to outstrip our feeble powers. . . At some stage therefore we should have to expect the machines to take control, in the way that is mentioned in Samuel Butler's *Erewhon*.

These concerns have only become more widespread with recent advances in deep learning, the publication of books such as *Superintelligence* by Nick Bostrom (2014), and public pronouncements from Stephen Hawking, Bill Gates, Martin Rees, and Elon Musk.

Experiencing a general sense of unease with the idea of creating superintelligent machines is only natural. We might call this the **gorilla problem**: about seven million years ago, a now-extinct primate evolved, with one branch leading to gorillas and one to humans. Today, the gorillas are not too happy about the human branch; they have essentially no control over their future. If this is the result of success in creating superhuman AI—that humans cede control over their future—then perhaps we should stop work on AI, and, as a corollary, give up the benefits it might bring. This is the essence of Turing's warning: it is not obvious that we can control machines that are more intelligent than us.

If superhuman AI were a black box that arrived from outer space, then indeed it would be wise to exercise caution in opening the box. But it is not: we design the AI systems, so if they do end up “taking control,” as Turing suggests, it would be the result of a design failure.

To avoid such an outcome, we need to understand the source of potential failure. Norbert Wiener (1960), who was motivated to consider the long-term future of AI after seeing Arthur Samuel's checker-playing program learn to beat its creator, had this to say:

If we use, to achieve our purposes, a mechanical agency with whose operation we cannot interfere effectively . . . we had better be quite sure that the purpose put into the machine is the purpose which we really desire.

Many cultures have myths of humans who ask gods, genies, magicians, or devils for something. Invariably, in these stories, they get what they literally ask for, and then regret it. The third wish, if there is one, is to undo the first two. We will call this the **King Midas problem**: Midas, a legendary King in Greek mythology, asked that everything he touched should turn to gold, but then regretted it after touching his food, drink, and family members.<sup>16</sup>

We touched on this issue in Section 1.1.5, where we pointed out the need for a significant modification to the standard model of putting fixed objectives into the machine. The solution to Wiener's predicament is not to have a definite “purpose put into the machine” at all. Instead, we want machines that strive to achieve human objectives but know that they don't know for certain exactly what those objectives are.

<sup>15</sup> Even earlier, in 1847, Richard Thornton, editor of the *Primitive Expounder*, railed against mechanical calculators: “Mind . . . outruns itself and does away with the necessity of its own existence by inventing machines to do its own thinking. . . But who knows that such machines when brought to greater perfection, may not think of a plan to remedy all their own defects and then grind out ideas beyond the ken of mortal mind!”

<sup>16</sup> Midas would have done better if he had followed basic principles of safety and included an “undo” button and a “pause” button in his wish.

Artificial  
superintelligence  
(ASI)

Gorilla problem

King Midas problem

Assistance game

Inverse reinforcement learning

It is perhaps unfortunate that almost all AI research to date has been carried out within the standard model, which means that almost all of the technical material in this edition reflects that intellectual framework. There are, however, some early results within the new framework. In Chapter 15, we show that a machine has a positive incentive to allow itself to be switched off if and only if it is uncertain about the human objective. In Chapter 17, we formulate and study **assistance games**, which describe mathematically the situation in which a human has an objective and a machine tries to achieve it, but is initially uncertain about what it is. In Chapter 23, we explain the methods of **inverse reinforcement learning** that allow machines to learn more about human preferences from observations of the choices that humans make. In Chapter 28, we explore two of the principal difficulties: first, that our choices depend on our preferences through a very complex cognitive architecture that is hard to invert; and, second, that we humans may not have consistent preferences in the first place—either individually or as a group—so it may not be clear what AI systems *should* be doing for us.

## Summary

---

This chapter defines AI and establishes the cultural background against which it has developed. Some of the important points are as follows:

- Different people approach AI with different goals in mind. Two important questions to ask are: Are you concerned with thinking, or behavior? Do you want to model humans, or try to achieve the optimal results?
- According to what we have called the standard model, AI is concerned mainly with **rational action**. An ideal **intelligent agent** takes the best possible action in a situation. We study the problem of building agents that are intelligent in this sense.
- Two refinements to this simple idea are needed: first, the ability of any agent, human or otherwise, to choose rational actions is limited by the computational intractability of doing so; second, the concept of a machine that pursues a definite objective needs to be replaced with that of a machine pursuing objectives to benefit humans, but uncertain as to what those objectives are.
- Philosophers (going back to 400 BCE) made AI conceivable by suggesting that the mind is in some ways like a machine, that it operates on knowledge encoded in some internal language, and that thought can be used to choose what actions to take.
- Mathematicians provided the tools to manipulate statements of logical certainty as well as uncertain, probabilistic statements. They also set the groundwork for understanding computation and reasoning about algorithms.
- Economists formalized the problem of making decisions that maximize the expected utility to the decision maker.
- Neuroscientists discovered some facts about how the brain works and the ways in which it is similar to and different from computers.
- Psychologists adopted the idea that humans and animals can be considered information-processing machines. Linguists showed that language use fits into this model.
- Computer engineers provided the ever-more-powerful machines that make AI applications possible, and software engineers made them more usable.

- Control theory deals with designing devices that act optimally on the basis of feedback from the environment. Initially, the mathematical tools of control theory were quite different from those used in AI, but the fields are coming closer together.
- The history of AI has had cycles of success, misplaced optimism, and resulting cutbacks in enthusiasm and funding. There have also been cycles of introducing new, creative approaches and systematically refining the best ones.
- AI has matured considerably compared to its early decades, both theoretically and methodologically. As the problems that AI deals with became more complex, the field moved from Boolean logic to probabilistic reasoning, and from hand-crafted knowledge to machine learning from data. This has led to improvements in the capabilities of real systems and greater integration with other disciplines.
- As AI systems find application in the real world, it has become necessary to consider a wide range of risks and ethical consequences.
- In the longer term, we face the difficult problem of controlling superintelligent AI systems that may evolve in unpredictable ways. Solving this problem seems to necessitate a change in our conception of AI.

## Bibliographical and Historical Notes

---

A comprehensive history of AI is given by Nils Nilsson (2009), one of the early pioneers of the field. Pedro Domingos (2015) and Melanie Mitchell (2019) give overviews of machine learning for a general audience, and Kai-Fu Lee (2018) describes the race for international leadership in AI. Martin Ford (2018) interviews 23 leading AI researchers.

The main professional societies for AI are the Association for the Advancement of Artificial Intelligence (AAAI), the ACM Special Interest Group in Artificial Intelligence (SIGAI, formerly SIGART), the European Association for AI, and the Society for Artificial Intelligence and Simulation of Behaviour (AISB). The Partnership on AI brings together many commercial and nonprofit organizations concerned with the ethical and social impacts of AI. AAAI's *AI Magazine* contains many topical and tutorial articles, and its Web site, [aaai.org](http://aaai.org), contains news, tutorials, and background information.

The most recent work appears in the proceedings of the major AI conferences: the International Joint Conference on AI (IJCAI), the annual European Conference on AI (ECAI), and the AAAI Conference. Machine learning is covered by the International Conference on Machine Learning and the Neural Information Processing Systems (NeurIPS) meeting. The major journals for general AI are *Artificial Intelligence*, *Computational Intelligence*, the *IEEE Transactions on Pattern Analysis and Machine Intelligence*, *IEEE Intelligent Systems*, and the *Journal of Artificial Intelligence Research*. There are also many conferences and journals devoted to specific areas, which we cover in the appropriate chapters.

# CHAPTER 2

## INTELLIGENT AGENTS

*In which we discuss the nature of agents, perfect or otherwise, the diversity of environments, and the resulting menagerie of agent types.*

Chapter 1 identified the concept of **rational agents** as central to our approach to artificial intelligence. In this chapter, we make this notion more concrete. We will see that the concept of rationality can be applied to a wide variety of agents operating in any imaginable environment. Our plan in this book is to use this concept to develop a small set of design principles for building successful agents—systems that can reasonably be called **intelligent**.

We begin by examining agents, environments, and the coupling between them. The observation that some agents behave better than others leads naturally to the idea of a rational agent—one that behaves as well as possible. How well an agent can behave depends on the nature of the environment; some environments are more difficult than others. We give a crude categorization of environments and show how properties of an environment influence the design of suitable agents for that environment. We describe a number of basic “skeleton” agent designs, which we flesh out in the rest of the book.

### 2.1 Agents and Environments

Environment

Sensor

Actuator

Percept

Percept sequence

Agent function

An **agent** is anything that can be viewed as perceiving its **environment** through **sensors** and acting upon that environment through **actuators**. This simple idea is illustrated in Figure 2.1. A human agent has eyes, ears, and other organs for sensors and hands, legs, vocal tract, and so on for actuators. A robotic agent might have cameras and infrared range finders for sensors and various motors for actuators. A software agent receives file contents, network packets, and human input (keyboard/mouse/touchscreen/voice) as sensory inputs and acts on the environment by writing files, sending network packets, and displaying information or generating sounds. The environment could be everything—the entire universe! In practice it is just that part of the universe whose state we care about when designing this agent—the part that affects what the agent perceives and that is affected by the agent’s actions.

We use the term **percept** to refer to the content an agent’s sensors are perceiving. An agent’s **percept sequence** is the complete history of everything the agent has ever perceived.

In general, *an agent’s choice of action at any given instant can depend on its built-in knowledge and on the entire percept sequence observed to date, but not on anything it hasn’t perceived*. By specifying the agent’s choice of action for every possible percept sequence, we have said more or less everything there is to say about the agent. Mathematically speaking, we say that an agent’s behavior is described by the **agent function** that maps any given percept sequence to an action.

**Figure 2.1** Agents interact with environments through sensors and actuators.

We can imagine *tabulating* the agent function that describes any given agent; for most agents, this would be a very large table—*infinite*, in fact, unless we place a bound on the length of percept sequences we want to consider. Given an agent to experiment with, we can, in principle, construct this table by trying out all possible percept sequences and recording which actions the agent does in response.<sup>1</sup> The table is, of course, an *external* characterization of the agent. *Internally*, the agent function for an artificial agent will be implemented by an **agent program**. It is important to keep these two ideas distinct. The agent function is an abstract mathematical description; the agent program is a concrete implementation, running within some physical system.

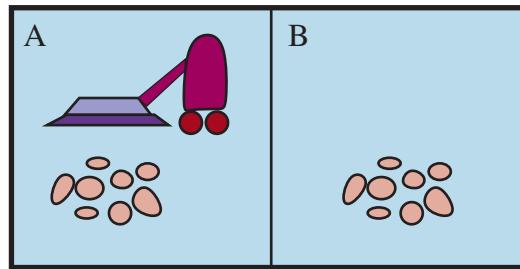

Agent program

To illustrate these ideas, we use a simple example—the vacuum-cleaner world, which consists of a robotic vacuum-cleaning agent in a world consisting of squares that can be either dirty or clean. Figure 2.2 shows a configuration with just two squares, A and B. The vacuum agent perceives which square it is in and whether there is dirt in the square. The agent starts in square A. The available actions are to move to the right, move to the left, suck up the dirt, or do nothing.<sup>2</sup> One very simple agent function is the following: if the current square is dirty, then suck; otherwise, move to the other square. A partial tabulation of this agent function is shown in Figure 2.3 and an agent program that implements it appears in Figure 2.8 on page 67.

Looking at Figure 2.3, we see that various vacuum-world agents can be defined simply by filling in the right-hand column in various ways. The obvious question, then, is this: *What is the right way to fill out the table?* In other words, what makes an agent good or bad, intelligent or stupid? We answer these questions in the next section.

<sup>1</sup> If the agent uses some randomization to choose its actions, then we would have to try each sequence many times to identify the probability of each action. One might imagine that acting randomly is rather silly, but we show later in this chapter that it can be very intelligent.

<sup>2</sup> In a real robot, it would be unlikely to have an actions like “move right” and “move left.” Instead the actions would be “spin wheels forward” and “spin wheels backward.” We have chosen the actions to be easier to follow on the page, not for ease of implementation in an actual robot.

**Figure 2.2** A vacuum-cleaner world with just two locations. Each location can be clean or dirty, and the agent can move left or right and can clean the square that it occupies. Different versions of the vacuum world allow for different rules about what the agent can perceive, whether its actions always succeed, and so on.

Percept sequence	Action
[A, Clean]	Right
[A, Dirty]	Suck
[B, Clean]	Left
[B, Dirty]	Suck
[A, Clean], [A, Clean]	Right
[A, Clean], [A, Dirty]	Suck
:	:
[A, Clean], [A, Clean], [A, Clean]	Right
[A, Clean], [A, Clean], [A, Dirty]	Suck
:	:

**Figure 2.3** Partial tabulation of a simple agent function for the vacuum-cleaner world shown in Figure 2.2. The agent cleans the current square if it is dirty, otherwise it moves to the other square. Note that the table is of unbounded size unless there is a restriction on the length of possible percept sequences.

Before closing this section, we should emphasize that the notion of an agent is meant to be a tool for analyzing systems, not an absolute characterization that divides the world into agents and non-agents. One could view a hand-held calculator as an agent that chooses the action of displaying “4” when given the percept sequence “2 + 2 =,” but such an analysis would hardly aid our understanding of the calculator. In a sense, all areas of engineering can be seen as designing artifacts that interact with the world; AI operates at (what the authors consider to be) the most interesting end of the spectrum, where the artifacts have significant computational resources and the task environment requires nontrivial decision making.

## 2.2 Good Behavior: The Concept of Rationality

A rational agent is one that does the right thing. Obviously, doing the right thing is better than doing the wrong thing, but what does it mean to do the right thing? Rational agent

### 2.2.1 Performance measures

Moral philosophy has developed several different notions of the “right thing,” but AI has generally stuck to one notion called **consequentialism**: we evaluate an agent’s behavior by its consequences. When an agent is plunked down in an environment, it generates a sequence of actions according to the percepts it receives. This sequence of actions causes the environment to go through a sequence of states. If the sequence is desirable, then the agent has performed well. This notion of desirability is captured by a **performance measure** that evaluates any given sequence of environment states. Consequentialism  
Performance measure

Humans have desires and preferences of their own, so the notion of rationality as applied to humans has to do with their success in choosing actions that produce sequences of environment states that are desirable *from their point of view*. Machines, on the other hand, do *not* have desires and preferences of their own; the performance measure is, initially at least, in the mind of the designer of the machine, or in the mind of the users the machine is designed for. We will see that some agent designs have an explicit representation of (a version of) the performance measure, while in other designs the performance measure is entirely implicit—the agent may do the right thing, but it doesn’t know why.

Recalling Norbert Wiener’s warning to ensure that “the purpose put into the machine is the purpose which we really desire” (page 51), notice that it can be quite hard to formulate a performance measure correctly. Consider, for example, the vacuum-cleaner agent from the preceding section. We might propose to measure performance by the amount of dirt cleaned up in a single eight-hour shift. With a rational agent, of course, what you ask for is what you get. A rational agent can maximize this performance measure by cleaning up the dirt, then dumping it all on the floor, then cleaning it up again, and so on. A more suitable performance measure would reward the agent for having a clean floor. For example, one point could be awarded for each clean square at each time step (perhaps with a penalty for electricity consumed and noise generated). As a general rule, it is better to design performance measures according to what one actually wants to be achieved in the environment, rather than according to how one thinks the agent should behave. ◀

Even when the obvious pitfalls are avoided, some knotty problems remain. For example, the notion of “clean floor” in the preceding paragraph is based on average cleanliness over time. Yet the same average cleanliness can be achieved by two different agents, one of which does a mediocre job all the time while the other cleans energetically but takes long breaks. Which is preferable might seem to be a fine point of janitorial science, but in fact it is a deep philosophical question with far-reaching implications. Which is better—a reckless life of highs and lows, or a safe but humdrum existence? Which is better—an economy where everyone lives in moderate poverty, or one in which some live in plenty while others are very poor? We leave these questions as an exercise for the diligent reader.

For most of the book, we will assume that the performance measure can be specified correctly. For the reasons given above, however, we must accept the possibility that we might put the wrong purpose into the machine—precisely the King Midas problem described on

page 51. Moreover, when designing one piece of software, copies of which will belong to different users, we cannot anticipate the exact preferences of each individual user. Thus, we may need to build agents that reflect initial uncertainty about the true performance measure and learn more about it as time goes by; such agents are described in Chapters 15, 17, and 23.

### 2.2.2 Rationality

What is rational at any given time depends on four things:

- The performance measure that defines the criterion of success.
- The agent's prior knowledge of the environment.
- The actions that the agent can perform.
- The agent's percept sequence to date.

Definition of a rational agent

This leads to a **definition of a rational agent**:

*For each possible percept sequence, a rational agent should select an action that is expected to maximize its performance measure, given the evidence provided by the percept sequence and whatever built-in knowledge the agent has.*

Consider the simple vacuum-cleaner agent that cleans a square if it is dirty and moves to the other square if not; this is the agent function tabulated in Figure 2.3. Is this a rational agent? That depends! First, we need to say what the performance measure is, what is known about the environment, and what sensors and actuators the agent has. Let us assume the following:

- The performance measure awards one point for each clean square at each time step, over a “lifetime” of 1000 time steps.
- The “geography” of the environment is known *a priori* (Figure 2.2) but the dirt distribution and the initial location of the agent are not. Clean squares stay clean and sucking cleans the current square. The *Right* and *Left* actions move the agent one square except when this would take the agent outside the environment, in which case the agent remains where it is.
- The only available actions are *Right*, *Left*, and *Suck*.
- The agent correctly perceives its location and whether that location contains dirt.

Under these circumstances the agent is indeed rational; its expected performance is at least as good as any other agent's.

One can see easily that the same agent would be irrational under different circumstances. For example, once all the dirt is cleaned up, the agent will oscillate needlessly back and forth; if the performance measure includes a penalty of one point for each movement, the agent will fare poorly. A better agent for this case would do nothing once it is sure that all the squares are clean. If clean squares can become dirty again, the agent should occasionally check and re-clean them if needed. If the geography of the environment is unknown, the agent will need to **explore** it. Exercise 2.VACR asks you to design agents for these cases.

### 2.2.3 Omniscience, learning, and autonomy

Omniscience

We need to be careful to distinguish between rationality and **omniscience**. An omniscient agent knows the *actual* outcome of its actions and can act accordingly; but omniscience is impossible in reality. Consider the following example: I am walking along the Champs Elysées one day and I see an old friend across the street. There is no traffic nearby and I'm

not otherwise engaged, so, being rational, I start to cross the street. Meanwhile, at 33,000 feet, a cargo door falls off a passing airliner,<sup>3</sup> and before I make it to the other side of the street I am flattened. Was I irrational to cross the street? It is unlikely that my obituary would read “Idiot attempts to cross street.”

This example shows that rationality is not the same as perfection. Rationality maximizes *expected* performance, while perfection maximizes *actual* performance. Retreating from a requirement of perfection is not just a question of being fair to agents. The point is that if we expect an agent to do what turns out after the fact to be the best action, it will be impossible to design an agent to fulfill this specification—unless we improve the performance of crystal balls or time machines.

Our definition of rationality does not require omniscience, then, because the rational choice depends only on the percept sequence *to date*. We must also ensure that we haven’t inadvertently allowed the agent to engage in decidedly underintelligent activities. For example, if an agent does not look both ways before crossing a busy road, then its percept sequence will not tell it that there is a large truck approaching at high speed. Does our definition of rationality say that it’s now OK to cross the road? Far from it!

First, it would not be rational to cross the road given this uninformative percept sequence: the risk of accident from crossing without looking is too great. Second, a rational agent should choose the “looking” action before stepping into the street, because looking helps maximize the expected performance. Doing actions *in order to modify future percepts*—sometimes called **information gathering**—is an important part of rationality and is covered in depth in Chapter 15. A second example of information gathering is provided by the **exploration** that must be undertaken by a vacuum-cleaning agent in an initially unknown environment.

Our definition requires a rational agent not only to gather information but also to **learn** as much as possible from what it perceives. The agent’s initial configuration could reflect some prior knowledge of the environment, but as the agent gains experience this may be modified and augmented. There are extreme cases in which the environment is completely known *a priori* and completely predictable. In such cases, the agent need not perceive or learn; it simply acts correctly.

Of course, such agents are fragile. Consider the lowly dung beetle. After digging its nest and laying its eggs, it fetches a ball of dung from a nearby heap to plug the entrance. If the ball of dung is removed from its grasp *en route*, the beetle continues its task and pantomimes plugging the nest with the nonexistent dung ball, never noticing that it is missing. Evolution has built an assumption into the beetle’s behavior, and when it is violated, unsuccessful behavior results.

Slightly more intelligent is the sphex wasp. The female sphex will dig a burrow, go out and sting a caterpillar and drag it to the burrow, enter the burrow again to check all is well, drag the caterpillar inside, and lay its eggs. The caterpillar serves as a food source when the eggs hatch. So far so good, but if an entomologist moves the caterpillar a few inches away while the sphex is doing the check, it will revert to the “drag the caterpillar” step of its plan and will continue the plan without modification, re-checking the burrow, even after dozens of caterpillar-moving interventions. The sphex is unable to learn that its innate plan is failing, and thus will not change it.

Information gathering

Learning

<sup>3</sup> See N. Henderson, “New door latches urged for Boeing 747 jumbo jets,” *Washington Post*, August 24, 1989.

To the extent that an agent relies on the prior knowledge of its designer rather than on its own percepts and learning processes, we say that the agent lacks **autonomy**. A rational agent should be autonomous—it should learn what it can to compensate for partial or incorrect prior knowledge. For example, a vacuum-cleaning agent that learns to predict where and when additional dirt will appear will do better than one that does not.

As a practical matter, one seldom requires complete autonomy from the start: when the agent has had little or no experience, it would have to act randomly unless the designer gave some assistance. Just as evolution provides animals with enough built-in reflexes to survive long enough to learn for themselves, it would be reasonable to provide an artificial intelligent agent with some initial knowledge as well as an ability to learn. After sufficient experience of its environment, the behavior of a rational agent can become effectively *independent* of its prior knowledge. Hence, the incorporation of learning allows one to design a single rational agent that will succeed in a vast variety of environments.

## 2.3 The Nature of Environments

---

Now that we have a definition of rationality, we are almost ready to think about building rational agents. First, however, we must think about **task environments**, which are essentially the “problems” to which rational agents are the “solutions.” We begin by showing how to specify a task environment, illustrating the process with a number of examples. We then show that task environments come in a variety of flavors. The nature of the task environment directly affects the appropriate design for the agent program.

In our discussion of the rationality of the simple vacuum-cleaner agent, we had to specify the performance measure, the environment, and the agent’s actuators and sensors. We group all these under the heading of the **task environment**. For the acronymically minded, we call this the **PEAS** (**P**erformance, **E**nvironment, **A**ctuators, **S**ensors) description. In designing an agent, the first step must always be to specify the task environment as fully as possible.

The vacuum world was a simple example; let us consider a more complex problem: an **automated taxi driver**. Figure 2.4 summarizes the PEAS description for the taxi’s task environment. We discuss each element in more detail in the following paragraphs.

First, what is the **performance measure** to which we would like our automated driver to aspire? Desirable qualities include getting to the correct destination; minimizing fuel consumption and wear and tear; minimizing the trip time or cost; minimizing violations of traffic laws and disturbances to other drivers; maximizing safety and passenger comfort; maximizing profits. Obviously, some of these goals conflict, so tradeoffs will be required.

Next, what is the driving **environment** that the taxi will face? Any taxi driver must deal with a variety of roads, ranging from rural lanes and urban alleys to 12-lane freeways. The roads contain other traffic, pedestrians, stray animals, road works, police cars, puddles, and potholes. The taxi must also interact with potential and actual passengers. There are also some optional choices. The taxi might need to operate in Southern California, where snow is seldom a problem, or in Alaska, where it seldom is not. It could always be driving on the right, or we might want it to be flexible enough to drive on the left when in Britain or Japan. Obviously, the more restricted the environment, the easier the design problem.

Agent Type	Performance Measure	Environment	Actuators	Sensors
Taxi driver	Safe, fast, legal, comfortable trip, maximize profits, minimize impact on other road users	Roads, other traffic, police, pedestrians, customers, weather	Steering, accelerator, brake, signal, horn, display, speech	Cameras, radar, speedometer, GPS, engine sensors, accelerometer, microphones, touchscreen

Figure 2.4 PEAS description of the task environment for an automated taxi driver.

The **actuators** for an automated taxi include those available to a human driver: control over the engine through the accelerator and control over steering and braking. In addition, it will need output to a display screen or voice synthesizer to talk back to the passengers, and perhaps some way to communicate with other vehicles, politely or otherwise.

The basic **sensors** for the taxi will include one or more video cameras so that it can see, as well as lidar and ultrasound sensors to detect distances to other cars and obstacles. To avoid speeding tickets, the taxi should have a speedometer, and to control the vehicle properly, especially on curves, it should have an accelerometer. To determine the mechanical state of the vehicle, it will need the usual array of engine, fuel, and electrical system sensors. Like many human drivers, it might want to access GPS signals so that it doesn't get lost. Finally, it will need touchscreen or voice input for the passenger to request a destination.

In Figure 2.5, we have sketched the basic PEAS elements for a number of additional agent types. Further examples appear in Exercise 2.PEAS. The examples include physical as well as virtual environments. Note that virtual task environments can be just as complex as the “real” world: for example, a **software agent** (or software robot or **softbot**) that trades on auction and reselling Web sites deals with millions of other users and billions of objects, many with real images.

Software agent  
Softbot

### 2.3.2 Properties of task environments

The range of task environments that might arise in AI is obviously vast. We can, however, identify a fairly small number of dimensions along which task environments can be categorized. These dimensions determine, to a large extent, the appropriate agent design and the applicability of each of the principal families of techniques for agent implementation. First we list the dimensions, then we analyze several task environments to illustrate the ideas. The definitions here are informal; later chapters provide more precise statements and examples of each kind of environment.

**Fully observable vs. partially observable:** If an agent's sensors give it access to the complete state of the environment at each point in time, then we say that the task environment is **fully observable**. A task environment is effectively fully observable if the sensors detect all aspects that are *relevant* to the choice of action; relevance, in turn, depends on the

Fully observable

Partially observable

Agent Type	Performance Measure	Environment	Actuators	Sensors
Medical diagnosis system	Healthy patient, reduced costs	Patient, hospital, staff	Display of questions, tests, diagnoses, treatments	Touchscreen/voice entry of symptoms and findings
Satellite image analysis system	Correct categorization of objects, terrain	Orbiting satellite, downlink, weather	Display of scene categorization	High-resolution digital camera
Part-picking robot	Percentage of parts in correct bins	Conveyor belt with parts; bins	Jointed arm and hand	Camera, tactile and joint angle sensors
Refinery controller	Purity, yield, safety	Refinery, raw materials, operators	Valves, pumps, heaters, stirrers, displays	Temperature, pressure, flow, chemical sensors
Interactive English tutor	Student's score on test	Set of students, testing agency	Display of exercises, feedback, speech	Keyboard entry, voice

**Figure 2.5** Examples of agent types and their PEAS descriptions.

performance measure. Fully observable environments are convenient because the agent need not maintain any internal state to keep track of the world. An environment might be partially observable because of noisy and inaccurate sensors or because parts of the state are simply missing from the sensor data—for example, a vacuum agent with only a local dirt sensor cannot tell whether there is dirt in other squares, and an automated taxi cannot see what other drivers are thinking. If the agent has no sensors at all then the environment is **unobservable**. One might think that in such cases the agent's plight is hopeless, but, as we discuss in Chapter 4, the agent's goals may still be achievable, sometimes with certainty.

**Single-agent vs. multiagent:** The distinction between single-agent and multiagent environments may seem simple enough. For example, an agent solving a crossword puzzle by itself is clearly in a single-agent environment, whereas an agent playing chess is in a two-agent environment. However, there are some subtle issues. First, we have described how an entity *may* be viewed as an agent, but we have not explained which entities *must* be viewed as agents. Does an agent *A* (the taxi driver for example) have to treat an object *B* (another vehicle) as an agent, or can it be treated merely as an object behaving according to the laws of physics, analogous to waves at the beach or leaves blowing in the wind? The key distinction is whether *B*'s behavior is best described as maximizing a performance measure whose value depends on agent *A*'s behavior.

**Unobservable**

**Single-agent**

**Multiagent**

All actions are performed by a single agent in the environment. Real-life Example: Playing tennis against the ball is a single agent environment where there is only one player. If two or more agents are taking actions in the environment, it is known as a multi-agent environment

For example, in chess, the opponent entity *B* is trying to maximize its performance measure, which, by the rules of chess, minimizes agent *A*'s performance measure. Thus, chess is a **competitive** multiagent environment. On the other hand, in the taxi-driving environment, avoiding collisions maximizes the performance measure of all agents, so it is a partially **cooperative** multiagent environment. It is also partially competitive because, for example, only one car can occupy a parking space.

Competitive

Cooperative

The agent-design problems in multiagent environments are often quite different from those in single-agent environments; for example, communication often emerges as a rational behavior in multiagent environments; in some competitive environments, randomized behavior is rational because it avoids the pitfalls of predictability.

**Deterministic vs. nondeterministic.** If the next state of the environment is completely determined by the current state and the action executed by the agent(s), then we say the environment is deterministic; otherwise, it is nondeterministic. In principle, an agent need not worry about uncertainty in a fully observable, deterministic environment. If the environment is partially observable, however, then it could *appear* to be nondeterministic.

Deterministic

Nondeterministic

Most real situations are so complex that it is impossible to keep track of all the unobserved aspects; for practical purposes, they must be treated as nondeterministic. Taxi driving is clearly nondeterministic in this sense, because one can never predict the behavior of traffic exactly; moreover, one's tires may blow out unexpectedly and one's engine may seize up without warning. The vacuum world as we described it is deterministic, but variations can include nondeterministic elements such as randomly appearing dirt and an unreliable suction mechanism (Exercise 2.VFIN).

Stochastic

One final note: the word **stochastic** is used by some as a synonym for “nondeterministic,” but we make a distinction between the two terms; we say that a model of the environment is stochastic if it explicitly deals with probabilities (e.g., “there’s a 25% chance of rain tomorrow”) and “nondeterministic” if the possibilities are listed without being quantified (e.g., “there’s a chance of rain tomorrow”).

**Episodic vs. sequential:** In an episodic task environment, the agent’s experience is divided into atomic episodes. In each episode the agent receives a percept and then performs a single action. Crucially, the next episode does not depend on the actions taken in previous episodes. Many classification tasks are episodic. For example, an agent that has to spot defective parts on an assembly line bases each decision on the current part, regardless of previous decisions; moreover, the current decision doesn’t affect whether the next part is defective. In sequential environments, on the other hand, the current decision could affect all future decisions.<sup>4</sup> Chess and taxi driving are sequential: in both cases, short-term actions can have long-term consequences. Episodic environments are much simpler than sequential environments because the agent does not need to think ahead.

Episodic

Sequential

**Static vs. dynamic:** If the environment can change while an agent is deliberating, then we say the environment is dynamic for that agent; otherwise, it is static. Static environments are easy to deal with because the agent need not keep looking at the world while it is deciding on an action, nor need it worry about the passage of time. Dynamic environments, on the other hand, are continuously asking the agent what it wants to do; if it hasn’t decided yet,

Static

Dynamic

<sup>4</sup> The word “sequential” is also used in computer science as the antonym of “parallel.” The two meanings are largely unrelated.

Semidynamic

Discrete

Continuous

Known

Unknown

that counts as deciding to do nothing. If the environment itself does not change with the passage of time but the agent's performance score does, then we say the environment is **semidynamic**. Taxi driving is clearly dynamic: the other cars and the taxi itself keep moving while the driving algorithm dithers about what to do next. Chess, when played with a clock, is semidynamic. Crossword puzzles are static.

**Discrete vs. continuous:** The discrete/continuous distinction applies to the *state* of the environment, to the way *time* is handled, and to the *percepts* and *actions* of the agent. For example, the chess environment has a finite number of distinct states (excluding the clock). Chess also has a discrete set of percepts and actions. Taxi driving is a continuous-state and continuous-time problem: the speed and location of the taxi and of the other vehicles sweep through a range of continuous values and do so smoothly over time. Taxi-driving actions are also continuous (steering angles, etc.). Input from digital cameras is discrete, strictly speaking, but is typically treated as representing continuously varying intensities and locations.

**Known vs. unknown:** Strictly speaking, this distinction refers not to the environment itself but to the agent's (or designer's) state of knowledge about the "laws of physics" of the environment. In a known environment, the outcomes (or outcome probabilities if the environment is nondeterministic) for all actions are given. Obviously, if the environment is unknown, the agent will have to learn how it works in order to make good decisions.

The distinction between known and unknown environments is not the same as the one between fully and partially observable environments. It is quite possible for a *known* environment to be *partially* observable—for example, in solitaire card games, I know the rules but am still unable to see the cards that have not yet been turned over. Conversely, an *unknown* environment can be *fully* observable—in a new video game, the screen may show the entire game state but I still don't know what the buttons do until I try them.

As noted on page 57, the performance measure itself may be unknown, either because the designer is not sure how to write it down correctly or because the ultimate user—whose preferences matter—is not known. For example, a taxi driver usually won't know whether a new passenger prefers a leisurely or speedy journey, a cautious or aggressive driving style. A virtual personal assistant starts out knowing nothing about the personal preferences of its new owner. In such cases, the agent may learn more about the performance measure based on further interactions with the designer or user. This, in turn, suggests that the task environment is necessarily viewed as a multiagent environment.

The hardest case is *partially observable, multiagent, nondeterministic, sequential, dynamic, continuous*, and *unknown*. Taxi driving is hard in all these senses, except that the driver's environment is mostly known. Driving a rented car in a new country with unfamiliar geography, different traffic laws, and nervous passengers is a lot more exciting.

Figure 2.6 lists the properties of a number of familiar environments. Note that the properties are not always cut and dried. For example, we have listed the medical-diagnosis task as single-agent because the disease process in a patient is not profitably modeled as an agent; but a medical-diagnosis system might also have to deal with recalcitrant patients and skeptical staff, so the environment could have a multiagent aspect. Furthermore, medical diagnosis is episodic if one conceives of the task as selecting a diagnosis given a list of symptoms; the problem is sequential if the task can include proposing a series of tests, evaluating progress over the course of treatment, handling multiple patients, and so on.

Task Environment	Observable	Agents	Deterministic	Episodic	Static	Discrete
Crossword puzzle	Fully	Single	Deterministic	Sequential	Static	Discrete
Chess with a clock	Fully	Multi	Deterministic	Sequential	Semi	Discrete
Poker	Partially	Multi	Stochastic	Sequential	Static	Discrete
Backgammon	Fully	Multi	Stochastic	Sequential	Static	Discrete
Taxi driving	Partially	Multi	Stochastic	Sequential	Dynamic	Continuous
Medical diagnosis	Partially	Single	Stochastic	Sequential	Dynamic	Continuous
Image analysis	Fully	Single	Deterministic	Episodic	Semi	Continuous
Part-picking robot	Partially	Single	Stochastic	Episodic	Dynamic	Continuous
Refinery controller	Partially	Single	Stochastic	Sequential	Dynamic	Continuous
English tutor	Partially	Multi	Stochastic	Sequential	Dynamic	Discrete

**Figure 2.6** Examples of task environments and their characteristics.

We have not included a “known/unknown” column because, as explained earlier, this is not strictly a property of the environment. For some environments, such as chess and poker, it is quite easy to supply the agent with full knowledge of the rules, but it is nonetheless interesting to consider how an agent might learn to play these games without such knowledge.

The code repository associated with this book (`aima.cs.berkeley.edu`) includes multiple environment implementations, together with a general-purpose environment simulator for evaluating an agent’s performance. Experiments are often carried out not for a single environment but for many environments drawn from an **environment class**. For example, to evaluate a taxi driver in simulated traffic, we would want to run many simulations with different traffic, lighting, and weather conditions. We are then interested in the agent’s average performance over the environment class.

`Environment class`

## 2.4 The Structure of Agents

So far we have talked about agents by describing *behavior*—the action that is performed after any given sequence of percepts. Now we must bite the bullet and talk about how the insides work. The job of AI is to design an **agent program** that implements the agent function—the mapping from percepts to actions. We assume this program will run on some sort of computing device with physical sensors and actuators—we call this the **agent architecture**:

`Agent program`

`Agent architecture`

$$\text{agent} = \text{architecture} + \text{program}.$$

Obviously, the program we choose has to be one that is appropriate for the architecture. If the program is going to recommend actions like *Walk*, the architecture had better have legs. The architecture might be just an ordinary PC, or it might be a robotic car with several onboard computers, cameras, and other sensors. In general, the architecture makes the percepts from the sensors available to the program, runs the program, and feeds the program’s action choices to the actuators as they are generated. Most of this book is about designing agent programs, although Chapters 26 and 27 deal directly with the sensors and actuators.

```

function TABLE-DRIVEN-AGENT(percept) returns an action
  persistent: percepts, a sequence, initially empty
    table, a table of actions, indexed by percept sequences, initially fully specified

  append percept to the end of percepts
  action  $\leftarrow$  LOOKUP(percepts, table)
  return action

```

**Figure 2.7** The TABLE-DRIVEN-AGENT program is invoked for each new percept and returns an action each time. It retains the complete percept sequence in memory.

---

### 2.4.1 Agent programs

The agent programs that we design in this book all have the same skeleton: they take the current percept as input from the sensors and return an action to the actuators.<sup>5</sup> Notice the difference between the agent program, which takes the current percept as input, and the agent function, which may depend on the entire percept history. The agent program has no choice but to take just the current percept as input because nothing more is available from the environment; if the agent’s actions need to depend on the entire percept sequence, the agent will have to remember the percepts.

We describe the agent programs in the simple pseudocode language that is defined in Appendix B. (The online code repository contains implementations in real programming languages.) For example, Figure 2.7 shows a rather trivial agent program that keeps track of the percept sequence and then uses it to index into a table of actions to decide what to do. The table—an example of which is given for the vacuum world in Figure 2.3—represents explicitly the agent function that the agent program embodies. To build a rational agent in this way, we as designers must construct a table that contains the appropriate action for every possible percept sequence.

It is instructive to consider why the table-driven approach to agent construction is doomed to failure. Let  $\mathcal{P}$  be the set of possible percepts and let  $T$  be the lifetime of the agent (the total number of percepts it will receive). The lookup table will contain  $\sum_{t=1}^T |\mathcal{P}|^t$  entries. Consider the automated taxi: the visual input from a single camera (eight cameras is typical) comes in at the rate of roughly 70 megabytes per second (30 frames per second,  $1080 \times 720$  pixels with 24 bits of color information). This gives a lookup table with over  $10^{600,000,000,000}$  entries for an hour’s driving. Even the lookup table for chess—a tiny, well-behaved fragment of the real world—has (it turns out) at least  $10^{150}$  entries. In comparison, the number of atoms in the observable universe is less than  $10^{80}$ . The daunting size of these tables means that (a) no physical agent in this universe will have the space to store the table; (b) the designer would not have time to create the table; and (c) no agent could ever learn all the right table entries from its experience.

Despite all this, TABLE-DRIVEN-AGENT *does* do what we want, assuming the table is filled in correctly: it implements the desired agent function.

<sup>5</sup> There are other choices for the agent program skeleton; for example, we could have the agent programs be **coroutines** that run asynchronously with the environment. Each such coroutine has an input and output port and consists of a loop that reads the input port for percepts and writes actions to the output port.

---

```
function REFLEX-VACUUM-AGENT([location,status]) returns an action
  if status = Dirty then return Suck
  else if location = A then return Right
  else if location = B then return Left
```

**Figure 2.8** The agent program for a simple reflex agent in the two-location vacuum environment. This program implements the agent function tabulated in Figure 2.3.

---

*The key challenge for AI is to find out how to write programs that, to the extent possible, produce rational behavior from a smallish program rather than from a vast table.*

We have many examples showing that this can be done successfully in other areas: for example, the huge tables of square roots used by engineers and schoolchildren prior to the 1970s have now been replaced by a five-line program for Newton's method running on electronic calculators. The question is, can AI do for general intelligent behavior what Newton did for square roots? We believe the answer is yes.

In the remainder of this section, we outline four basic kinds of agent programs that embody the principles underlying almost all intelligent systems:

- Simple reflex agents;
- Model-based reflex agents;
- Goal-based agents; and
- Utility-based agents.

Each kind of agent program combines particular components in particular ways to generate actions. Section 2.4.6 explains in general terms how to convert all these agents into *learning agents* that can improve the performance of their components so as to generate better actions. Finally, Section 2.4.7 describes the variety of ways in which the components themselves can be represented within the agent. This variety provides a major organizing principle for the field and for the book itself.

## 2.4.2 Simple reflex agents

The simplest kind of agent is the **simple reflex agent**. These agents select actions on the basis of the *current* percept, ignoring the rest of the percept history. For example, the vacuum agent whose agent function is tabulated in Figure 2.3 is a simple reflex agent, because its decision is based only on the current location and on whether that location contains dirt. An agent program for this agent is shown in Figure 2.8.

Notice that the vacuum agent program is very small indeed compared to the corresponding table. The most obvious reduction comes from ignoring the percept history, which cuts down the number of relevant percept sequences from  $4^T$  to just 4. A further, small reduction comes from the fact that when the current square is dirty, the action does not depend on the location. Although we have written the agent program using if-then-else statements, it is simple enough that it can also be implemented as a Boolean circuit.

Simple reflex behaviors occur even in more complex environments. Imagine yourself as the driver of the automated taxi. If the car in front brakes and its brake lights come on, then you should notice this and initiate braking. In other words, some processing is done on the

Simple reflex agent

**Figure 2.9** Schematic diagram of a simple reflex agent. We use rectangles to denote the current internal state of the agent’s decision process, and ovals to represent the background information used in the process.

Condition-action rule

visual input to establish the condition we call “The car in front is braking.” Then, this triggers some established connection in the agent program to the action “initiate braking.” We call such a connection a **condition–action rule**,<sup>6</sup> written as

**if** *car-in-front-is-braking* **then** *initiate-braking*.

Humans also have many such connections, some of which are learned responses (as for driving) and some of which are innate reflexes (such as blinking when something approaches the eye). In the course of the book, we show several different ways in which such connections can be learned and implemented.

The program in Figure 2.8 is specific to one particular vacuum environment. A more general and flexible approach is first to build a general-purpose interpreter for condition–action rules and then to create rule sets for specific task environments. Figure 2.9 gives the structure of this general program in schematic form, showing how the condition–action rules allow the agent to make the connection from percept to action. Do not worry if this seems trivial; it gets more interesting shortly.

An agent program for Figure 2.9 is shown in Figure 2.10. The INTERPRET-INPUT function generates an abstracted description of the current state from the percept, and the RULE-MATCH function returns the first rule in the set of rules that matches the given state description. Note that the description in terms of “rules” and “matching” is purely conceptual; as noted above, actual implementations can be as simple as a collection of logic gates implementing a Boolean circuit. Alternatively, a “neural” circuit can be used, where the logic gates are replaced by the nonlinear units of artificial neural networks (see Chapter 22).

Simple reflex agents have the admirable property of being simple, but they are of limited intelligence. The agent in Figure 2.10 will work *only if the correct decision can be made on the basis of just the current percept—that is, only if the environment is fully observable.*

<sup>6</sup> Also called **situation–action rules**, **productions**, or **if–then rules**.

---

```

function SIMPLE-REFLEX-AGENT(percept) returns an action
  persistent: rules, a set of condition–action rules

    state  $\leftarrow$  INTERPRET-INPUT(percept)
    rule  $\leftarrow$  RULE-MATCH(state, rules)
    action  $\leftarrow$  rule.ACTION
  return action

```

**Figure 2.10** A simple reflex agent. It acts according to a rule whose condition matches the current state, as defined by the percept.

---

Even a little bit of unobservability can cause serious trouble. For example, the braking rule given earlier assumes that the condition *car-in-front-is-braking* can be determined from the current percept—a single frame of video. This works if the car in front has a centrally mounted (and hence uniquely identifiable) brake light. Unfortunately, older models have different configurations of taillights, brake lights, and turn-signal lights, and it is not always possible to tell from a single image whether the car is braking or simply has its taillights on. A simple reflex agent driving behind such a car would either brake continuously and unnecessarily, or, worse, never brake at all.

We can see a similar problem arising in the vacuum world. Suppose that a simple reflex vacuum agent is deprived of its location sensor and has only a dirt sensor. Such an agent has just two possible percepts: [*Dirty*] and [*Clean*]. It can *Suck* in response to [*Dirty*]; what should it do in response to [*Clean*]? Moving *Left* fails (forever) if it happens to start in square *A*, and moving *Right* fails (forever) if it happens to start in square *B*. Infinite loops are often unavoidable for simple reflex agents operating in partially observable environments.

Escape from infinite loops is possible if the agent can **randomize** its actions. For example, if the vacuum agent perceives [*Clean*], it might flip a coin to choose between *Right* and *Left*. It is easy to show that the agent will reach the other square in an average of two steps. Then, if that square is dirty, the agent will clean it and the task will be complete. Hence, a randomized simple reflex agent might outperform a deterministic simple reflex agent.

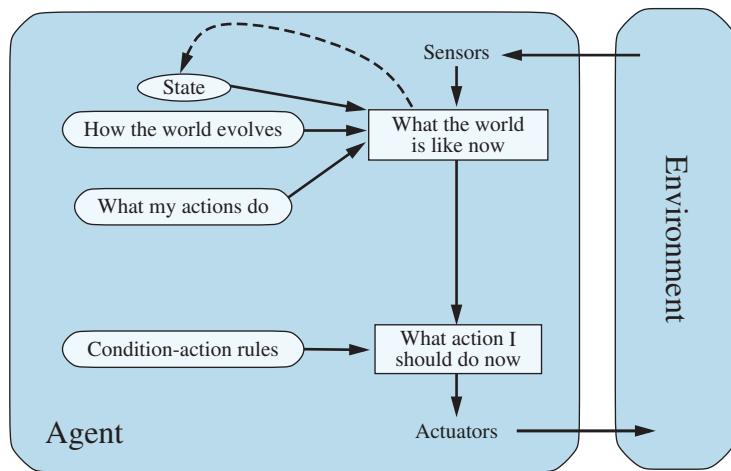

Randomization

We mentioned in Section 2.3 that randomized behavior of the right kind can be rational in some multiagent environments. In single-agent environments, randomization is usually *not* rational. It is a useful trick that helps a simple reflex agent in some situations, but in most cases we can do much better with more sophisticated deterministic agents.

### 2.4.3 Model-based reflex agents

The most effective way to handle partial observability is for the agent to *keep track of the part of the world it can't see now*. That is, the agent should maintain some sort of **internal state** that depends on the percept history and thereby reflects at least some of the unobserved aspects of the current state. For the braking problem, the internal state is not too extensive—just the previous frame from the camera, allowing the agent to detect when two red lights at the edge of the vehicle go on or off simultaneously. For other driving tasks such as changing lanes, the agent needs to keep track of where the other cars are if it can't see them all at once. And for any driving to be possible at all, the agent needs to keep track of where its keys are.

Internal state

**Figure 2.11** A model-based reflex agent.

Transition model

Updating this internal state information as time goes by requires two kinds of knowledge to be encoded in the agent program in some form. First, we need some information about how the world changes over time, which can be divided roughly into two parts: the effects of the agent’s actions and how the world evolves independently of the agent. For example, when the agent turns the steering wheel clockwise, the car turns to the right, and when it’s raining the car’s cameras can get wet. This knowledge about “how the world works”—whether implemented in simple Boolean circuits or in complete scientific theories—is called a **transition model** of the world.

Sensor model

Second, we need some information about how the state of the world is reflected in the agent’s percepts. For example, when the car in front initiates braking, one or more illuminated red regions appear in the forward-facing camera image, and, when the camera gets wet, droplet-shaped objects appear in the image partially obscuring the road. This kind of knowledge is called a **sensor model**.

Model-based agent

Together, the transition model and sensor model allow an agent to keep track of the state of the world—to the extent possible given the limitations of the agent’s sensors. An agent that uses such models is called a **model-based agent**. Figure 2.11 gives the structure of the model-based reflex agent with internal state, showing how the current percept is combined with the old internal state to generate the updated description of the current state, based on the agent’s model of how the world works. The agent program is shown in Figure 2.12. The interesting part is the function UPDATE-STATE, which is responsible for creating the new internal state description. The details of how models and states are represented vary widely depending on the type of environment and the particular technology used in the agent design.

Regardless of the kind of representation used, it is seldom possible for the agent to determine the current state of a partially observable environment *exactly*. Instead, the box labeled “what the world is like now” (Figure 2.11) represents the agent’s “best guess” (or sometimes best guesses, if the agent entertains multiple possibilities). For example, an automated taxi

---

```

function MODEL-BASED-REFLEX-AGENT(percept) returns an action
  persistent: state, the agent's current conception of the world state
    transition-model, a description of how the next state depends on
      the current state and action
    sensor-model, a description of how the current world state is reflected
      in the agent's percepts
    rules, a set of condition-action rules
    action, the most recent action, initially none

  state  $\leftarrow$  UPDATE-STATE(state, action, percept, transition-model, sensor-model)
  rule  $\leftarrow$  RULE-MATCH(state, rules)
  action  $\leftarrow$  rule.ACTION
  return action

```

**Figure 2.12** A model-based reflex agent. It keeps track of the current state of the world, using an internal model. It then chooses an action in the same way as the reflex agent.

---

may not be able to see around the large truck that has stopped in front of it and can only guess about what may be causing the hold-up. Thus, uncertainty about the current state may be unavoidable, but the agent still has to make a decision.

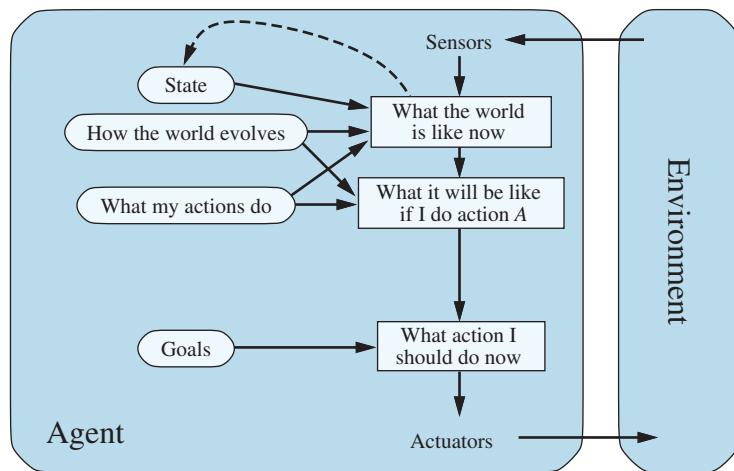

#### 2.4.4 Goal-based agents

Knowing something about the current state of the environment is not always enough to decide what to do. For example, at a road junction, the taxi can turn left, turn right, or go straight on. The correct decision depends on where the taxi is trying to get to. In other words, as well as a current state description, the agent needs some sort of **goal** information that describes situations that are desirable—for example, being at a particular destination. The agent program can combine this with the model (the same information as was used in the model-based reflex agent) to choose actions that achieve the goal. Figure 2.13 shows the goal-based agent’s structure.

Sometimes goal-based action selection is straightforward—for example, when goal satisfaction results immediately from a single action. Sometimes it will be more tricky—for example, when the agent has to consider long sequences of twists and turns in order to find a way to achieve the goal. **Search** (Chapters 3, 4, and 6) and **planning** (Chapter 11) are the subfields of AI devoted to finding action sequences that achieve the agent’s goals.

Notice that decision making of this kind is fundamentally different from the condition-action rules described earlier, in that it involves consideration of the future—both “What will happen if I do such-and-such?” and “Will that make me happy?” In the reflex agent designs, this information is not explicitly represented, because the built-in rules map directly from percepts to actions. The reflex agent brakes when it sees brake lights, period. It has no idea why. A goal-based agent brakes when it sees brake lights because that’s the only action that it predicts will achieve its goal of not hitting other cars.

Although the goal-based agent appears less efficient, it is more flexible because the knowledge that supports its decisions is represented explicitly and can be modified. For example, a goal-based agent’s behavior can easily be changed to go to a different destination,

**Figure 2.13** A model-based, goal-based agent. It keeps track of the world state as well as a set of goals it is trying to achieve, and chooses an action that will (eventually) lead to the achievement of its goals.

simply by specifying that destination as the goal. The reflex agent’s rules for when to turn and when to go straight will work only for a single destination; they must all be replaced to go somewhere new.

#### 2.4.5 Utility-based agents

Goals alone are not enough to generate high-quality behavior in most environments. For example, many action sequences will get the taxi to its destination (thereby achieving the goal), but some are quicker, safer, more reliable, or cheaper than others. Goals just provide a crude binary distinction between “happy” and “unhappy” states. A more general performance measure should allow a comparison of different world states according to exactly how happy they would make the agent. Because “happy” does not sound very scientific, economists and computer scientists use the term **utility** instead.<sup>7</sup>

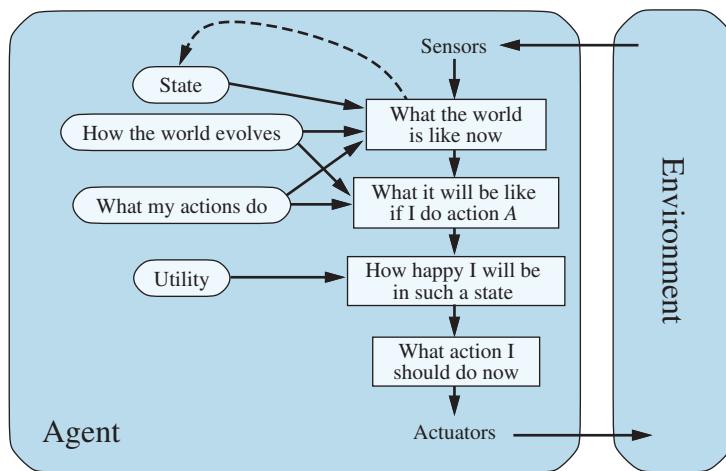

Utility

Utility function

We have already seen that a performance measure assigns a score to any given sequence of environment states, so it can easily distinguish between more and less desirable ways of getting to the taxi’s destination. An agent’s **utility function** is essentially an internalization of the performance measure. Provided that the internal utility function and the external performance measure are in agreement, an agent that chooses actions to maximize its utility will be rational according to the external performance measure.

Let us emphasize again that this is not the *only* way to be rational—we have already seen a rational agent program for the vacuum world (Figure 2.8) that has no idea what its utility function is—but, like goal-based agents, a utility-based agent has many advantages in terms of flexibility and learning. Furthermore, in two kinds of cases, goals are inadequate but a utility-based agent can still make rational decisions. First, when there are conflicting goals, only some of which can be achieved (for example, speed and safety), the utility function specifies the appropriate tradeoff. Second, when there are several goals that the agent can

<sup>7</sup> The word “utility” here refers to “the quality of being useful,” not to the electric company or waterworks.

**Figure 2.14** A model-based, utility-based agent. It uses a model of the world, along with a utility function that measures its preferences among states of the world. Then it chooses the action that leads to the best expected utility, where expected utility is computed by averaging over all possible outcome states, weighted by the probability of the outcome.

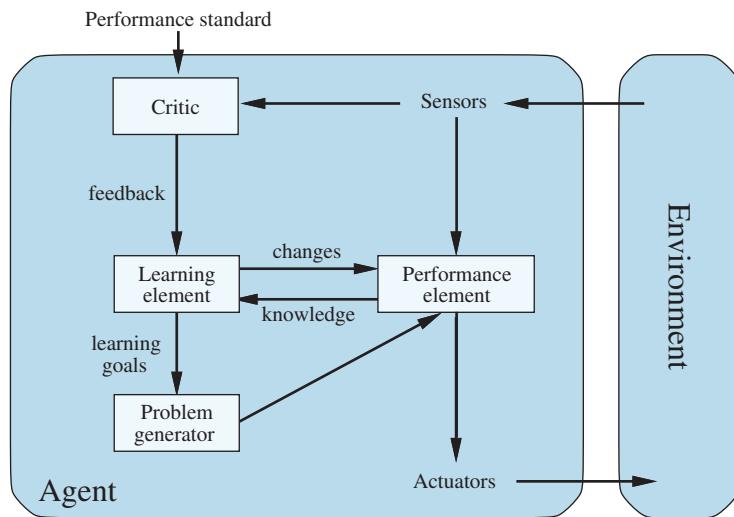

aim for, none of which can be achieved with certainty, utility provides a way in which the likelihood of success can be weighed against the importance of the goals.

Partial observability and nondeterminism are ubiquitous in the real world, and so, therefore, is decision making under uncertainty. Technically speaking, a rational utility-based agent chooses the action that maximizes the **expected utility** of the action outcomes—that is, the utility the agent expects to derive, on average, given the probabilities and utilities of each outcome. (Appendix A defines expectation more precisely.) In Chapter 15, we show that any rational agent must behave *as if* it possesses a utility function whose expected value it tries to maximize. An agent that possesses an *explicit* utility function can make rational decisions with a general-purpose algorithm that does not depend on the specific utility function being maximized. In this way, the “global” definition of rationality—designating as rational those agent functions that have the highest performance—is turned into a “local” constraint on rational-agent designs that can be expressed in a simple program.

Expected utility

The utility-based agent structure appears in Figure 2.14. Utility-based agent programs appear in Chapters 15 and 16, where we design decision-making agents that must handle the uncertainty inherent in nondeterministic or partially observable environments. Decision making in multiagent environments is also studied in the framework of utility theory, as explained in Chapter 17.

At this point, the reader may be wondering, “Is it that simple? We just build agents that maximize expected utility, and we’re done?” It’s true that such agents would be intelligent, but it’s not simple. A utility-based agent has to model and keep track of its environment, tasks that have involved a great deal of research on perception, representation, reasoning, and learning. The results of this research fill many of the chapters of this book. Choosing the utility-maximizing course of action is also a difficult task, requiring ingenious algorithms that fill several more chapters. Even with these algorithms, perfect rationality is usually

**Figure 2.15** A general learning agent. The “performance element” box represents what we have previously considered to be the whole agent program. Now, the “learning element” box gets to modify that program to improve its performance.

Model-free agent

unachievable in practice because of computational complexity, as we noted in Chapter 1. We also note that not all utility-based agents are model-based; we will see in Chapters 23 and 26 that a **model-free agent** can learn what action is best in a particular situation without ever learning exactly how that action changes the environment.

Finally, all of this assumes that the designer can specify the utility function correctly; Chapters 16, 17, and 23 consider the issue of unknown utility functions in more depth.

#### 2.4.6 Learning agents

We have described agent programs with various methods for selecting actions. We have not, so far, explained how the agent programs *come into being*. In his famous early paper, Turing (1950) considers the idea of actually programming his intelligent machines by hand. He estimates how much work this might take and concludes, “Some more expeditious method seems desirable.” The method he proposes is to build learning machines and then to teach them. In many areas of AI, this is now the preferred method for creating state-of-the-art systems. Any type of agent (model-based, goal-based, utility-based, etc.) can be built as a learning agent (or not).

Learning has another advantage, as we noted earlier: it allows the agent to operate in initially unknown environments and to become more competent than its initial knowledge alone might allow. In this section, we briefly introduce the main ideas of learning agents. Throughout the book, we comment on opportunities and methods for learning in particular kinds of agents. Chapters 19, 21, 22, and 23 go into much more depth on the learning algorithms themselves.

Learning element  
Performance element

A learning agent can be divided into four conceptual components, as shown in Figure 2.15. The most important distinction is between the **learning element**, which is responsible for making improvements, and the **performance element**, which is responsible for selecting external actions. The performance element is what we have previously considered

to be the entire agent: it takes in percepts and decides on actions. The learning element uses feedback from the **critic** on how the agent is doing and determines how the performance element should be modified to do better in the future.

The design of the learning element depends very much on the design of the performance element. When trying to design an agent that learns a certain capability, the first question is not “How am I going to get it to learn this?” but “What kind of performance element will my agent use to do this once it has learned how?” Given a design for the performance element, learning mechanisms can be constructed to improve every part of the agent.

The critic tells the learning element how well the agent is doing with respect to a fixed performance standard. The critic is necessary because the percepts themselves provide no indication of the agent’s success. For example, a chess program could receive a percept indicating that it has checkmated its opponent, but it needs a performance standard to know that this is a good thing; the percept itself does not say so. It is important that the performance standard be fixed. Conceptually, one should think of it as being outside the agent altogether because the agent must not modify it to fit its own behavior.

The last component of the learning agent is the **problem generator**. It is responsible for suggesting actions that will lead to new and informative experiences. If the performance element had its way, it would keep doing the actions that are best, given what it knows, but if the agent is willing to explore a little and do some perhaps suboptimal actions in the short run, it might discover much better actions for the long run. The problem generator’s job is to suggest these exploratory actions. This is what scientists do when they carry out experiments. Galileo did not think that dropping rocks from the top of a tower in Pisa was valuable in itself. He was not trying to break the rocks or to modify the brains of unfortunate pedestrians. His aim was to modify his own brain by identifying a better theory of the motion of objects.

The learning element can make changes to any of the “knowledge” components shown in the agent diagrams (Figures 2.9, 2.11, 2.13, and 2.14). The simplest cases involve learning directly from the percept sequence. Observation of pairs of successive states of the environment can allow the agent to learn “What my actions do” and “How the world evolves” in response to its actions. For example, if the automated taxi exerts a certain braking pressure when driving on a wet road, then it will soon find out how much deceleration is actually achieved, and whether it skids off the road. The problem generator might identify certain parts of the model that are in need of improvement and suggest experiments, such as trying out the brakes on different road surfaces under different conditions.

Improving the model components of a model-based agent so that they conform better with reality is almost always a good idea, regardless of the external performance standard. (In some cases, it is better from a computational point of view to have a simple but slightly inaccurate model rather than a perfect but fiendishly complex model.) Information from the external standard is needed when trying to learn a reflex component or a utility function.

For example, suppose the taxi-driving agent receives no tips from passengers who have been thoroughly shaken up during the trip. The external performance standard must inform the agent that the loss of tips is a negative contribution to its overall performance; then the agent might be able to learn that violent maneuvers do not contribute to its own utility. In a sense, the performance standard distinguishes part of the incoming percept as a **reward** (or **penalty**) that provides direct feedback on the quality of the agent’s behavior. Hard-wired performance standards such as pain and hunger in animals can be understood in this way.

Critic

Problem generator

Reward  
Penalty

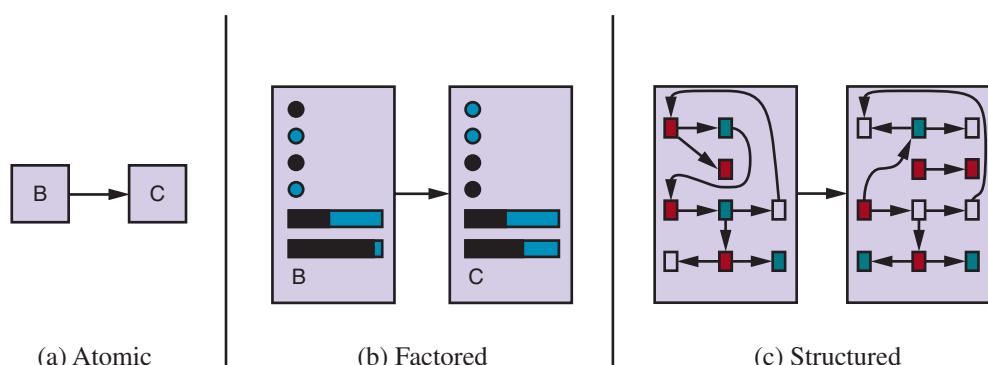

More generally, *human choices* can provide information about human preferences. For example, suppose the taxi does not know that people generally don't like loud noises, and settles on the idea of blowing its horn continuously as a way of ensuring that pedestrians know it's coming. The consequent human behavior—covering ears, using bad language, and possibly cutting the wires to the horn—would provide evidence to the agent with which to update its utility function. This issue is discussed further in Chapter 23.

In summary, agents have a variety of components, and those components can be represented in many ways within the agent program, so there appears to be great variety among learning methods. There is, however, a single unifying theme. Learning in intelligent agents can be summarized as a process of modification of each component of the agent to bring the components into closer agreement with the available feedback information, thereby improving the overall performance of the agent.

### 2.4.7 How the components of agent programs work

We have described agent programs (in very high-level terms) as consisting of various components, whose function it is to answer questions such as: “What is the world like now?” “What action should I do now?” “What do my actions do?” The next question for a student of AI is, “How on Earth do these components work?” It takes about a thousand pages to begin to answer that question properly, but here we want to draw the reader’s attention to some basic distinctions among the various ways that the components can represent the environment that the agent inhabits.

Roughly speaking, we can place the representations along an axis of increasing complexity and expressive power—atomic, factored, and structured. To illustrate these ideas, it helps to consider a particular agent component, such as the one that deals with “What my actions do.” This component describes the changes that might occur in the environment as the result of taking an action, and Figure 2.16 provides schematic depictions of how those transitions might be represented.

**Figure 2.16** Three ways to represent states and the transitions between them. (a) Atomic representation: a state (such as B or C) is a black box with no internal structure; (b) Factored representation: a state consists of a vector of attribute values; values can be Boolean, real-valued, or one of a fixed set of symbols. (c) Structured representation: a state includes objects, each of which may have attributes of its own as well as relationships to other objects.

In an **atomic representation** each state of the world is indivisible—it has no internal structure. Consider the task of finding a driving route from one end of a country to the other via some sequence of cities (we address this problem in Figure 3.1 on page 82). For the purposes of solving this problem, it may suffice to reduce the state of the world to just the name of the city we are in—a single atom of knowledge, a “black box” whose only discernible property is that of being identical to or different from another black box. The standard algorithms underlying search and game-playing (Chapters 3, 4, and 6), hidden Markov models (Chapter 14), and Markov decision processes (Chapter 16) all work with atomic representations.

A **factored representation** splits up each state into a fixed set of **variables** or **attributes**, each of which can have a **value**. Consider a higher-fidelity description for the same driving problem, where we need to be concerned with more than just atomic location in one city or another; we might need to pay attention to how much gas is in the tank, our current GPS coordinates, whether or not the oil warning light is working, how much money we have for tolls, what station is on the radio, and so on. While two different atomic states have nothing in common—they are just different black boxes—two different factored states can share some attributes (such as being at some particular GPS location) and not others (such as having lots of gas or having no gas); this makes it much easier to work out how to turn one state into another. Many important areas of AI are based on factored representations, including constraint satisfaction algorithms (Chapter 5), propositional logic (Chapter 7), planning (Chapter 11), Bayesian networks (Chapters 12, 13, 14, 15, and 18), and various machine learning algorithms.

For many purposes, we need to understand the world as having *things* in it that are *related* to each other, not just variables with values. For example, we might notice that a large truck ahead of us is reversing into the driveway of a dairy farm, but a loose cow is blocking the truck’s path. A factored representation is unlikely to be pre-equipped with the attribute *TruckAheadBackingIntoDairyFarmDrivewayBlockedByLooseCow* with value *true* or *false*. Instead, we would need a **structured representation**, in which objects such as cows and trucks and their various and varying relationships can be described explicitly (see Figure 2.16(c)). Structured representations underlie relational databases and first-order logic (Chapters 8, 9, and 10), first-order probability models (Chapter 18), and much of natural language understanding (Chapters 24 and 25). In fact, much of what humans express in natural language concerns objects and their relationships.

As we mentioned earlier, the axis along which atomic, factored, and structured representations lie is the axis of increasing **expressiveness**. Roughly speaking, a more expressive representation can capture, at least as concisely, everything a less expressive one can capture, plus some more. Often, the more expressive language is *much* more concise; for example, the rules of chess can be written in a page or two of a structured-representation language such as first-order logic but require thousands of pages when written in a factored-representation language such as propositional logic and around  $10^{38}$  pages when written in an atomic language such as that of finite-state automata. On the other hand, reasoning and learning become more complex as the expressive power of the representation increases. To gain the benefits of expressive representations while avoiding their drawbacks, intelligent systems for the real world may need to operate at all points along the axis simultaneously.

Another axis for representation involves the mapping of concepts to locations in physical memory, whether in a computer or in a brain. If there is a one-to-one mapping between concepts and memory locations, we call that a **localist representation**. On the other hand,

Atomic representation

Factored representation  
Variable  
Attribute  
Value

Structured representation

Expressiveness

Localist representation

if the representation of a concept is spread over many memory locations, and each memory location is employed as part of the representation of multiple different concepts, we call that a **distributed representation**. Distributed representations are more robust against noise and information loss. With a localist representation, the mapping from concept to memory location is arbitrary, and if a transmission error garbles a few bits, we might confuse *Truck* with the unrelated concept *Truce*. But with a distributed representation, you can think of each concept representing a point in multidimensional space, and if you garble a few bits you move to a nearby point in that space, which will have similar meaning.

## Summary

---

This chapter has been something of a whirlwind tour of AI, which we have conceived of as the science of agent design. The major points to recall are as follows:

- An **agent** is something that perceives and acts in an environment. The **agent function** for an agent specifies the action taken by the agent in response to any percept sequence.
- The **performance measure** evaluates the behavior of the agent in an environment. A **rational agent** acts so as to maximize the expected value of the performance measure, given the percept sequence it has seen so far.
- A **task environment** specification includes the performance measure, the external environment, the actuators, and the sensors. In designing an agent, the first step must always be to specify the task environment as fully as possible.
- Task environments vary along several significant dimensions. They can be fully or partially observable, single-agent or multiagent, deterministic or nondeterministic, episodic or sequential, static or dynamic, discrete or continuous, and known or unknown.
- In cases where the performance measure is unknown or hard to specify correctly, there is a significant risk of the agent optimizing the wrong objective. In such cases the agent design should reflect uncertainty about the true objective.
- The **agent program** implements the agent function. There exists a variety of basic agent program designs reflecting the kind of information made explicit and used in the decision process. The designs vary in efficiency, compactness, and flexibility. The appropriate design of the agent program depends on the nature of the environment.
- **Simple reflex agents** respond directly to percepts, whereas **model-based reflex agents** maintain internal state to track aspects of the world that are not evident in the current percept. **Goal-based agents** act to achieve their goals, and **utility-based agents** try to maximize their own expected “happiness.”
- All agents can improve their performance through **learning**.

## Bibliographical and Historical Notes

---

The central role of action in intelligence—the notion of practical reasoning—goes back at least as far as Aristotle’s *Nicomachean Ethics*. Practical reasoning was also the subject of McCarthy’s influential paper “Programs with Common Sense” (1958). The fields of robotics and control theory are, by their very nature, concerned principally with physical agents. The

concept of a **controller** in control theory is identical to that of an agent in AI. Perhaps surprisingly, AI has concentrated for most of its history on isolated components of agents—question-answering systems, theorem-provers, vision systems, and so on—rather than on whole agents. The discussion of agents in the text by Genesereth and Nilsson (1987) was an influential exception. The whole-agent view is now widely accepted and is a central theme in recent texts (Padgham and Winikoff, 2004; Jones, 2007; Poole and Mackworth, 2017).

Chapter 1 traced the roots of the concept of rationality in philosophy and economics. In AI, the concept was of peripheral interest until the mid-1980s, when it began to suffuse many discussions about the proper technical foundations of the field. A paper by Jon Doyle (1983) predicted that rational agent design would come to be seen as the core mission of AI, while other popular topics would spin off to form new disciplines.

Careful attention to the properties of the environment and their consequences for rational agent design is most apparent in the control theory tradition—for example, classical control systems (Dorf and Bishop, 2004; Kirk, 2004) handle fully observable, deterministic environments; stochastic optimal control (Kumar and Varaiya, 1986; Bertsekas and Shreve, 2007) handles partially observable, stochastic environments; and hybrid control (Henzinger and Sastry, 1998; Cassandras and Lygeros, 2006) deals with environments containing both discrete and continuous elements. The distinction between fully and partially observable environments is also central in the **dynamic programming** literature developed in the field of operations research (Puterman, 1994), which we discuss in Chapter 16.

Although simple reflex agents were central to behaviorist psychology (see Chapter 1), most AI researchers view them as too simple to provide much leverage. (Rosenschein (1985) and Brooks (1986) questioned this assumption; see Chapter 26.) A great deal of work has gone into finding efficient algorithms for keeping track of complex environments (Bar-Shalom *et al.*, 2001; Choset *et al.*, 2005; Simon, 2006), most of it in the probabilistic setting.

Goal-based agents are presupposed in everything from Aristotle's view of practical reasoning to McCarthy's early papers on logical AI. Shakey the Robot (Fikes and Nilsson, 1971; Nilsson, 1984) was the first robotic embodiment of a logical, goal-based agent. A full logical analysis of goal-based agents appeared in Genesereth and Nilsson (1987), and a goal-based programming methodology called agent-oriented programming was developed by Shoham (1993). The agent-based approach is now extremely popular in software engineering (Ciancarini and Wooldridge, 2001). It has also infiltrated the area of operating systems, where **autonomic computing** refers to computer systems and networks that monitor and control themselves with a perceive–act loop and machine learning methods (Kephart and Chess, 2003). Noting that a collection of agent programs designed to work well together in a true multiagent environment necessarily exhibits modularity—the programs share no internal state and communicate with each other only through the environment—it is common within the field of **multiagent systems** to design the agent program of a single agent as a collection of autonomous sub-agents. In some cases, one can even prove that the resulting system gives the same optimal solutions as a monolithic design.

The goal-based view of agents also dominates the cognitive psychology tradition in the area of problem solving, beginning with the enormously influential *Human Problem Solving* (Newell and Simon, 1972) and running through all of Newell's later work (Newell, 1990). Goals, further analyzed as *desires* (general) and *intentions* (currently pursued), are central to the influential theory of agents developed by Michael Bratman (1987).

Controller

Autonomic computing

As noted in Chapter 1, the development of utility theory as a basis for rational behavior goes back hundreds of years. In AI, early research eschewed utilities in favor of goals, with some exceptions (Feldman and Sproull, 1977). The resurgence of interest in probabilistic methods in the 1980s led to the acceptance of maximization of expected utility as the most general framework for decision making (Horvitz *et al.*, 1988). The text by Pearl (1988) was the first in AI to cover probability and utility theory in depth; its exposition of practical methods for reasoning and decision making under uncertainty was probably the single biggest factor in the rapid shift towards utility-based agents in the 1990s (see Chapter 15). The formalization of reinforcement learning within a decision-theoretic framework also contributed to this shift (Sutton, 1988). Somewhat remarkably, almost all AI research until very recently has assumed that the performance measure can be exactly and correctly specified in the form of a utility function or reward function (Hadfield-Menell *et al.*, 2017a; Russell, 2019).

The general design for learning agents portrayed in Figure 2.15 is classic in the machine learning literature (Buchanan *et al.*, 1978; Mitchell, 1997). Examples of the design, as embodied in programs, go back at least as far as Arthur Samuel's (1959, 1967) learning program for playing checkers. Learning agents are discussed in depth in Chapters 19, 21, 22, and 23.

Some early papers on agent-based approaches are collected by Huhns and Singh (1998) and Wooldridge and Rao (1999). Texts on multiagent systems provide a good introduction to many aspects of agent design (Weiss, 2000a; Wooldridge, 2009). Several conference series devoted to agents began in the 1990s, including the International Workshop on Agent Theories, Architectures, and Languages (ATAL), the International Conference on Autonomous Agents (AGENTS), and the International Conference on Multi-Agent Systems (ICMAS). In 2002, these three merged to form the International Joint Conference on Autonomous Agents and Multi-Agent Systems (AAMAS). From 2000 to 2012 there were annual workshops on Agent-Oriented Software Engineering (AOSE). The journal *Autonomous Agents and Multi-Agent Systems* was founded in 1998. Finally, *Dung Beetle Ecology* (Hanski and Cambefort, 1991) provides a wealth of interesting information on the behavior of dung beetles. YouTube has inspiring video recordings of their activities.

# CHAPTER 3

## SOLVING PROBLEMS BY SEARCHING

*In which we see how an agent can look ahead to find a sequence of actions that will eventually achieve its goal.*

When the correct action to take is not immediately obvious, an agent may need to *plan ahead*: to consider a *sequence* of actions that form a path to a goal state. Such an agent is called a **problem-solving agent**, and the computational process it undertakes is called **search**.

Problem-solving agents use **atomic** representations, as described in Section 2.4.7—that is, states of the world are considered as wholes, with no internal structure visible to the problem-solving algorithms. Agents that use **factored** or **structured** representations of states are called **planning agents** and are discussed in Chapters 7 and 11.

We will cover several search algorithms. In this chapter, we consider only the simplest environments: episodic, single agent, fully observable, deterministic, static, discrete, and known. We distinguish between **informed** algorithms, in which the agent can estimate how far it is from the goal, and **uninformed** algorithms, where no such estimate is available. Chapter 4 relaxes the constraints on environments, and Chapter 6 considers multiple agents.

This chapter uses the concepts of asymptotic complexity (that is,  $O(n)$  notation). Readers unfamiliar with these concepts should consult Appendix A.

### 3.1 Problem-Solving Agents

Imagine an agent enjoying a touring vacation in Romania. The agent wants to take in the sights, improve its Romanian, enjoy the nightlife, avoid hangovers, and so on. The decision problem is a complex one. Now, suppose the agent is currently in the city of Arad and has a nonrefundable ticket to fly out of Bucharest the following day. The agent observes street signs and sees that there are three roads leading out of Arad: one toward Sibiu, one to Timisoara, and one to Zerind. None of these are the goal, so unless the agent is familiar with the geography of Romania, it will not know which road to follow.<sup>1</sup>

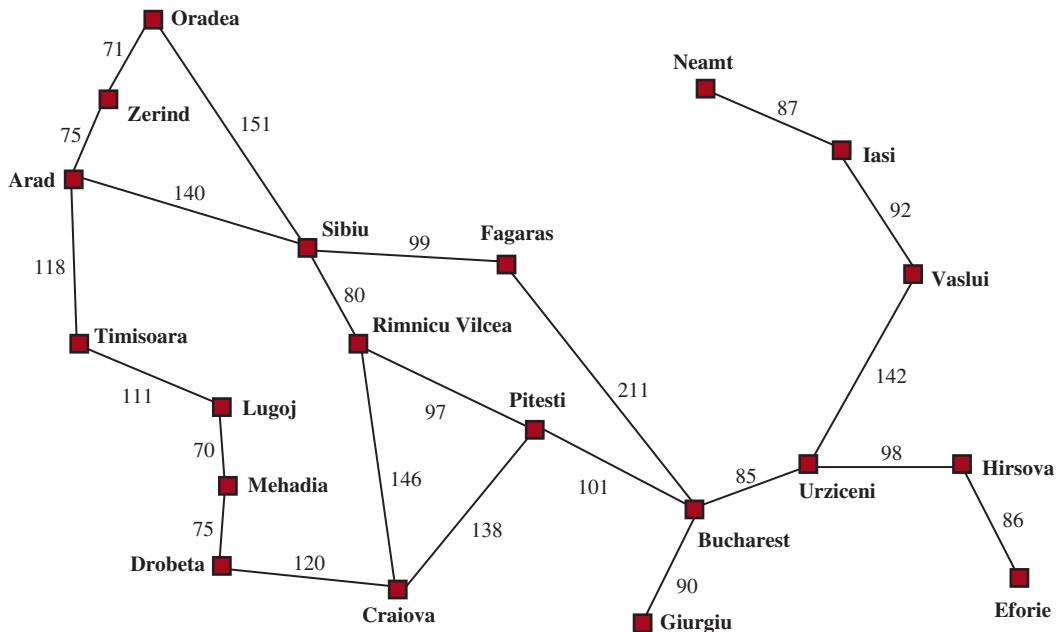

If the agent has no additional information—that is, if the environment is **unknown**—then the agent can do no better than to execute one of the actions at random. This sad situation is discussed in Chapter 4. In this chapter, we will assume our agents always have access to information about the world, such as the map in Figure 3.1. With that information, the agent can follow this four-phase problem-solving process:

- **Goal formulation:** The agent adopts the **goal** of reaching Bucharest. Goals organize behavior by limiting the objectives and hence the actions to be considered.

Problem-solving  
agent  
Search

<sup>1</sup> We are assuming that most readers are in the same position and can easily imagine themselves to be as clueless as our agent. We apologize to Romanian readers who are unable to take advantage of this pedagogical device.

Goal formulation

**Figure 3.1** A simplified road map of part of Romania, with road distances in miles.

#### Problem formulation

- **Problem formulation:** The agent devises a description of the states and actions necessary to reach the goal—an abstract model of the relevant part of the world. For our agent, one good model is to consider the actions of traveling from one city to an adjacent city, and therefore the only fact about the state of the world that will change due to an action is the current city.

#### Search

- **Search:** Before taking any action in the real world, the agent simulates sequences of actions in its model, searching until it finds a sequence of actions that reaches the goal. Such a sequence is called a **solution**. The agent might have to simulate multiple sequences that do not reach the goal, but eventually it will find a solution (such as going from Arad to Sibiu to Fagaras to Bucharest), or it will find that no solution is possible.

#### Execution

- **Execution:** The agent can now execute the actions in the solution, one at a time.

► It is an important property that in a fully observable, deterministic, known environment, *the solution to any problem is a fixed sequence of actions*: drive to Sibiu, then Fagaras, then Bucharest. If the model is correct, then once the agent has found a solution, it can ignore its percepts while it is executing the actions—closing its eyes, so to speak—because the solution is guaranteed to lead to the goal. Control theorists call this an **open-loop** system: ignoring the percepts breaks the loop between agent and environment. If there is a chance that the model is incorrect, or the environment is nondeterministic, then the agent would be safer using a **closed-loop** approach that monitors the percepts (see Section 4.4).

#### Open-loop

In partially observable or nondeterministic environments, a solution would be a branching strategy that recommends different future actions depending on what percepts arrive. For example, the agent might plan to drive from Arad to Sibiu but might need a contingency plan in case it arrives in Zerind by accident or finds a sign saying “Drum Închis” (Road Closed).

#### Closed-loop

### 3.1.1 Search problems and solutions

A search **problem** can be defined formally as follows:

- A set of possible **states** that the environment can be in. We call this the **state space**. Problem States
- The **initial state** that the agent starts in. For example: *Arad*. Initial state
- A set of one or more **goal states**. Sometimes there is one goal state (e.g., *Bucharest*), sometimes there is a small set of alternative goal states, and sometimes the goal is defined by a property that applies to many states (potentially an infinite number). For example, in a vacuum-cleaner world, the goal might be to have no dirt in any location, regardless of any other facts about the state. We can account for all three of these possibilities by specifying an **IS-GOAL** method for a problem. In this chapter we will sometimes say “the goal” for simplicity, but what we say also applies to “any one of the possible goal states.” Goal states
- The **actions** available to the agent. Given a state  $s$ ,  $\text{ACTIONS}(s)$  returns a finite<sup>2</sup> set of actions that can be executed in  $s$ . We say that each of these actions is **applicable** in  $s$ . Action Applicable  
An example:

$$\text{ACTIONS}(\text{Arad}) = \{\text{ToSibiu}, \text{ToTimisoara}, \text{ToZerind}\}.$$

- A **transition model**, which describes what each action does.  $\text{RESULT}(s, a)$  returns the state that results from doing action  $a$  in state  $s$ . For example, Transition model

$$\text{RESULT}(\text{Arad}, \text{ToZerind}) = \text{Zerind}.$$

- An **action cost function**, denoted by  $\text{ACTION-COST}(s, a, s')$  when we are programming or  $c(s, a, s')$  when we are doing math, that gives the numeric cost of applying action  $a$  in state  $s$  to reach state  $s'$ . A problem-solving agent should use a cost function that reflects its own performance measure; for example, for route-finding agents, the cost of an action might be the length in miles (as seen in Figure 3.1), or it might be the time it takes to complete the action. Action cost function

A sequence of actions forms a **path**, and a **solution** is a path from the initial state to a goal state. We assume that action costs are additive; that is, the total cost of a path is the sum of the individual action costs. An **optimal solution** has the lowest path cost among all solutions. In this chapter, we assume that all action costs will be positive, to avoid certain complications.<sup>3</sup> Path Optimal solution

The state space can be represented as a **graph** in which the vertices are states and the directed edges between them are actions. The map of Romania shown in Figure 3.1 is such a graph, where each road indicates two actions, one in each direction. Graph

<sup>2</sup> For problems with an infinite number of actions we would need techniques that go beyond this chapter.

<sup>3</sup> In any problem with a cycle of net negative cost, the cost-optimal solution is to go around that cycle an infinite number of times. The Bellman–Ford and Floyd–Warshall algorithms (not covered here) handle negative-cost actions, as long as there are no negative cycles. It is easy to accommodate zero-cost actions, as long as the number of consecutive zero-cost actions is bounded. For example, we might have a robot where there is a cost to move, but zero cost to rotate 90°; the algorithms in this chapter can handle this as long as no more than three consecutive 90° turns are allowed. There is also a complication with problems that have an infinite number of arbitrarily small action costs. Consider a version of Zeno’s paradox where there is an action to move half way to the goal, at a cost of half of the previous move. This problem has no solution with a finite number of actions, but to prevent a search from taking an unbounded number of actions without quite reaching the goal, we can require that all action costs be at least  $\epsilon$ , for some small positive value  $\epsilon$ .

### 3.1.2 Formulating problems

Our formulation of the problem of getting to Bucharest is a **model**—an abstract mathematical description—and not the real thing. Compare the simple atomic state description *Arad* to an actual cross-country trip, where the state of the world includes so many things: the traveling companions, the current radio program, the scenery out of the window, the proximity of law enforcement officers, the distance to the next rest stop, the condition of the road, the weather, the traffic, and so on. All these considerations are left out of our model because they are irrelevant to the problem of finding a route to Bucharest.

**Abstraction**

The process of removing detail from a representation is called **abstraction**. A good problem formulation has the right level of detail. If the actions were at the level of “move the right foot forward a centimeter” or “turn the steering wheel one degree left,” the agent would probably never find its way out of the parking lot, let alone to Bucharest.

**Level of abstraction**

Can we be more precise about the appropriate **level of abstraction**? Think of the abstract states and actions we have chosen as corresponding to large sets of detailed world states and detailed action sequences. Now consider a solution to the abstract problem: for example, the path from Arad to Sibiu to Rimnicu Vilcea to Pitesti to Bucharest. This abstract solution corresponds to a large number of more detailed paths. For example, we could drive with the radio on between Sibiu and Rimnicu Vilcea, and then switch it off for the rest of the trip.

The abstraction is *valid* if we can elaborate any abstract solution into a solution in the more detailed world; a sufficient condition is that for every detailed state that is “in Arad,” there is a detailed path to some state that is “in Sibiu,” and so on.<sup>4</sup> The abstraction is *useful* if carrying out each of the actions in the solution is easier than the original problem; in our case, the action “drive from Arad to Sibiu” can be carried out without further search or planning by a driver with average skill. The choice of a good abstraction thus involves removing as much detail as possible while retaining validity and ensuring that the abstract actions are easy to carry out. Were it not for the ability to construct useful abstractions, intelligent agents would be completely swamped by the real world.

## 3.2 Example Problems

---

**Standardized problem**

The problem-solving approach has been applied to a vast array of task environments. We list some of the best known here, distinguishing between *standardized* and *real-world* problems. A **standardized problem** is intended to illustrate or exercise various problem-solving methods. It can be given a concise, exact description and hence is suitable as a benchmark for researchers to compare the performance of algorithms. A **real-world problem**, such as robot navigation, is one whose solutions people actually use, and whose formulation is idiosyncratic, not standardized, because, for example, each robot has different sensors that produce different data.

**Real-world problem**

**Grid world**

### 3.2.1 Standardized problems

A **grid world** problem is a two-dimensional rectangular array of square cells in which agents can move from cell to cell. Typically the agent can move to any obstacle-free adjacent cell—horizontally or vertically and in some problems diagonally. Cells can contain objects, which

<sup>4</sup> See Section 11.4.

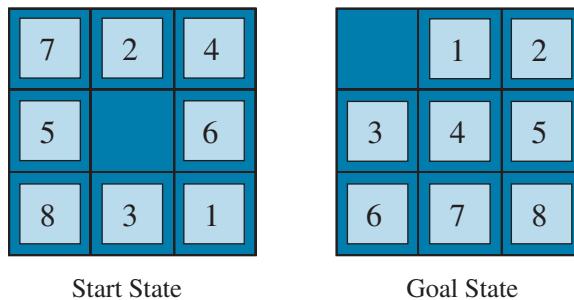

**Figure 3.2** The state-space graph for the two-cell vacuum world. There are 8 states and three actions for each state: L = Left, R = Right, S = Suck.

the agent can pick up, push, or otherwise act upon; a wall or other impassible obstacle in a cell prevents an agent from moving into that cell. The **vacuum world** from Section 2.1 can be formulated as a grid world problem as follows:

- **States:** A state of the world says which objects are in which cells. For the vacuum world, the objects are the agent and any dirt. In the simple two-cell version, the agent can be in either of the two cells, and each cell can either contain dirt or not, so there are  $2 \cdot 2 \cdot 2 = 8$  states (see Figure 3.2). In general, a vacuum environment with  $n$  cells has  $n \cdot 2^n$  states.
- **Initial state:** Any state can be designated as the initial state.
- **Actions:** In the two-cell world we defined three actions: *Suck*, move *Left*, and move *Right*. In a two-dimensional multi-cell world we need more movement actions. We could add *Upward* and *Downward*, giving us four **absolute** movement actions, or we could switch to **egocentric actions**, defined relative to the viewpoint of the agent—for example, *Forward*, *Backward*, *TurnRight*, and *TurnLeft*.
- **Transition model:** *Suck* removes any dirt from the agent's cell; *Forward* moves the agent ahead one cell in the direction it is facing, unless it hits a wall, in which case the action has no effect. *Backward* moves the agent in the opposite direction, while *TurnRight* and *TurnLeft* change the direction it is facing by 90°.
- **Goal states:** The states in which every cell is clean.
- **Action cost:** Each action costs 1.

Another type of grid world is the **sokoban puzzle**, in which the agent's goal is to push a number of boxes, scattered about the grid, to designated storage locations. There can be at most one box per cell. When an agent moves forward into a cell containing a box and there is an empty cell on the other side of the box, then both the box and the agent move forward.

[Sokoban puzzle](#)

**Figure 3.3** A typical instance of the 8-puzzle.**Sliding-tile puzzle****8-puzzle**  
**15-puzzle**

The agent can't push a box into another box or a wall. For a world with  $n$  non-obstacle cells and  $b$  boxes, there are  $n \times n!/(b!(n-b)!)$  states; for example on an  $8 \times 8$  grid with a dozen boxes, there are over 200 trillion states.

In a **sliding-tile puzzle**, a number of tiles (sometimes called blocks or pieces) are arranged in a grid with one or more blank spaces so that some of the tiles can slide into the blank space. One variant is the Rush Hour puzzle, in which cars and trucks slide around a  $6 \times 6$  grid in an attempt to free a car from the traffic jam. Perhaps the best-known variant is the **8-puzzle** (see Figure 3.3), which consists of a  $3 \times 3$  grid with eight numbered tiles and one blank space, and the **15-puzzle** on a  $4 \times 4$  grid. The object is to reach a specified goal state, such as the one shown on the right of the figure. The standard formulation of the 8 puzzle is as follows:

- **States:** A state description specifies the location of each of the tiles.
- **Initial state:** Any state can be designated as the initial state. Note that a parity property partitions the state space—any given goal can be reached from exactly half of the possible initial states (see Exercise 3.PART).
- **Actions:** While in the physical world it is a tile that slides, the simplest way of describing an action is to think of the blank space moving *Left*, *Right*, *Up*, or *Down*. If the blank is at an edge or corner then not all actions will be applicable.
- **Transition model:** Maps a state and action to a resulting state; for example, if we apply *Left* to the start state in Figure 3.3, the resulting state has the 5 and the blank switched.
- **Goal state:** Although any state could be the goal, we typically specify a state with the numbers in order, as in Figure 3.3.
- **Action cost:** Each action costs 1.

Note that every problem formulation involves abstractions. The 8-puzzle actions are abstracted to their beginning and final states, ignoring the intermediate locations where the tile is sliding. We have abstracted away actions such as shaking the board when tiles get stuck and ruled out extracting the tiles with a knife and putting them back again. We are left with a description of the rules, avoiding all the details of physical manipulations.

Our final standardized problem was devised by Donald Knuth (1964) and illustrates how infinite state spaces can arise. Knuth conjectured that starting with the number 4, a sequence

of square root, floor, and factorial operations can reach any desired positive integer. For example, we can reach 5 from 4 as follows:

$$\lfloor \sqrt{\sqrt{\sqrt{\sqrt{\sqrt{(4!)!}}}}} \rfloor = 5.$$

The problem definition is simple:

- **States:** Positive real numbers.
- **Initial state:** 4.
- **Actions:** Apply square root, floor, or factorial operation (factorial for integers only).
- **Transition model:** As given by the mathematical definitions of the operations.
- **Goal state:** The desired positive integer.
- **Action cost:** Each action costs 1.

The state space for this problem is infinite: for any integer greater than 2 the factorial operator will always yield a larger integer. The problem is interesting because it explores very large numbers: the shortest path to 5 goes through  $(4!)! = 620,448,401,733,239,439,360,000$ . Infinite state spaces arise frequently in tasks involving the generation of mathematical expressions, circuits, proofs, programs, and other recursively defined objects.

### 3.2.2 Real-world problems

We have already seen how the **route-finding problem** is defined in terms of specified locations and transitions along edges between them. Route-finding algorithms are used in a variety of applications. Some, such as Web sites and in-car systems that provide driving directions, are relatively straightforward extensions of the Romania example. (The main complications are varying costs due to traffic-dependent delays, and rerouting due to road closures.) Others, such as routing video streams in computer networks, military operations planning, and airline travel-planning systems, involve much more complex specifications. Consider the airline travel problems that must be solved by a travel-planning Web site:

- **States:** Each state obviously includes a location (e.g., an airport) and the current time. Furthermore, because the cost of an action (a flight segment) may depend on previous segments, their fare bases, and their status as domestic or international, the state must record extra information about these “historical” aspects.
- **Initial state:** The user’s home airport.
- **Actions:** Take any flight from the current location, in any seat class, leaving after the current time, leaving enough time for within-airport transfer if needed.
- **Transition model:** The state resulting from taking a flight will have the flight’s destination as the new location and the flight’s arrival time as the new time.
- **Goal state:** A destination city. Sometimes the goal can be more complex, such as “arrive at the destination on a nonstop flight.”
- **Action cost:** A combination of monetary cost, waiting time, flight time, customs and immigration procedures, seat quality, time of day, type of airplane, frequent-flyer reward points, and so on.

Commercial travel advice systems use a problem formulation of this kind, with many additional complications to handle the airlines' byzantine fare structures. Any seasoned traveler knows, however, that not all air travel goes according to plan. A really good system should include contingency plans—what happens if this flight is delayed and the connection is missed?

Touring problem

Traveling salesperson problem (TSP)

VLSI layout

Robot navigation

Automatic assembly sequencing

Protein design

**Touring problems** describe a set of locations that must be visited, rather than a single goal destination. The **traveling salesperson problem (TSP)** is a touring problem in which every city on a map must be visited. The aim is to find a tour with cost  $< C$  (or in the optimization version, to find a tour with the lowest cost possible). An enormous amount of effort has been expended to improve the capabilities of TSP algorithms. The algorithms can also be extended to handle fleets of vehicles. For example, a search and optimization algorithm for routing school buses in Boston saved \$5 million, cut traffic and air pollution, and saved time for drivers and students (Bertsimas *et al.*, 2019). In addition to planning trips, search algorithms have been used for tasks such as planning the movements of automatic circuit-board drills and of stocking machines on shop floors.

A **VLSI layout** problem requires positioning millions of components and connections on a chip to minimize area, minimize circuit delays, minimize stray capacitances, and maximize manufacturing yield. The layout problem comes after the logical design phase and is usually split into two parts: **cell layout** and **channel routing**. In cell layout, the primitive components of the circuit are grouped into cells, each of which performs some recognized function. Each cell has a fixed footprint (size and shape) and requires a certain number of connections to each of the other cells. The aim is to place the cells on the chip so that they do not overlap and so that there is room for the connecting wires to be placed between the cells. Channel routing finds a specific route for each wire through the gaps between the cells. These search problems are extremely complex, but definitely worth solving.

**Robot navigation** is a generalization of the route-finding problem described earlier. Rather than following distinct paths (such as the roads in Romania), a robot can roam around, in effect making its own paths. For a circular robot moving on a flat surface, the space is essentially two-dimensional. When the robot has arms and legs that must also be controlled, the search space becomes many-dimensional—one dimension for each joint angle. Advanced techniques are required just to make the essentially continuous search space finite (see Chapter 26). In addition to the complexity of the problem, real robots must also deal with errors in their sensor readings and motor controls, with partial observability, and with other agents that might alter the environment.

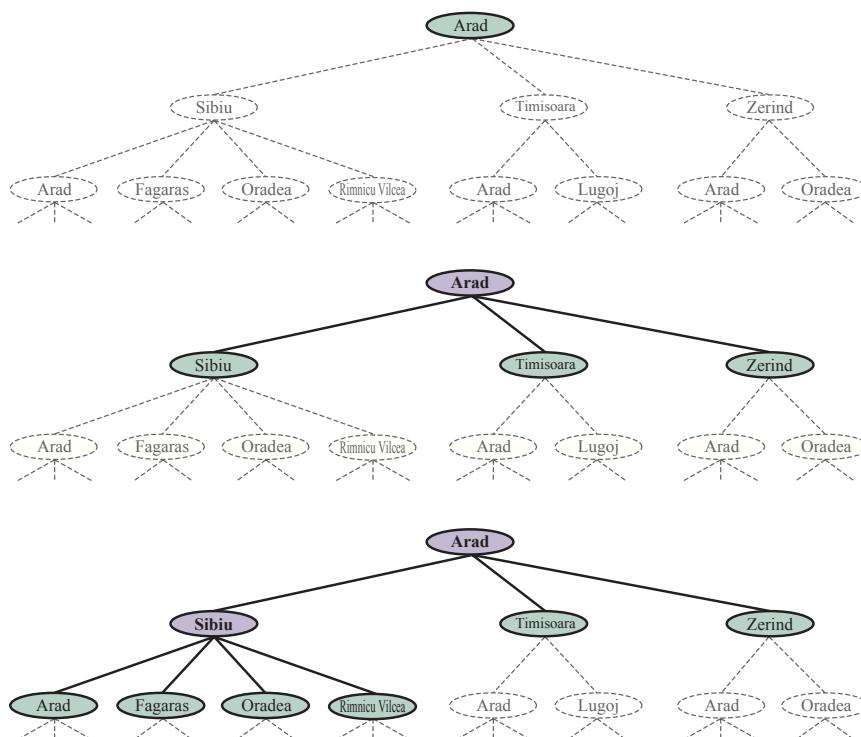

**Automatic assembly sequencing** of complex objects (such as electric motors) by a robot has been standard industry practice since the 1970s. Algorithms first find a feasible assembly sequence and then work to optimize the process. Minimizing the amount of manual human labor on the assembly line can produce significant savings in time and cost. In assembly problems, the aim is to find an order in which to assemble the parts of some object. If the wrong order is chosen, there will be no way to add some part later in the sequence without undoing some of the work already done. Checking an action in the sequence for feasibility is a difficult geometrical search problem closely related to robot navigation. Thus, the generation of legal actions is the expensive part of assembly sequencing. Any practical algorithm must avoid exploring all but a tiny fraction of the state space. One important assembly problem is **protein design**, in which the goal is to find a sequence of amino acids that will fold into a three-dimensional protein with the right properties to cure some disease.

### 3.3 Search Algorithms

A **search algorithm** takes a search problem as input and returns a solution, or an indication of failure. In this chapter we consider algorithms that superimpose a **search tree** over the state-space graph, forming various paths from the initial state, trying to find a path that reaches a goal state. Each **node** in the search tree corresponds to a state in the state space and the edges in the search tree correspond to actions. The root of the tree corresponds to the initial state of the problem.

It is important to understand the distinction between the state space and the search tree. The state space describes the (possibly infinite) set of states in the world, and the actions that allow transitions from one state to another. The search tree describes paths between these states, reaching towards the goal. The search tree may have multiple paths to (and thus multiple nodes for) any given state, but each node in the tree has a unique path back to the root (as in all trees).

Figure 3.4 shows the first few steps in finding a path from Arad to Bucharest. The root node of the search tree is at the initial state, *Arad*. We can **expand** the node, by considering

**Figure 3.4** Three partial search trees for finding a route from Arad to Bucharest. Nodes that have been *expanded* are lavender with bold letters; nodes on the frontier that have been *generated* but not yet expanded are in green; the set of states corresponding to these two types of nodes are said to have been *reached*. Nodes that could be generated next are shown in faint dashed lines. Notice in the bottom tree there is a cycle from Arad to Sibiu to Arad; that can't be an optimal path, so search should not continue from there.

**Figure 3.5** A sequence of search trees generated by a graph search on the Romania problem of Figure 3.1. At each stage, we have expanded every node on the frontier, extending every path with all applicable actions that don't result in a state that has already been reached. Notice that at the third stage, the topmost city (Oradea) has two successors, both of which have already been reached by other paths, so no paths are extended from Oradea.

**Figure 3.6** The separation property of graph search, illustrated on a rectangular-grid problem. The frontier (green) separates the interior (lavender) from the exterior (faint dashed). The frontier is the set of nodes (and corresponding states) that have been reached but not yet expanded; the interior is the set of nodes (and corresponding states) that have been expanded; and the exterior is the set of states that have not been reached. In (a), just the root has been expanded. In (b), the top frontier node is expanded. In (c), the remaining successors of the root are expanded in clockwise order.

Generating	
Child node	
Successor node	
Parent node	
Frontier	
Reached	
Separator	

the available ACTIONS for that state, using the RESULT function to see where those actions lead to, and **generating** a new node (called a **child node** or **successor node**) for each of the resulting states. Each child node has *Arad* as its **parent node**.

Now we must choose which of these three child nodes to consider next. This is the essence of search—following up one option now and putting the others aside for later. Suppose we choose to expand Sibiu first. Figure 3.4 (bottom) shows the result: a set of 6 unexpanded nodes (outlined in bold). We call this the **frontier** of the search tree. We say that any state that has had a node generated for it has been **reached** (whether or not that node has been expanded).<sup>5</sup> Figure 3.5 shows the search tree superimposed on the state-space graph.

Note that the frontier **separates** two regions of the state-space graph: an interior region where every state has been expanded, and an exterior region of states that have not yet been reached. This property is illustrated in Figure 3.6.

<sup>5</sup> Some authors call the frontier the **open list**, which is both geographically less evocative and computationally less appropriate, because a queue is more efficient than a list here. Those authors use the term **closed list** to refer to the set of previously expanded nodes, which in our terminology would be the *reached* nodes minus the *frontier*.

---

```

function BEST-FIRST-SEARCH(problem,f) returns a solution node or failure
  node  $\leftarrow$  NODE(STATE=problem.INITIAL)
  frontier  $\leftarrow$  a priority queue ordered by f, with node as an element
  reached  $\leftarrow$  a lookup table, with one entry with key problem.INITIAL and value node
  while not IS-EMPTY(frontier) do
    node  $\leftarrow$  POP(frontier)
    if problem.IS-GOAL(node.STATE) then return node
    for each child in EXPAND(problem, node) do
      s  $\leftarrow$  child.STATE
      if s is not in reached or child.PATH-COST < reached[s].PATH-COST then
        reached[s]  $\leftarrow$  child
        add child to frontier
    return failure

function EXPAND(problem, node) yields nodes
  s  $\leftarrow$  node.STATE
  for each action in problem.ACTIONS(s) do
    s'  $\leftarrow$  problem.RESULT(s, action)
    cost  $\leftarrow$  node.PATH-COST + problem.ACTION-COST(s, action, s')
    yield NODE(STATE=s', PARENT=node, ACTION=action, PATH-COST=cost)

```

**Figure 3.7** The best-first search algorithm, and the function for expanding a node. The data structures used here are described in Section 3.3.2. See Appendix B for **yield**.

---

### 3.3.1 Best-first search

How do we decide which node from the frontier to expand next? A very general approach is called **best-first search**, in which we choose a node, *n*, with minimum value of some **evaluation function**, *f(n)*. Figure 3.7 shows the algorithm. On each iteration we choose a node on the frontier with minimum *f(n)* value, return it if its state is a goal state, and otherwise apply EXPAND to generate child nodes. Each child node is added to the frontier if it has not been reached before, or is re-added if it is now being reached with a path that has a lower path cost than any previous path. The algorithm returns either an indication of failure, or a node that represents a path to a goal. By employing different *f(n)* functions, we get different specific algorithms, which this chapter will cover.

Best-first search  
Evaluation function

### 3.3.2 Search data structures

Search algorithms require a data structure to keep track of the search tree. A **node** in the tree is represented by a data structure with four components:

- *node.STATE*: the state to which the node corresponds;
- *node.PARENT*: the node in the tree that generated this node;
- *node.ACTION*: the action that was applied to the parent's state to generate this node;
- *node.PATH-COST*: the total cost of the path from the initial state to this node. In mathematical formulas, we use  $g(\text{node})$  as a synonym for PATH-COST.

Following the PARENT pointers back from a node allows us to recover the states and actions along the path to that node. Doing this from a goal node gives us the solution.

## Queue

We need a data structure to store the **frontier**. The appropriate choice is a **queue** of some kind, because the operations on a frontier are:

- $\text{IS-EMPTY}(\text{frontier})$  returns true only if there are no nodes in the frontier.
- $\text{POP}(\text{frontier})$  removes the top node from the frontier and returns it.
- $\text{TOP}(\text{frontier})$  returns (but does not remove) the top node of the frontier.
- $\text{ADD}(\text{node}, \text{frontier})$  inserts node into its proper place in the queue.

Three kinds of queues are used in search algorithms:

## Priority queue

- A **priority queue** first pops the node with the minimum cost according to some evaluation function,  $f$ . It is used in best-first search.

## FIFO queue

- A **FIFO queue** or first-in-first-out queue first pops the node that was added to the queue first; we shall see it is used in breadth-first search.

## LIFO queue

- A **LIFO queue** or last-in-first-out queue (also known as a **stack**) pops first the most recently added node; we shall see it is used in depth-first search.

## Stack

The reached states can be stored as a lookup table (e.g. a hash table) where each key is a state and each value is the node for that state.

### 3.3.3 Redundant paths

## Repeated state

## Cycle

## Loopy path

## Redundant path

The search tree shown in Figure 3.4 (bottom) includes a path from Arad to Sibiu and back to Arad again. We say that *Arad* is a **repeated state** in the search tree, generated in this case by a **cycle** (also known as a **loopy path**). So even though the state space has only 20 states, the complete search tree is *infinite* because there is no limit to how often one can traverse a loop.

A cycle is a special case of a **redundant path**. For example, we can get to Sibiu via the path Arad–Sibiu (140 miles long) or the path Arad–Zerind–Oradea–Sibiu (297 miles long). This second path is redundant—it's just a worse way to get to the same state—and need not be considered in our quest for optimal paths.

Consider an agent in a  $10 \times 10$  grid world, with the ability to move to any of 8 adjacent squares. If there are no obstacles, the agent can reach any of the 100 squares in 9 moves or fewer. But the number of paths of length 9 is almost  $8^9$  (a bit less because of the edges of the grid), or more than 100 million. In other words, the average cell can be reached by over a million redundant paths of length 9, and if we eliminate redundant paths, we can complete a search roughly a million times faster. As the saying goes, *algorithms that cannot remember the past are doomed to repeat it*. There are three approaches to this issue.

First, we can remember all previously reached states (as best-first search does), allowing us to detect all redundant paths, and keep only the best path to each state. This is appropriate for state spaces where there are many redundant paths, and is the preferred choice when the table of reached states will fit in memory.

Second, we can not worry about repeating the past. There are some problem formulations where it is rare or impossible for two paths to reach the same state. An example would be an assembly problem where each action adds a part to an evolving assemblage, and there is an ordering of parts so that it is possible to add *A* and then *B*, but not *B* and then *A*. For those problems, we could save memory space if we *don't* track reached states and we don't check for redundant paths. We call a search algorithm a **graph search** if it checks for redundant paths and a **tree-like search**<sup>6</sup> if it does not check. The BEST-FIRST-SEARCH algorithm in

## Graph search

## Tree-like search

Figure 3.7 is a graph search algorithm; if we remove all references to *reached* we get a tree-like search that uses less memory but will examine redundant paths to the same state, and thus will run slower.<sup>6</sup>

Third, we can compromise and check for cycles, but not for redundant paths in general. Since each node has a chain of parent pointers, we can check for cycles with no need for additional memory by following up the chain of parents to see if the state at the end of the path has appeared earlier in the path. Some implementations follow this chain all the way up, and thus eliminate all cycles; other implementations follow only a few links (e.g., to the parent, grandparent, and great-grandparent), and thus take only a constant amount of time, while eliminating all short cycles (and relying on other mechanisms to deal with long cycles).

### 3.3.4 Measuring problem-solving performance

Before we get into the design of various search algorithms, we will consider the criteria used to choose among them. We can evaluate an algorithm’s performance in four ways:

- **Completeness:** Is the algorithm guaranteed to find a solution when there is one, and to correctly report failure when there is not? Completeness
- **Cost optimality:** Does it find a solution with the lowest path cost of all solutions?<sup>7</sup> Cost optimality
- **Time complexity:** How long does it take to find a solution? This can be measured in seconds, or more abstractly by the number of states and actions considered. Time complexity
- **Space complexity:** How much memory is needed to perform the search? Space complexity

To understand completeness, consider a search problem with a single goal. That goal could be anywhere in the state space; therefore a complete algorithm must be capable of systematically exploring every state that is reachable from the initial state. In finite state spaces that is straightforward to achieve: as long as we keep track of paths and cut off ones that are cycles (e.g. Arad to Sibiu to Arad), eventually we will reach every reachable state.

In infinite state spaces, more care is necessary. For example, an algorithm that repeatedly applied the “factorial” operator in Knuth’s “4” problem would follow an infinite path from 4 to 4! to (4!)!, and so on. Similarly, on an infinite grid with no obstacles, repeatedly moving forward in a straight line also follows an infinite path of new states. In both cases the algorithm never returns to a state it has reached before, but is incomplete because wide expanses of the state space are never reached.

To be complete, a search algorithm must be **systematic** in the way it explores an infinite state space, making sure it can eventually reach any state that is connected to the initial state. For example, on the infinite grid, one kind of systematic search is a spiral path that covers all the cells that are  $s$  steps from the origin before moving out to cells that are  $s + 1$  steps away. Unfortunately, in an infinite state space with no solution, a sound algorithm needs to keep searching forever; it can’t terminate because it can’t know if the next state will be a goal.

Time and space complexity are considered with respect to some measure of the problem difficulty. In theoretical computer science, the typical measure is the size of the state-space graph,  $|V| + |E|$ , where  $|V|$  is the number of vertices (state nodes) of the graph and  $|E|$  is

<sup>6</sup> We say “tree-like search” because the state space is still the same graph no matter how we search it; we are just choosing to treat it *as if* it were a tree, with only one path from each node back to the root.

<sup>7</sup> Some authors use the term “admissibility” for the property of finding the lowest-cost solution, and some use just “optimality,” but that can be confused with other types of optimality.

Depth

Branching factor

the number of edges (distinct state/action pairs). This is appropriate when the graph is an explicit data structure, such as the map of Romania. But in many AI problems, the graph is represented only *implicitly* by the initial state, actions, and transition model. For an implicit state space, complexity can be measured in terms of  $d$ , the **depth** or number of actions in an optimal solution;  $m$ , the maximum number of actions in any path; and  $b$ , the **branching factor** or number of successors of a node that need to be considered.

## 3.4 Uninformed Search Strategies

An uninformed search algorithm is given no clue about how close a state is to the goal(s). For example, consider our agent in Arad with the goal of reaching Bucharest. An uninformed agent with no knowledge of Romanian geography has no clue whether going to Zerind or Sibiu is a better first step. In contrast, an informed agent (Section 3.5) who knows the location of each city knows that Sibiu is much closer to Bucharest and thus more likely to be on the shortest path.

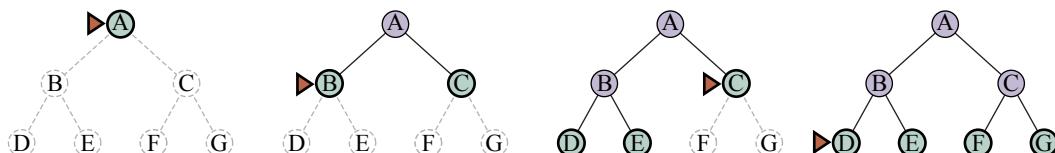

### 3.4.1 Breadth-first search

Breadth-first search

When all actions have the same cost, an appropriate strategy is **breadth-first search**, in which the root node is expanded first, then all the successors of the root node are expanded next, then *their* successors, and so on. This is a systematic search strategy that is therefore complete even on infinite state spaces. We could implement breadth-first search as a call to BEST-FIRST-SEARCH where the evaluation function  $f(n)$  is the depth of the node—that is, the number of actions it takes to reach the node.

However, we can get additional efficiency with a couple of tricks. A first-in-first-out queue will be faster than a priority queue, and will give us the correct order of nodes: new nodes (which are always deeper than their parents) go to the back of the queue, and old nodes, which are shallower than the new nodes, get expanded first. In addition, *reached* can be a set of states rather than a mapping from states to nodes, because once we've reached a state, we can never find a better path to the state. That also means we can do an **early goal test**, checking whether a node is a solution as soon as it is *generated*, rather than the **late goal test** that best-first search uses, waiting until a node is popped off the queue. Figure 3.8 shows the progress of a breadth-first search on a binary tree, and Figure 3.9 shows the algorithm with the early-goal efficiency enhancements.

Breadth-first search always finds a solution with a minimal number of actions, because when it is generating nodes at depth  $d$ , it has already generated all the nodes at depth  $d - 1$ , so if one of them were a solution, it would have been found. That means it is cost-optimal

**Figure 3.8** Breadth-first search on a simple binary tree. At each stage, the node to be expanded next is indicated by the triangular marker.

---

```

function BREADTH-FIRST-SEARCH(problem) returns a solution node or failure
  node  $\leftarrow$  NODE(problem.INITIAL)
  if problem.Is-GOAL(node.STATE) then return node
  frontier  $\leftarrow$  a FIFO queue, with node as an element
  reached  $\leftarrow \{problem.INITIAL\}
  while not IS-EMPTY(frontier) do
    node  $\leftarrow$  POP(frontier)
    for each child in EXPAND(problem, node) do
      s  $\leftarrow$  child.STATE
      if problem.Is-GOAL(s) then return child
      if s is not in reached then
        add s to reached
        add child to frontier
  return failure

function UNIFORM-COST-SEARCH(problem) returns a solution node, or failure
  return BEST-FIRST-SEARCH(problem, PATH-COST)$ 
```

**Figure 3.9** Breadth-first search and uniform-cost search algorithms.

---

for problems where all actions have the same cost, but not for problems that don't have that property. It is complete in either case. In terms of time and space, imagine searching a uniform tree where every state has  $b$  successors. The root of the search tree generates  $b$  nodes, each of which generates  $b$  more nodes, for a total of  $b^2$  at the second level. Each of these generates  $b$  more nodes, yielding  $b^3$  nodes at the third level, and so on. Now suppose that the solution is at depth  $d$ . Then the total number of nodes generated is

$$1 + b + b^2 + b^3 + \dots + b^d = O(b^d)$$

All the nodes remain in memory, so both time and space complexity are  $O(b^d)$ . Exponential bounds like that are scary. As a typical real-world example, consider a problem with branching factor  $b = 10$ , processing speed 1 million nodes/second, and memory requirements of 1 Kbyte/node. A search to depth  $d = 10$  would take less than 3 hours, but would require 10 terabytes of memory. *The memory requirements are a bigger problem for breadth-first search than the execution time.* But time is still an important factor. At depth  $d = 14$ , even with infinite memory, the search would take 3.5 years. In general, *exponential-complexity search problems cannot be solved by uninformed search for any but the smallest instances.*

### 3.4.2 Dijkstra's algorithm or uniform-cost search

When actions have different costs, an obvious choice is to use best-first search where the evaluation function is the cost of the path from the root to the current node. This is called Dijkstra's algorithm by the theoretical computer science community, and **uniform-cost search** by the AI community. The idea is that while breadth-first search spreads out in waves of uniform depth—first depth 1, then depth 2, and so on—uniform-cost search spreads out in waves of uniform path-cost. The algorithm can be implemented as a call to BEST-FIRST-SEARCH with PATH-COST as the evaluation function, as shown in Figure 3.9.

Uniform-cost search

**Figure 3.10** Part of the Romania state space, selected to illustrate uniform-cost search.

Consider Figure 3.10, where the problem is to get from Sibiu to Bucharest. The successors of Sibiu are Rimnicu Vilcea and Fagaras, with costs 80 and 99, respectively. The least-cost node, Rimnicu Vilcea, is expanded next, adding Pitesti with cost  $80 + 97 = 177$ . The least-cost node is now Fagaras, so it is expanded, adding Bucharest with cost  $99 + 211 = 310$ . Bucharest is the goal, but the algorithm tests for goals only when it expands a node, not when it generates a node, so it has not yet detected that this is a path to the goal.

The algorithm continues on, choosing Pitesti for expansion next and adding a second path to Bucharest with cost  $80 + 97 + 101 = 278$ . It has a lower cost, so it replaces the previous path in *reached* and is added to the *frontier*. It turns out this node now has the lowest cost, so it is considered next, found to be a goal, and returned. Note that if we had checked for a goal upon generating a node rather than when expanding the lowest-cost node, then we would have returned a higher-cost path (the one through Fagaras).

The complexity of uniform-cost search is characterized in terms of  $C^*$ , the cost of the optimal solution,<sup>8</sup> and  $\epsilon$ , a lower bound on the cost of each action, with  $\epsilon > 0$ . Then the algorithm's worst-case time and space complexity is  $O(b^{1+\lfloor C^*/\epsilon \rfloor})$ , which can be much greater than  $b^d$ . This is because uniform-cost search can explore large trees of actions with low costs before exploring paths involving a high-cost and perhaps useful action. When all action costs are equal,  $b^{1+\lfloor C^*/\epsilon \rfloor}$  is just  $b^{d+1}$ , and uniform-cost search is similar to breadth-first search.

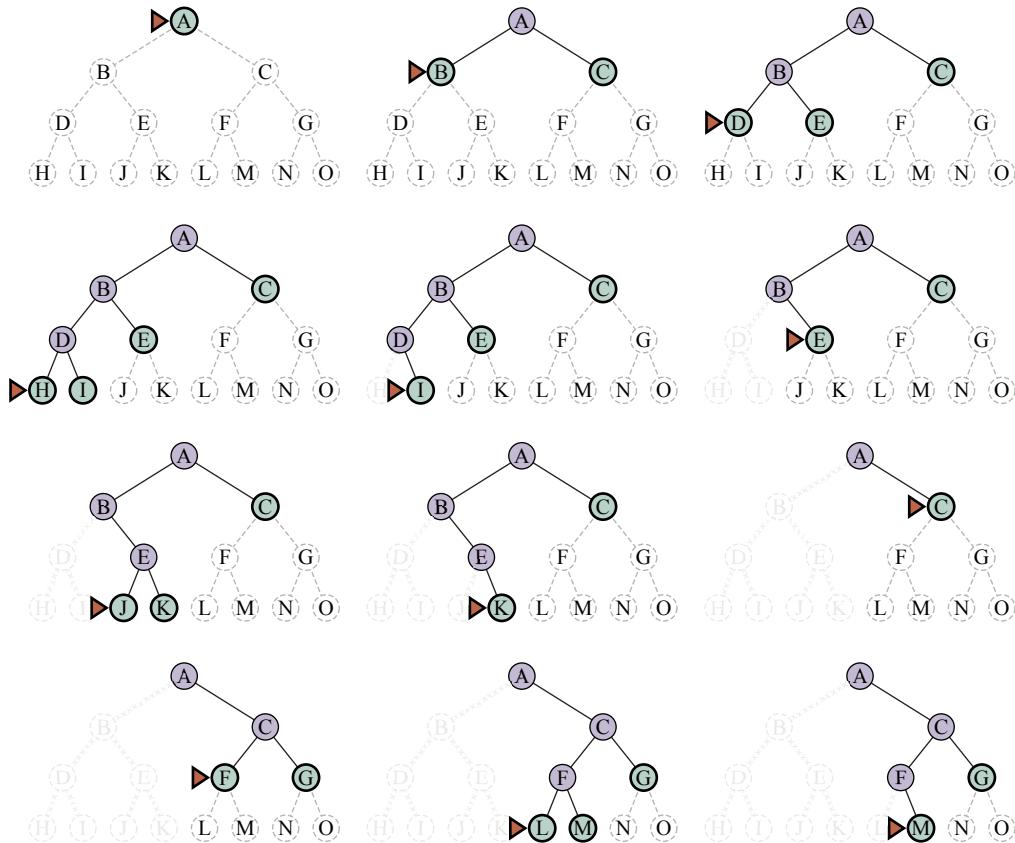

Uniform-cost search is complete and is cost-optimal, because the first solution it finds will have a cost that is at least as low as the cost of any other node in the frontier. Uniform-cost search considers all paths systematically in order of increasing cost, never getting caught going down a single infinite path (assuming that all action costs are  $> \epsilon > 0$ ).

### 3.4.3 Depth-first search and the problem of memory

#### Depth-first search

**Depth-first search** always expands the *deepest* node in the frontier first. It could be implemented as a call to **BEST-FIRST-SEARCH** where the evaluation function  $f$  is the negative of the depth. However, it is usually implemented not as a graph search but as a tree-like search that does not keep a table of reached states. The progress of the search is illustrated in Figure 3.11; search proceeds immediately to the deepest level of the search tree, where the nodes have no successors. The search then “backs up” to the next deepest node that still has

<sup>8</sup> Here, and throughout the book, the “star” in  $C^*$  means an optimal value for  $C$ .

**Figure 3.11** A dozen steps (left to right, top to bottom) in the progress of a depth-first search on a binary tree from start state A to goal M. The frontier is in green, with a triangle marking the node to be expanded next. Previously expanded nodes are lavender, and potential future nodes have faint dashed lines. Expanded nodes with no descendants in the frontier (very faint lines) can be discarded.

unexpanded successors. Depth-first search is not cost-optimal; it returns the first solution it finds, even if it is not cheapest.

For finite state spaces that are trees it is efficient and complete; for acyclic state spaces it may end up expanding the same state many times via different paths, but will (eventually) systematically explore the entire space.

In cyclic state spaces it can get stuck in an infinite loop; therefore some implementations of depth-first search check each new node for cycles. Finally, in infinite state spaces, depth-first search is not systematic: it can get stuck going down an infinite path, even if there are no cycles. Thus, depth-first search is incomplete.

With all this bad news, why would anyone consider using depth-first search rather than breadth-first or best-first? The answer is that for problems where a tree-like search is feasible, depth-first search has much smaller needs for memory. We don't keep a *reached* table at all, and the frontier is very small: think of the frontier in breadth-first search as the surface of an ever-expanding sphere, while the frontier in depth-first search is just a radius of the sphere.

For a finite tree-shaped state-space like the one in Figure 3.11, a depth-first tree-like search takes time proportional to the number of states, and has memory complexity of only  $O(bm)$ , where  $b$  is the branching factor and  $m$  is the maximum depth of the tree. Some problems that would require exabytes of memory with breadth-first search can be handled with only kilobytes using depth-first search. Because of its parsimonious use of memory, depth-first tree-like search has been adopted as the basic workhorse of many areas of AI, including constraint satisfaction (Chapter 5), propositional satisfiability (Chapter 7), and logic programming (Chapter 9).

#### Backtracking search

A variant of depth-first search called **backtracking search** uses even less memory. (See Chapter 5 for more details.) In backtracking, only one successor is generated at a time rather than all successors; each partially expanded node remembers which successor to generate next. In addition, successors are generated by *modifying* the current state description directly rather than allocating memory for a brand-new state. This reduces the memory requirements to just one state description and a path of  $O(m)$  actions; a significant savings over  $O(bm)$  states for depth-first search. With backtracking we also have the option of maintaining an efficient set data structure for the states on the current path, allowing us to check for a cyclic path in  $O(1)$  time rather than  $O(m)$ . For backtracking to work, we must be able to *undo* each action when we backtrack. Backtracking is critical to the success of many problems with large state descriptions, such as robotic assembly.

#### 3.4.4 Depth-limited and iterative deepening search

##### Depth-limited search

To keep depth-first search from wandering down an infinite path, we can use **depth-limited search**, a version of depth-first search in which we supply a depth limit,  $\ell$ , and treat all nodes at depth  $\ell$  as if they had no successors (see Figure 3.12). The time complexity is  $O(b^\ell)$  and the space complexity is  $O(b\ell)$ . Unfortunately, if we make a poor choice for  $\ell$  the algorithm will fail to reach the solution, making it incomplete again.

Since depth-first search is a tree-like search, we can't keep it from wasting time on redundant paths in general, but we can eliminate cycles at the cost of some computation time. If we look only a few links up in the parent chain we can catch most cycles; longer cycles are handled by the depth limit.

##### Diameter

Sometimes a good depth limit can be chosen based on knowledge of the problem. For example, on the map of Romania there are 20 cities. Therefore,  $\ell = 19$  is a valid limit. But if we studied the map carefully, we would discover that any city can be reached from any other city in at most 9 actions. This number, known as the **diameter** of the state-space graph, gives us a better depth limit, which leads to a more efficient depth-limited search. However, for most problems we will not know a good depth limit until we have solved the problem.

##### Iterative deepening search

**Iterative deepening search** solves the problem of picking a good value for  $\ell$  by trying all values: first 0, then 1, then 2, and so on—until either a solution is found, or the depth-limited search returns the *failure* value rather than the *cutoff* value. The algorithm is shown in Figure 3.12. Iterative deepening combines many of the benefits of depth-first and breadth-first search. Like depth-first search, its memory requirements are modest:  $O(bd)$  when there is a solution, or  $O(bm)$  on finite state spaces with no solution. Like breadth-first search, iterative deepening is optimal for problems where all actions have the same cost, and is complete on finite acyclic state spaces, or on any finite state space when we check nodes for cycles all the way up the path.

---

```

function ITERATIVE-DEEPENING-SEARCH(problem) returns a solution node or failure
  for depth = 0 to  $\infty$  do
    result  $\leftarrow$  DEPTH-LIMITED-SEARCH(problem, depth)
    if result  $\neq$  cutoff then return result

function DEPTH-LIMITED-SEARCH(problem,  $\ell$ ) returns a node or failure or cutoff
  frontier  $\leftarrow$  a LIFO queue (stack) with NODE(problem.INITIAL) as an element
  result  $\leftarrow$  failure
  while not IS-EMPTY(frontier) do
    node  $\leftarrow$  POP(frontier)
    if problem.IS-GOAL(node.STATE) then return node
    if DEPTH(node)  $>$   $\ell$  then
      result  $\leftarrow$  cutoff
    else if not IS-CYCLE(node) do
      for each child in EXPAND(problem, node) do
        add child to frontier
    return result

```

**Figure 3.12** Iterative deepening and depth-limited tree-like search. Iterative deepening repeatedly applies depth-limited search with increasing limits. It returns one of three different types of values: either a solution node; or *failure*, when it has exhausted all nodes and proved there is no solution at any depth; or *cutoff*, to mean there might be a solution at a deeper depth than  $\ell$ . This is a tree-like search algorithm that does not keep track of *reached* states, and thus uses much less memory than best-first search, but runs the risk of visiting the same state multiple times on different paths. Also, if the IS-CYCLE check does not check *all* cycles, then the algorithm may get caught in a loop.

---

The time complexity is  $O(b^d)$  when there is a solution, or  $O(b^m)$  when there is none. Each iteration of iterative deepening search generates a new level, in the same way that breadth-first search does, but breadth-first does this by storing all nodes in memory, while iterative-deepening does it by repeating the previous levels, thereby saving memory at the cost of more time. Figure 3.13 shows four iterations of iterative-deepening search on a binary search tree, where the solution is found on the fourth iteration.

Iterative deepening search may seem wasteful because states near the top of the search tree are re-generated multiple times. But for many state spaces, most of the nodes are in the bottom level, so it does not matter much that the upper levels are repeated. In an iterative deepening search, the nodes on the bottom level (depth  $d$ ) are generated once, those on the next-to-bottom level are generated twice, and so on, up to the children of the root, which are generated  $d$  times. So the total number of nodes generated in the worst case is

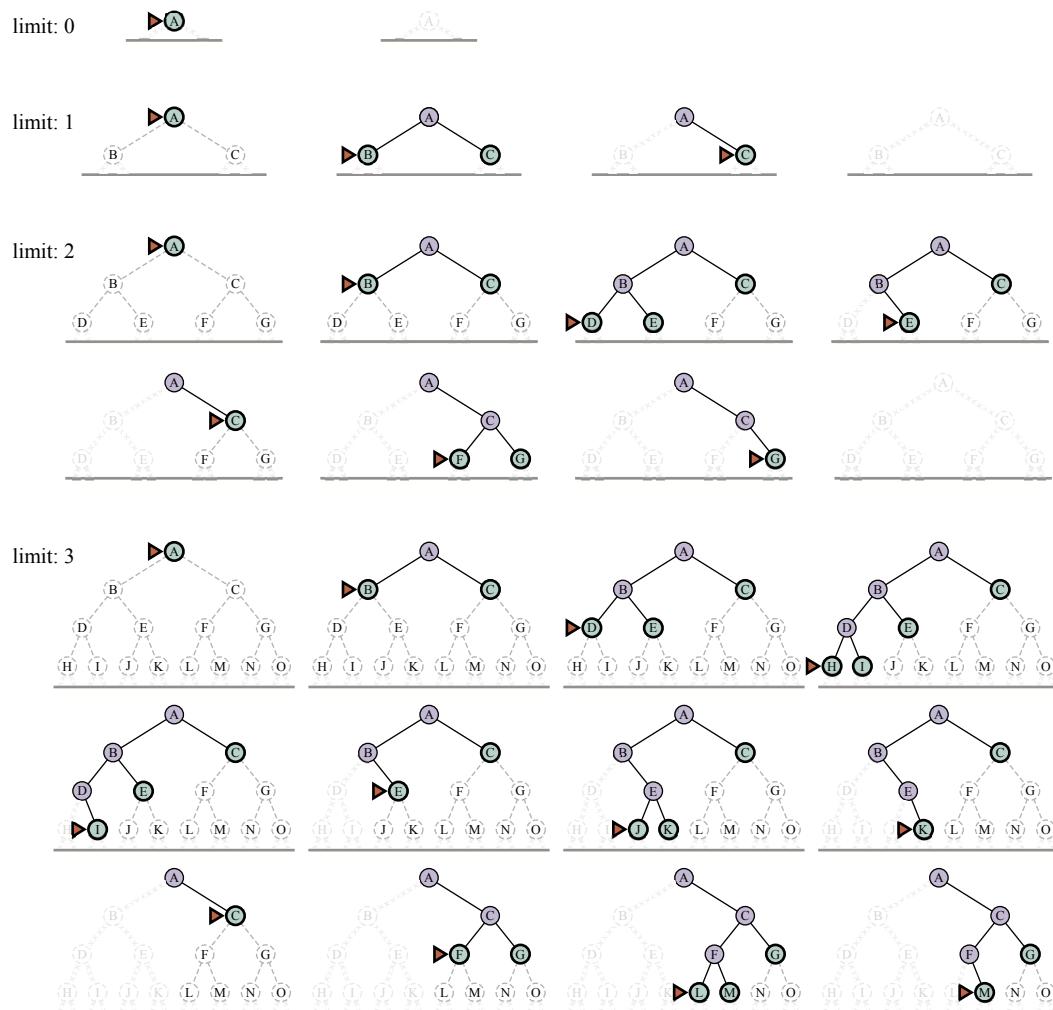

$$N(\text{IDS}) = (d)b^1 + (d-1)b^2 + (d-2)b^3 \cdots + b^d,$$

which gives a time complexity of  $O(b^d)$ —asymptotically the same as breadth-first search. For example, if  $b = 10$  and  $d = 5$ , the numbers are

$$N(\text{IDS}) = 50 + 400 + 3,000 + 20,000 + 100,000 = 123,450$$

$$N(\text{BFS}) = 10 + 100 + 1,000 + 10,000 + 100,000 = 111,110.$$

If you are really concerned about the repetition, you can use a hybrid approach that runs

**Figure 3.13** Four iterations of iterative deepening search for goal M on a binary tree, with the depth limit varying from 0 to 3. Note the interior nodes form a single path. The triangle marks the node to expand next; green nodes with dark outlines are on the frontier; the very faint nodes provably can't be part of a solution with this depth limit.

breadth-first search until almost all the available memory is consumed, and then runs iterative deepening from all the nodes in the frontier. *In general, iterative deepening is the preferred uninformed search method when the search state space is larger than can fit in memory and the depth of the solution is not known.*

### 3.4.5 Bidirectional search

The algorithms we have covered so far start at an initial state and can reach any one of multiple possible goal states. An alternative approach called **bidirectional search** simultaneously searches forward from the initial state and backwards from the goal state(s), hoping that the two searches will meet. The motivation is that  $b^{d/2} + b^{d/2}$  is much less than  $b^d$  (e.g., 50,000 times less when  $b=d=10$ ).

---

```

function B1BF-SEARCH(problemF, fF, problemB, fB) returns a solution node, or failure
  nodeF  $\leftarrow$  NODE(problemF.INITIAL) // Node for a start state
  nodeB  $\leftarrow$  NODE(problemB.INITIAL) // Node for a goal state
  frontierF  $\leftarrow$  a priority queue ordered by fF, with nodeF as an element
  frontierB  $\leftarrow$  a priority queue ordered by fB, with nodeB as an element
  reachedF  $\leftarrow$  a lookup table, with one key nodeF.STATE and value nodeF
  reachedB  $\leftarrow$  a lookup table, with one key nodeB.STATE and value nodeB
  solution  $\leftarrow$  failure
  while not TERMINATED(solution, frontierF, frontierB) do
    if fF(TOP(frontierF))  $<$  fB(TOP(frontierB)) then
      solution  $\leftarrow$  PROCEED(F, problemF, frontierF, reachedF, reachedB, solution)
    else solution  $\leftarrow$  PROCEED(B, problemB, frontierB, reachedB, reachedF, solution)
  return solution

function PROCEED(dir, problem, frontier, reached, reached2, solution) returns a solution
  // Expand node on frontier; check against the other frontier in reached2.
  // The variable "dir" is the direction: either F for forward or B for backward.
  node  $\leftarrow$  POP(frontier)
  for each child in EXPAND(problem, node) do
    s  $\leftarrow$  child.STATE
    if s not in reached or PATH-COST(child)  $<$  PATH-COST(reached[s]) then
      reached[s]  $\leftarrow$  child
      add child to frontier
      if s is in reached2 then
        solution2  $\leftarrow$  JOIN-NODES(dir, child, reached2[s]))
        if PATH-COST(solution2)  $<$  PATH-COST(solution) then
          solution  $\leftarrow$  solution2
    return solution

```

**Figure 3.14** Bidirectional best-first search keeps two frontiers and two tables of reached states. When a path in one frontier reaches a state that was also reached in the other half of the search, the two paths are joined (by the function JOIN-NODES) to form a solution. The first solution we get is not guaranteed to be the best; the function TERMINATED determines when to stop looking for new solutions.

---

For this to work, we need to keep track of two frontiers and two tables of reached states, and we need to be able to reason backwards: if state  $s'$  is a successor of  $s$  in the forward direction, then we need to know that  $s$  is a successor of  $s'$  in the backward direction. We have a solution when the two frontiers collide.<sup>9</sup>

There are many different versions of bidirectional search, just as there are many different unidirectional search algorithms. In this section, we describe bidirectional best-first search. Although there are two separate frontiers, the node to be expanded next is always one with a minimum value of the evaluation function, across either frontier. When the evaluation

<sup>9</sup> In our implementation, the *reached* data structure supports a query asking whether a given state is a member, and the frontier data structure (a priority queue) does not, so we check for a collision using *reached*; but conceptually we are asking if the two frontiers have met up. The implementation can be extended to handle multiple goal states by loading the node for each goal state into the backwards frontier and backwards reached table.

function is the path cost, we get bidirectional uniform-cost search, and if the cost of the optimal path is  $C^*$ , then no node with cost  $> \frac{C^*}{2}$  will be expanded. This can result in a considerable speedup.

The general best-first bidirectional search algorithm is shown in Figure 3.14. We pass in two versions of the problem and the evaluation function, one in the forward direction (subscript  $F$ ) and one in the backward direction (subscript  $B$ ). When the evaluation function is the path cost, we know that the first solution found will be an optimal solution, but with different evaluation functions that is not necessarily true. Therefore, we keep track of the best solution found so far, and might have to update that several times before the TERMINATED test proves that there is no possible better solution remaining.

### 3.4.6 Comparing uninformed search algorithms

Figure 3.15 compares uninformed search algorithms in terms of the four evaluation criteria set forth in Section 3.3.4. This comparison is for tree-like search versions which don't check for repeated states. For graph searches which do check, the main differences are that depth-first search is complete for finite state spaces, and the space and time complexities are bounded by the size of the state space (the number of vertices and edges,  $|V| + |E|$ ).

Criterion	Breadth-First	Uniform-Cost	Depth-First	Depth-Limited	Iterative Deepening	Bidirectional (if applicable)
Complete?	Yes <sup>1</sup>	Yes <sup>1,2</sup>	No	No	Yes <sup>1</sup>	Yes <sup>1,4</sup>
Optimal cost?	Yes <sup>3</sup>	Yes	No	No	Yes <sup>3</sup>	Yes <sup>3,4</sup>
Time	$O(b^d)$	$O(b^{1+\lfloor C^*/\epsilon \rfloor})$	$O(b^m)$	$O(b^\ell)$	$O(b^d)$	$O(b^{d/2})$
Space	$O(b^d)$	$O(b^{1+\lfloor C^*/\epsilon \rfloor})$	$O(bm)$	$O(b\ell)$	$O(bd)$	$O(b^{d/2})$

**Figure 3.15** Evaluation of search algorithms.  $b$  is the branching factor;  $m$  is the maximum depth of the search tree;  $d$  is the depth of the shallowest solution, or is  $m$  when there is no solution;  $\ell$  is the depth limit. Superscript caveats are as follows: <sup>1</sup> complete if  $b$  is finite, and the state space either has a solution or is finite. <sup>2</sup> complete if all action costs are  $\geq \epsilon > 0$ ; <sup>3</sup> cost-optimal if action costs are all identical; <sup>4</sup> if both directions are breadth-first or uniform-cost.

---

## 3.5 Informed (Heuristic) Search Strategies

Informed search

Heuristic function

This section shows how an **informed search** strategy—one that uses domain-specific hints about the location of goals—can find solutions more efficiently than an uninformed strategy. The hints come in the form of a **heuristic function**, denoted  $h(n)$ .<sup>10</sup>

$h(n) =$  estimated cost of the cheapest path from the state at node  $n$  to a goal state.

For example, in route-finding problems, we can estimate the distance from the current state to a goal by computing the straight-line distance on the map between the two points. We study heuristics and where they come from in more detail in Section 3.6.

---

<sup>10</sup> It may seem odd that the heuristic function operates on a node, when all it really needs is the node's state. It is traditional to use  $h(n)$  rather than  $h(s)$  to be consistent with the evaluation function  $f(n)$  and the path cost  $g(n)$ .

Arad	366	Mehadia	241
Bucharest	0	Neamt	234
Craiova	160	Oradea	380

Iasi	226	Vaslui	199
Lugoj	244	Zerind	374

Figure 3.16 Values of  $h_{SLD}$ —straight-line distances to Bucharest.

### 3.5.1 Greedy best-first search

**Greedy best-first search** is a form of best-first search that expands first the node with the lowest  $h(n)$  value—the node that appears to be closest to the goal—on the grounds that this is likely to lead to a solution quickly. So the evaluation function  $f(n) = h(n)$ .

Let us see how this works for route-finding problems in Romania; we use the **straight-line distance** heuristic, which we will call  $h_{SLD}$ . If the goal is Bucharest, we need to know the straight-line distances to Bucharest, which are shown in Figure 3.16. For example,  $h_{SLD}(Arad) = 366$ . Notice that the values of  $h_{SLD}$  cannot be computed from the problem description itself (that is, the ACTIONS and RESULT functions). Moreover, it takes a certain amount of world knowledge to know that  $h_{SLD}$  is correlated with actual road distances and is, therefore, a useful heuristic.

Figure 3.17 shows the progress of a greedy best-first search using  $h_{SLD}$  to find a path from Arad to Bucharest. The first node to be expanded from Arad will be Sibiu because the heuristic says it is closer to Bucharest than is either Zerind or Timisoara. The next node to be expanded will be Fagaras because it is now closest according to the heuristic. Fagaras in turn generates Bucharest, which is the goal. For this particular problem, greedy best-first search using  $h_{SLD}$  finds a solution without ever expanding a node that is not on the solution path. The solution it found does not have optimal cost, however: the path via Sibiu and Fagaras to Bucharest is 32 miles longer than the path through Rimnicu Vilcea and Pitesti. This is why the algorithm is called “greedy”—on each iteration it tries to get as close to a goal as it can, but greediness can lead to worse results than being careful.

Greedy best-first graph search is complete in finite state spaces, but not in infinite ones. The worst-case time and space complexity is  $O(|V|)$ . With a good heuristic function, however, the complexity can be reduced substantially, on certain problems reaching  $O(bm)$ .

### 3.5.2 A\* search

The most common informed search algorithm is **A\* search** (pronounced “A-star search”), a best-first search that uses the evaluation function

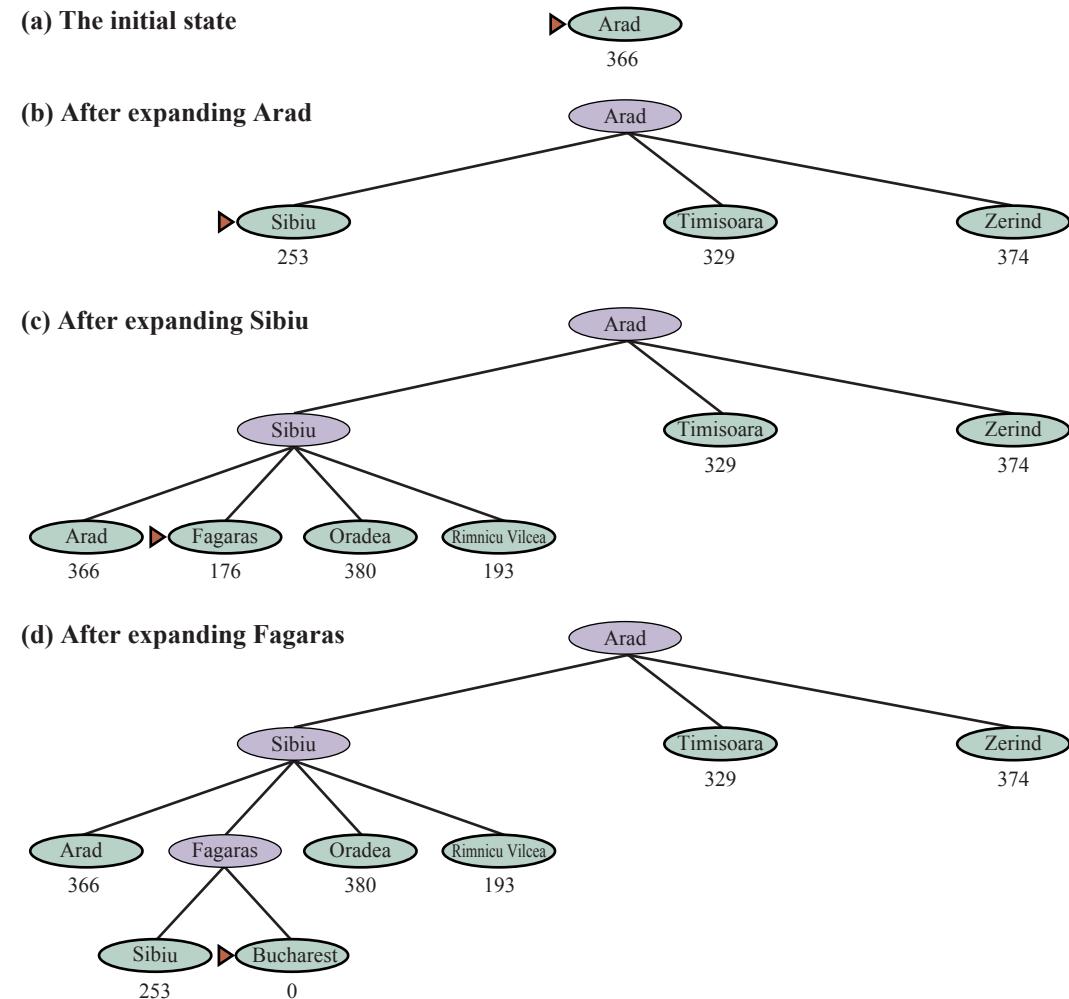

$$f(n) = g(n) + h(n)$$

where  $g(n)$  is the path cost from the initial state to node  $n$ , and  $h(n)$  is the *estimated* cost of the shortest path from  $n$  to a goal state, so we have

$f(n)$  = estimated cost of the best path that continues from  $n$  to a goal.

Greedy best-first search

Straight-line distance

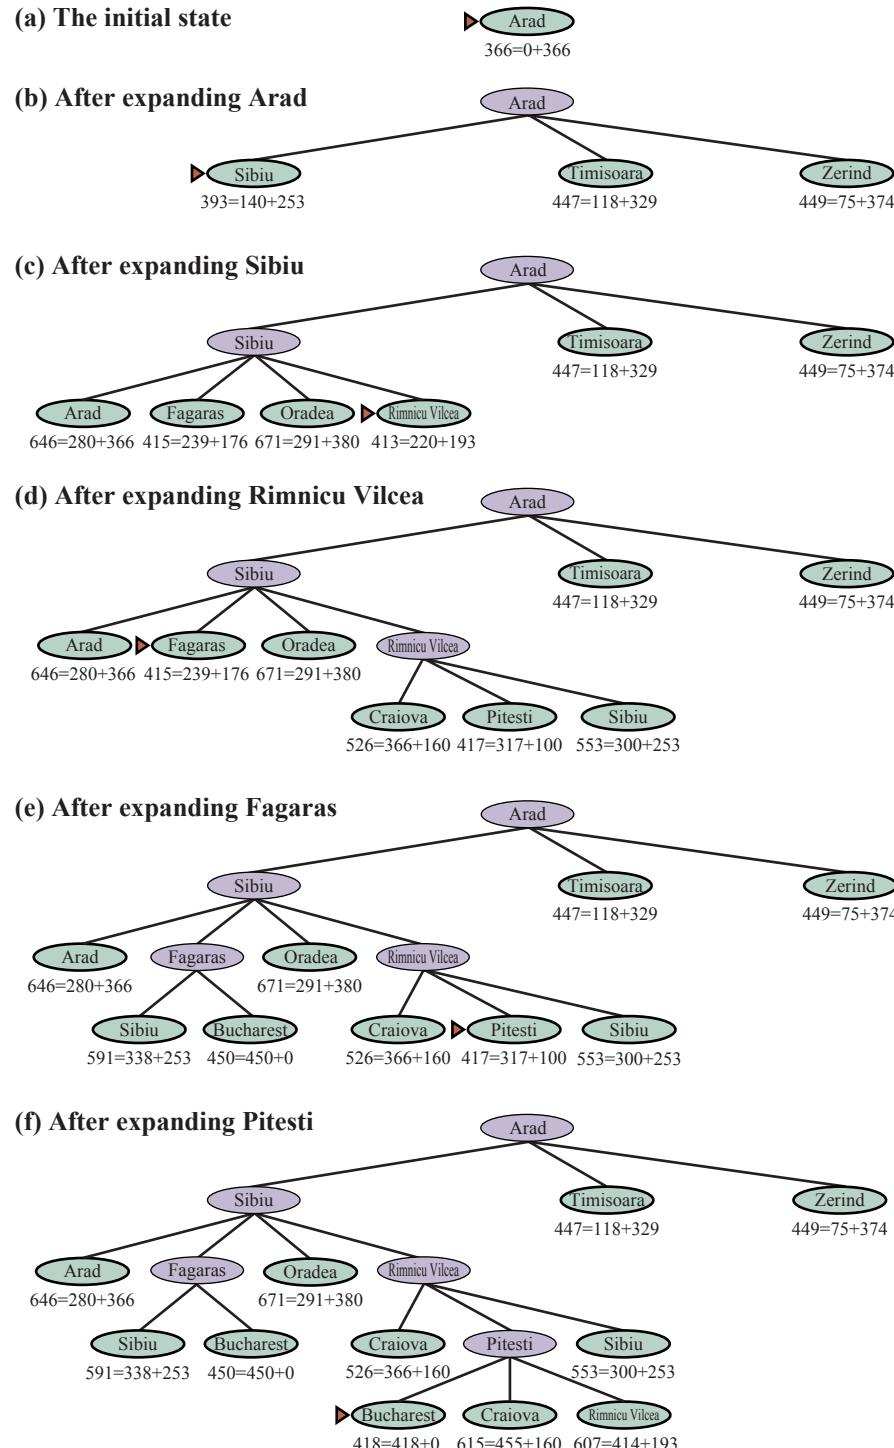

**Figure 3.17** Stages in a greedy best-first tree-like search for Bucharest with the straight-line distance heuristic  $h_{SLD}$ . Nodes are labeled with their  $h$ -values.

In Figure 3.18, we show the progress of an A\* search with the goal of reaching Bucharest. The values of  $g$  are computed from the action costs in Figure 3.1, and the values of  $h_{SLD}$  are given in Figure 3.16. Notice that Bucharest first appears on the frontier at step (e), but it is not selected for expansion (and thus not detected as a solution) because at  $f = 450$  it is not the lowest-cost node on the frontier—that would be Pitesti, at  $f = 417$ . Another way to say this is that there *might* be a solution through Pitesti whose cost is as low as 417, so the algorithm will not settle for a solution that costs 450. At step (f), a different path to Bucharest is now the lowest-cost node, at  $f = 418$ , so it is selected and detected as the optimal solution.

A\* search is complete.<sup>11</sup> Whether A\* is cost-optimal depends on certain properties of the heuristic. A key property is **admissibility**: an **admissible heuristic** is one that *never overestimates* the cost to reach a goal. (An admissible heuristic is therefore *optimistic*.) With

<sup>11</sup> Again, assuming all action costs are  $> \epsilon > 0$ , and the state space either has a solution or is finite.

**Figure 3.18** Stages in an A\* search for Bucharest. Nodes are labeled with  $f = g + h$ . The  $h$  values are the straight-line distances to Bucharest taken from Figure 3.16.

**Figure 3.19** Triangle inequality: If the heuristic  $h$  is **consistent**, then the single number  $h(n)$  will be less than the sum of the cost  $c(n, a, a')$  of the action from  $n$  to  $n'$  plus the heuristic estimate  $h(n')$ .

an admissible heuristic,  $A^*$  is cost-optimal, which we can show with a proof by contradiction. Suppose the optimal path has cost  $C^*$ , but the algorithm returns a path with cost  $C > C^*$ . Then there must be some node  $n$  which is on the optimal path and is unexpanded (because if all the nodes on the optimal path had been expanded, then we would have returned that optimal solution). So then, using the notation  $g^*(n)$  to mean the cost of the optimal path from the start to  $n$ , and  $h^*(n)$  to mean the cost of the optimal path from  $n$  to the nearest goal, we have:

$$\begin{aligned} f(n) &> C^* \quad (\text{otherwise } n \text{ would have been expanded}) \\ f(n) &= g(n) + h(n) \quad (\text{by definition}) \\ f(n) &= g^*(n) + h(n) \quad (\text{because } n \text{ is on an optimal path}) \\ f(n) &\leq g^*(n) + h^*(n) \quad (\text{because of admissibility, } h(n) \leq h^*(n)) \\ f(n) &\leq C^* \quad (\text{by definition, } C^* = g^*(n) + h^*(n)) \end{aligned}$$

The first and last lines form a contradiction, so the supposition that the algorithm could return a suboptimal path must be wrong—it must be that  $A^*$  returns only cost-optimal paths.

#### Consistency

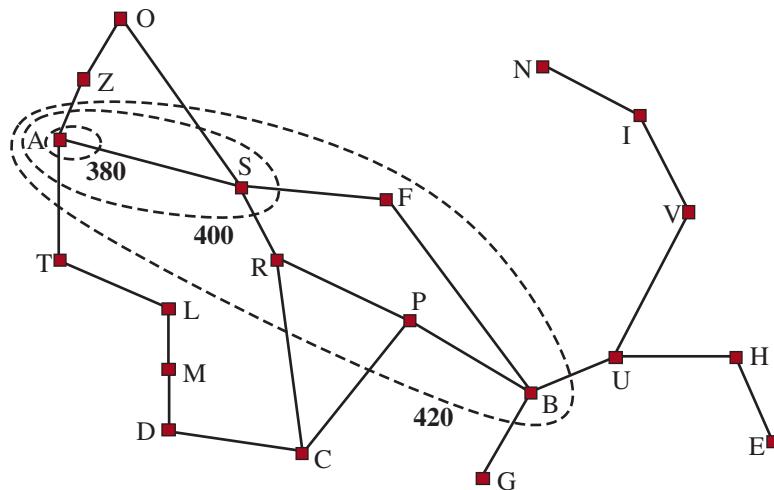

A slightly stronger property is called **consistency**. A heuristic  $h(n)$  is consistent if, for every node  $n$  and every successor  $n'$  of  $n$  generated by an action  $a$ , we have:

$$h(n) \leq c(n, a, n') + h(n').$$

#### Triangle inequality

This is a form of the **triangle inequality**, which stipulates that a side of a triangle cannot be longer than the sum of the other two sides (see Figure 3.19). An example of a consistent heuristic is the straight-line distance  $h_{SLD}$  that we used in getting to Bucharest.

Every consistent heuristic is admissible (but not vice versa), so with a consistent heuristic,  $A^*$  is cost-optimal. In addition, with a consistent heuristic, the first time we reach a state it will be on an optimal path, so we never have to re-add a state to the frontier, and never have to change an entry in *reached*. But with an inconsistent heuristic, we may end up with multiple paths reaching the same state, and if each new path has a lower path cost than the previous one, then we will end up with multiple nodes for that state in the frontier, costing us both time and space. Because of that, some implementations of  $A^*$  take care to only enter a state into the frontier once, and if a better path to the state is found, all the successors of the state are updated (which requires that nodes have child pointers as well as parent pointers). These complications have led many implementers to avoid inconsistent heuristics, but Felner *et al.* (2011) argues that the worst effects rarely happen in practice, and one shouldn't be afraid of inconsistent heuristics.

**Figure 3.20** Map of Romania showing contours at  $f = 380$ ,  $f = 400$ , and  $f = 420$ , with Arad as the start state. Nodes inside a given contour have  $f = g + h$  costs less than or equal to the contour value.

With an inadmissible heuristic,  $A^*$  may or may not be cost-optimal. Here are two cases where it is: First, if there is even one cost-optimal path on which  $h(n)$  is admissible for all nodes  $n$  on the path, then that path will be found, no matter what the heuristic says for states off the path. Second, if the optimal solution has cost  $C^*$ , and the second-best has cost  $C_2$ , and if  $h(n)$  overestimates some costs, but never by more than  $C_2 - C^*$ , then  $A^*$  is guaranteed to return cost-optimal solutions.

### 3.5.3 Search contours

A useful way to visualize a search is to draw **contours** in the state space, just like the contours in a topographic map. Figure 3.20 shows an example. Inside the contour labeled 400, all nodes have  $f(n) = g(n) + h(n) \leq 400$ , and so on. Then, because  $A^*$  expands the frontier node of lowest  $f$ -cost, we can see that an  $A^*$  search fans out from the start node, adding nodes in concentric bands of increasing  $f$ -cost.

With uniform-cost search, we also have contours, but of  $g$ -cost, not  $g + h$ . The contours with uniform-cost search will be “circular” around the start state, spreading out equally in all directions with no preference towards the goal. With  $A^*$  search using a good heuristic, the  $g + h$  bands will stretch toward a goal state (as in Figure 3.20) and become more narrowly focused around an optimal path.

It should be clear that as you extend a path, the  $g$  costs are **monotonic**: the path cost always increases as you go along a path, because action costs are always positive.<sup>12</sup> Therefore you get concentric contour lines that don’t cross each other, and if you choose to draw the lines fine enough, you can put a line between any two nodes on any path.

<sup>12</sup> Technically, we say “strictly monotonic” for costs that always increase, and “monotonic” for costs that never decrease, but might remain the same.

But it is not obvious whether the  $f = g + h$  cost will monotonically increase. As you extend a path from  $n$  to  $n'$ , the cost goes from  $g(n) + h(n)$  to  $g(n) + c(n, a, n') + h(n')$ . Canceling out the  $g(n)$  term, we see that the path's cost will be monotonically increasing if and only if  $h(n) \leq c(n, a, n') + h(n')$ ; in other words if and only if the heuristic is consistent.<sup>13</sup> But note that a path might contribute several nodes in a row with the same  $g(n) + h(n)$  score; this will happen whenever the decrease in  $h$  is exactly equal to the action cost just taken (for example, in a grid problem, when  $n$  is in the same row as the goal and you take a step towards the goal,  $g$  is increased by 1 and  $h$  is decreased by 1). If  $C^*$  is the cost of the optimal solution path, then we can say the following:

- A\* expands all nodes that can be reached from the initial state on a path where every node on the path has  $f(n) < C^*$ . We say these are **surely expanded nodes**.
- A\* might then expand some of the nodes right on the “goal contour” (where  $f(n) = C^*$ ) before selecting a goal node.
- A\* expands no nodes with  $f(n) > C^*$ .

**Surely expanded nodes**

**Optimally efficient**

We say that A\* with a consistent heuristic is **optimally efficient** in the sense that any algorithm that extends search paths from the initial state, and uses the same heuristic information, must expand all nodes that are surely expanded by A\* (because any one of them could have been part of an optimal solution). Among the nodes with  $f(n) = C^*$ , one algorithm could get lucky and choose the optimal one first while another algorithm is unlucky; we don't consider this difference in defining optimal efficiency.

**Pruning**

A\* is efficient because it **prunes** away search tree nodes that are not necessary for finding an optimal solution. In Figure 3.18(b) we see that Timisoara has  $f = 447$  and Zerind has  $f = 449$ . Even though they are children of the root and would be among the first nodes expanded by uniform-cost or breadth-first search, they are never expanded by A\* search because the solution with  $f = 418$  is found first. The concept of pruning—eliminating possibilities from consideration without having to examine them—is important for many areas of AI.

That A\* search is complete, cost-optimal, and optimally efficient among all such algorithms is rather satisfying. Unfortunately, it does not mean that A\* is the answer to all our searching needs. The catch is that for many problems, the number of nodes expanded can be exponential in the length of the solution. For example, consider a version of the vacuum world with a super-powerful vacuum that can clean up any one square at a cost of 1 unit, without even having to visit the square; in that scenario, squares can be cleaned in any order. With  $N$  initially dirty squares, there are  $2^N$  states where some subset has been cleaned; all of those states are on an optimal solution path, and hence satisfy  $f(n) < C^*$ , so all of them would be visited by A\*.

### 3.5.4 Satisficing search: Inadmissible heuristics and weighted A\*

**Inadmissible heuristic**

A\* search has many good qualities, but it expands a lot of nodes. We can explore fewer nodes (taking less time and space) if we are willing to accept solutions that are suboptimal, but are “good enough”—what we call **satisficing** solutions. If we allow A\* search to use an **inadmissible heuristic**—one that may overestimate—then we risk missing the optimal solution, but the heuristic can potentially be more accurate, thereby reducing the number of

<sup>13</sup> In fact, the term “monotonic heuristic” is a synonym for “consistent heuristic.” The two ideas were developed independently, and then it was proved that they are equivalent (Pearl, 1984).

**Figure 3.21** Two searches on the same grid: (a) an A\* search and (b) a weighted A\* search with weight  $W = 2$ . The gray bars are obstacles, the purple line is the path from the green start to red goal, and the small dots are states that were reached by each search. On this particular problem, weighted A\* explores 7 times fewer states and finds a path that is 5% more costly.

nodes expanded. For example, road engineers know the concept of a **detour index**, which is a multiplier applied to the straight-line distance to account for the typical curvature of roads. A detour index of 1.3 means that if two cities are 10 miles apart in straight-line distance, a good estimate of the best path between them is 13 miles. For most localities, the detour index ranges between 1.2 and 1.6.

We can apply this idea to any problem, not just ones involving roads, with an approach called **weighted A\* search** where we weight the heuristic value more heavily, giving us the evaluation function  $f(n) = g(n) + W \times h(n)$ , for some  $W > 1$ .

Figure 3.21 shows a search problem on a grid world. In (a), an A\* search finds the optimal solution, but has to explore a large portion of the state space to find it. In (b), a weighted A\* search finds a solution that is slightly costlier, but the search time is much faster. We see that the weighted search focuses the contour of reached states towards a goal. That means that fewer states are explored, but if the optimal path ever strays outside of the weighted search's contour (as it does in this case), then the optimal path will not be found. In general, if the optimal solution costs  $C^*$ , a weighted A\* search will find a solution that costs somewhere between  $C^*$  and  $W \times C^*$ ; but in practice we usually get results much closer to  $C^*$  than  $W \times C^*$ .

We have considered searches that evaluate states by combining  $g$  and  $h$  in various ways; weighted A\* can be seen as a generalization of the others:

A* search:	$g(n) + h(n)$	( $W = 1$ )
Uniform-cost search:	$g(n)$	( $W = 0$ )
Greedy best-first search:	$h(n)$	( $W = \infty$ )
Weighted A* search:	$g(n) + W \times h(n)$	( $1 < W < \infty$ )

You could call weighted A\* “somewhat-greedy search”: like greedy best-first search, it focuses the search towards a goal; on the other hand, it won’t ignore the path cost completely, and will suspend a path that is making little progress at great cost.

Bounded suboptimal search

Bounded-cost search  
Unbounded-cost search

Speedy search

Reference count

Beam search

There are a variety of suboptimal search algorithms, which can be characterized by the criteria for what counts as “good enough.” In **bounded suboptimal search**, we look for a solution that is guaranteed to be within a constant factor  $W$  of the optimal cost. Weighted A\* provides this guarantee. In **bounded-cost search**, we look for a solution whose cost is less than some constant  $C$ . And in **unbounded-cost search**, we accept a solution of any cost, as long as we can find it quickly.

An example of an unbounded-cost search algorithm is **speedy search**, which is a version of greedy best-first search that uses as a heuristic the estimated number of actions required to reach a goal, regardless of the cost of those actions. Thus, for problems where all actions have the same cost it is the same as greedy best-first search, but when actions have different costs, it tends to lead the search to find a solution quickly, even if it might have a high cost.

### 3.5.5 Memory-bounded search

The main issue with A\* is its use of memory. In this section we’ll cover some implementation tricks that save space, and then some entirely new algorithms that take better advantage of the available space.

Memory is split between the *frontier* and the *reached* states. In our implementation of best-first search, a state that is on the frontier is stored in two places: as a node in the frontier (so we can decide what to expand next) and as an entry in the table of reached states (so we know if we have visited the state before). For many problems (such as exploring a grid), this duplication is not a concern, because the size of *frontier* is much smaller than *reached*, so duplicating the states in the frontier requires a comparatively trivial amount of memory. But some implementations keep a state in only one of the two places, saving a bit of space at the cost of complicating (and perhaps slowing down) the algorithm.

Another possibility is to remove states from *reached* when we can prove that they are no longer needed. For some problems, we can use the separation property (Figure 3.6 on page 90), along with the prohibition of U-turn actions, to ensure that all actions either move outwards from the frontier or onto another frontier state. In that case, we need only check the frontier for redundant paths, and we can eliminate the *reached* table.

For other problems, we can keep **reference counts** of the number of times a state has been reached, and remove it from the *reached* table when there are no more ways to reach the state. For example, on a grid world where each state can be reached only from its four neighbors, once we have reached a state four times, we can remove it from the table.

Now let’s consider new algorithms that are designed to conserve memory usage.

**Beam search** limits the size of the frontier. The easiest approach is to keep only the  $k$  nodes with the best  $f$ -scores, discarding any other expanded nodes. This of course makes the search incomplete and suboptimal, but we can choose  $k$  to make good use of available memory, and the algorithm executes fast because it expands fewer nodes. For many problems it can find good near-optimal solutions. You can think of uniform-cost or A\* search as spreading out everywhere in concentric contours, and think of beam search as exploring only a focused portion of those contours, the portion that contains the  $k$  best candidates.

An alternative version of beam search doesn’t keep a strict limit on the size of the frontier but instead keeps every node whose  $f$ -score is within  $\delta$  of the best  $f$ -score. That way, when there are a few strong-scoring nodes only a few will be kept, but if there are no strong nodes then more will be kept until a strong one emerges.

**Iterative-deepening A\* search** (IDA\*) is to A\* what iterative-deepening search is to depth-first: IDA\* gives us the benefits of A\* without the requirement to keep all reached states in memory, at a cost of visiting some states multiple times. It is a very important and commonly used algorithm for problems that do not fit in memory.

In standard iterative deepening the cutoff is the depth, which is increased by one each iteration. In IDA\* the cutoff is the  $f$ -cost ( $g + h$ ); at each iteration, the cutoff value is the smallest  $f$ -cost of any node that exceeded the cutoff on the previous iteration. In other words, each iteration exhaustively searches an  $f$ -contour, finds a node just beyond that contour, and uses that node's  $f$ -cost as the next contour. For problems like the 8-puzzle where each path's  $f$ -cost is an integer, this works very well, resulting in steady progress towards the goal each iteration. If the optimal solution has cost  $C^*$ , then there can be no more than  $C^*$  iterations (for example, no more than 31 iterations on the hardest 8-puzzle problems). But for a problem where every node has a different  $f$ -cost, each new contour might contain only one new node, and the number of iterations could be equal to the number of states.

**Recursive best-first search** (RBFS) (Figure 3.22) attempts to mimic the operation of standard best-first search, but using only linear space. RBFS resembles a recursive depth-first search, but rather than continuing indefinitely down the current path, it uses the  $f\_limit$  variable to keep track of the  $f$ -value of the best *alternative* path available from any ancestor of the current node. If the current node exceeds this limit, the recursion unwinds back to the alternative path. As the recursion unwinds, RBFS replaces the  $f$ -value of each node along the path with a **backed-up value**—the best  $f$ -value of its children. In this way, RBFS remembers the  $f$ -value of the best leaf in the forgotten subtree and can therefore decide whether it's worth reexpanding the subtree at some later time. Figure 3.23 shows how RBFS reaches Bucharest.

RBFS is somewhat more efficient than IDA\*, but still suffers from excessive node regeneration. In the example in Figure 3.23, RBFS follows the path via Rimnicu Vilcea, then

    if best.f  $>$  f_limit then return failure, best.f
    alternative  $\leftarrow$  the second-lowest  $f$ -value among successors
    result, best.f  $\leftarrow$  RBFS(problem, best, min(f_limit, alternative))
    if result  $\neq$  failure then return result, best.f

```

Figure 3.22 The algorithm for recursive best-first search.

**Figure 3.23** Stages in an RBFS search for the shortest route to Bucharest. The *f-limit* value for each recursive call is shown on top of each current node, and every node is labeled with its *f*-cost. (a) The path via Rimnicu Vilcea is followed until the current best leaf (Pitesti) has a value that is worse than the best alternative path (Fagaras). (b) The recursion unwinds and the best leaf value of the forgotten subtree (417) is backed up to Rimnicu Vilcea; then Fagaras is expanded, revealing a best leaf value of 450. (c) The recursion unwinds and the best leaf value of the forgotten subtree (450) is backed up to Fagaras; then Rimnicu Vilcea is expanded. This time, because the best alternative path (through Timisoara) costs at least 447, the expansion continues to Bucharest.

“changes its mind” and tries Fagaras, and then changes its mind back again. These mind changes occur because every time the current best path is extended, its *f*-value is likely to increase—*h* is usually less optimistic for nodes closer to a goal. When this happens, the second-best path might become the best path, so the search has to backtrack to follow it. Each mind change corresponds to an iteration of IDA\* and could require many reexpansions of forgotten nodes to recreate the best path and extend it one more node.

RBFS is optimal if the heuristic function  $h(n)$  is admissible. Its space complexity is linear in the depth of the deepest optimal solution, but its time complexity is rather difficult to characterize: it depends both on the accuracy of the heuristic function and on how often the best path changes as nodes are expanded. It expands nodes in order of increasing  $f$ -score, even if  $f$  is nonmonotonic.

IDA\* and RBFS suffer from using *too little* memory. Between iterations, IDA\* retains only a single number: the current  $f$ -cost limit. RBFS retains more information in memory, but it uses only linear space: even if more memory were available, RBFS has no way to make use of it. Because they forget most of what they have done, both algorithms may end up reexploring the same states many times over.

It seems sensible, therefore, to determine how much memory we have available, and allow an algorithm to use all of it. Two algorithms that do this are **MA\*** (memory-bounded A\*) and **SMA\*** (simplified MA\*). SMA\* is—well—simpler, so we will describe it. SMA\* proceeds just like A\*, expanding the best leaf until memory is full. At this point, it cannot add a new node to the search tree without dropping an old one. SMA\* always drops the *worst* leaf node—the one with the highest  $f$ -value. Like RBFS, SMA\* then backs up the value of the forgotten node to its parent. In this way, the ancestor of a forgotten subtree knows the quality of the best path in that subtree. With this information, SMA\* regenerates the subtree only when all other paths have been shown to look worse than the path it has forgotten. Another way of saying this is that if all the descendants of a node  $n$  are forgotten, then we will not know which way to go from  $n$ , but we will still have an idea of how worthwhile it is to go anywhere from  $n$ .

The complete algorithm is described in the online code repository accompanying this book. There is one subtlety worth mentioning. We said that SMA\* expands the best leaf and deletes the worst leaf. What if *all* the leaf nodes have the same  $f$ -value? To avoid selecting the same node for deletion and expansion, SMA\* expands the *newest* best leaf and deletes the *oldest* worst leaf. These coincide when there is only one leaf, but in that case, the current search tree must be a single path from root to leaf that fills all of memory. If the leaf is not a goal node, then *even if it is on an optimal solution path*, that solution is not reachable with the available memory. Therefore, the node can be discarded exactly as if it had no successors.

SMA\* is complete if there is any reachable solution—that is, if  $d$ , the depth of the shallowest goal node, is less than the memory size (expressed in nodes). It is optimal if any optimal solution is reachable; otherwise, it returns the best reachable solution. In practical terms, SMA\* is a fairly robust choice for finding optimal solutions, particularly when the state space is a graph, action costs are not uniform, and node generation is expensive compared to the overhead of maintaining the frontier and the reached set.

On very hard problems, however, it will often be the case that SMA\* is forced to switch back and forth continually among many candidate solution paths, only a small subset of which can fit in memory. (This resembles the problem of **thrashing** in disk paging systems.) Then the extra time required for repeated regeneration of the same nodes means that problems that would be practically solvable by A\*, given unlimited memory, become intractable for SMA\*. That is to say, *memory limitations can make a problem intractable from the point of view of computation time*. Although no current theory explains the tradeoff between time and memory, it seems that this is an inescapable problem. The only way out is to drop the optimality requirement.

MA\*  
SMA\*

Thrashing

### 3.5.6 Bidirectional heuristic search

With unidirectional best-first search, we saw that using  $f(n) = g(n) + h(n)$  as the evaluation function gives us an A\* search that is guaranteed to find optimal-cost solutions (assuming an admissible  $h$ ) while being optimally efficient in the number of nodes expanded.

With bidirectional best-first search we could also try using  $f(n) = g(n) + h(n)$ , but unfortunately there is no guarantee that this would lead to an optimal-cost solution, nor that it would be optimally efficient, even with an admissible heuristic. With bidirectional search, it turns out that it is not individual nodes but rather *pairs* of nodes (one from each frontier) that can be proved to be surely expanded, so any proof of efficiency will have to consider pairs of nodes (Eckerle *et al.*, 2017).

We'll start with some new notation. We use  $f_F(n) = g_F(n) + h_F(n)$  for nodes going in the forward direction (with the initial state as root) and  $f_B(n) = g_B(n) + h_B(n)$  for nodes in the backward direction (with a goal state as root). Although both forward and backward searches are solving the same problem, they have different evaluation functions because, for example, the heuristics are different depending on whether you are striving for the goal or for the initial state. We'll assume admissible heuristics.

Consider a forward path from the initial state to a node  $m$  and a backward path from the goal to a node  $n$ . We can define a lower bound on the cost of a solution that follows the path from the initial state to  $m$ , then somehow gets to  $n$ , then follows the path to the goal as

$$lb(m, n) = \max(g_F(m) + g_B(n), f_F(m), f_B(n))$$

In other words, the cost of such a path must be at least as large as the sum of the path costs of the two parts (because the remaining connection between them must have nonnegative cost), and the cost must also be at least as much as the estimated  $f$  cost of either part (because the heuristic estimates are optimistic). Given that, the theorem is that for any pair of nodes  $m, n$  with  $lb(m, n)$  less than the optimal cost  $C^*$ , we must expand either  $m$  or  $n$ , because the path that goes through both of them is a potential optimal solution. The difficulty is that we don't know for sure which node is best to expand, and therefore no bidirectional search algorithm can be guaranteed to be optimally efficient—any algorithm might expand up to twice the minimum number of nodes if it always chooses the wrong member of a pair to expand first. Some bidirectional heuristic search algorithms explicitly manage a queue of  $(m, n)$  pairs, but we will stick with bidirectional best-first search (Figure 3.14), which has two frontier priority queues, and give it an evaluation function that mimics the  $lb$  criteria:

$$f_2(n) = \max(2g(n), g(n) + h(n))$$

The node to expand next will be the one that minimizes this  $f_2$  value; the node can come from either frontier. This  $f_2$  function guarantees that we will never expand a node (from either frontier) with  $g(n) > \frac{C^*}{2}$ . We say the two halves of the search “meet in the middle” in the sense that when the two frontiers touch, no node inside of either frontier has a path cost greater than the bound  $\frac{C^*}{2}$ . Figure 3.24 works through an example bidirectional search.

We have described an approach where the  $h_F$  heuristic estimates the distance to the goal (or, when the problem has multiple goal states, the distance to the closest goal) and  $h_B$  estimates the distance to the start. This is called a **front-to-end** search. An alternative, called **front-to-front** search, attempts to estimate the distance to the other frontier. Clearly, if a frontier has millions of nodes, it would be inefficient to apply the heuristic function to every

**Figure 3.24** Bidirectional search maintains two frontiers: on the left, nodes A and B are successors of Start; on the right, node F is an inverse successor of Goal. Each node is labeled with  $f = g + h$  values and the  $f_2 = \max(2g, g + h)$  value. (The  $g$  values are the sum of the action costs as shown on each arrow; the  $h$  values are arbitrary and cannot be derived from anything in the figure.) The optimal solution, Start-A-F-Goal, has cost  $C^* = 4 + 2 + 4 = 10$ , so that means that a meet-in-the-middle bidirectional algorithm should not expand any node with  $g > \frac{C^*}{2} = 5$ ; and indeed the next node to be expanded would be A or F (each with  $g = 4$ ), leading us to an optimal solution. If we expanded the node with lowest  $f$  cost first, then B and C would come next, and D and E would be tied with A, but they all have  $g > \frac{C^*}{2}$  and thus are never expanded when  $f_2$  is the evaluation function.

one of them and take the minimum. But it can work to sample a few nodes from the frontier. In certain specific problem domains it is possible to *summarize* the frontier—for example, in a grid search problem, we can incrementally compute a bounding box of the frontier, and use as a heuristic the distance to the bounding box.

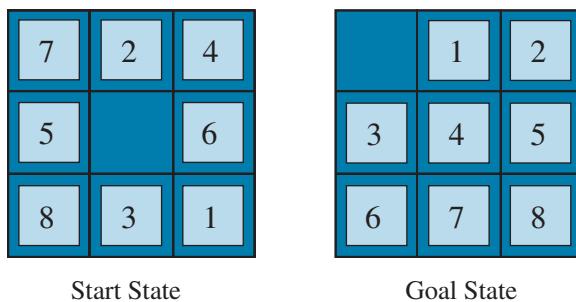

Bidirectional search is sometimes more efficient than unidirectional search, sometimes not. In general, if we have a very good heuristic, then A\* search produces search contours that are focused on the goal, and adding bidirectional search does not help much. With an average heuristic, bidirectional search that meets in the middle tends to expand fewer nodes and is preferred. In the worst case of a poor heuristic, the search is no longer focused on the goal, and bidirectional search has the same asymptotic complexity as A\*. Bidirectional search with the  $f_2$  evaluation function and an admissible heuristic  $h$  is complete and optimal.

## 3.6 Heuristic Functions

In this section, we look at how the accuracy of a heuristic affects search performance, and also consider how heuristics can be invented. As our main example we'll return to the 8-puzzle. As mentioned in Section 3.2, the object of the puzzle is to slide the tiles horizontally or vertically into the empty space until the configuration matches the goal configuration (Figure 3.25).

There are  $9!/2 = 181,400$  reachable states in an 8-puzzle, so a search could easily keep them all in memory. But for the 15-puzzle, there are  $16!/2$  states—over 10 trillion—so to search that space we will need the help of a good admissible heuristic function. There is a long history of such heuristics for the 15-puzzle; here are two commonly used candidates:

- $h_1$  = the number of misplaced tiles (blank not included). For Figure 3.25, all eight tiles are out of position, so the start state has  $h_1 = 8$ .  $h_1$  is an admissible heuristic because any tile that is out of place will require at least one move to get it to the right place.

**Figure 3.25** A typical instance of the 8-puzzle. The shortest solution is 26 actions long.

Manhattan distance

- $h_2$  = the sum of the distances of the tiles from their goal positions. Because tiles cannot move along diagonals, the distance is the sum of the horizontal and vertical distances—sometimes called the **city-block distance** or **Manhattan distance**.  $h_2$  is also admissible because all any move can do is move one tile one step closer to the goal. Tiles 1 to 8 in the start state of Figure 3.25 give a Manhattan distance of

$$h_2 = 3 + 1 + 2 + 2 + 2 + 3 + 3 + 2 = 18.$$

As expected, neither of these overestimates the true solution cost, which is 26.

Effective branching factor

### 3.6.1 The effect of heuristic accuracy on performance

One way to characterize the quality of a heuristic is the **effective branching factor**  $b^*$ . If the total number of nodes generated by  $A^*$  for a particular problem is  $N$  and the solution depth is  $d$ , then  $b^*$  is the branching factor that a uniform tree of depth  $d$  would have to have in order to contain  $N + 1$  nodes. Thus,

$$N + 1 = 1 + b^* + (b^*)^2 + \dots + (b^*)^d.$$

For example, if  $A^*$  finds a solution at depth 5 using 52 nodes, then the effective branching factor is 1.92. The effective branching factor can vary across problem instances, but usually for a specific domain (such as 8-puzzles) it is fairly constant across all nontrivial problem instances. Therefore, experimental measurements of  $b^*$  on a small set of problems can provide a good guide to the heuristic's overall usefulness. A well-designed heuristic would have a value of  $b^*$  close to 1, allowing fairly large problems to be solved at reasonable computational cost.

Effective depth

Korf and Reid (1998) argue that a better way to characterize the effect of  $A^*$  pruning with a given heuristic  $h$  is that it reduces the **effective depth** by a constant  $k_h$  compared to the true depth. This means that the total search cost is  $O(b^{d-k_h})$  compared to  $O(b^d)$  for an uninformed search. Their experiments on Rubik's Cube and  $n$ -puzzle problems show that this formula gives accurate predictions for total search cost for sampled problem instances across a wide range of solution lengths—at least for solution lengths larger than  $k_h$ .

For Figure 3.26 we generated random 8-puzzle problems and solved them with an uninformed breadth-first search and with  $A^*$  search using both  $h_1$  and  $h_2$ , reporting the average number of nodes generated and the corresponding effective branching factor for each search strategy and for each solution length. The results suggest that  $h_2$  is better than  $h_1$ , and both are better than no heuristic at all.

$d$	Search Cost (nodes generated)			Effective Branching Factor		
	BFS	$A^*(h_1)$	$A^*(h_2)$	BFS	$A^*(h_1)$	$A^*(h_2)$
6	128	24	19	2.01	1.42	1.34
8	368	48	31	1.91	1.40	1.30
10	1033	116	48	1.85	1.43	1.27
12	2672	279	84	1.80	1.45	1.28
14	6783	678	174	1.77	1.47	1.31
16	17270	1683	364	1.74	1.48	1.32
18	41558	4102	751	1.72	1.49	1.34
20	91493	9905	1318	1.69	1.50	1.34
22	175921	22955	2548	1.66	1.50	1.34
24	290082	53039	5733	1.62	1.50	1.36
26	395355	110372	10080	1.58	1.50	1.35
28	463234	202565	22055	1.53	1.49	1.36

**Figure 3.26** Comparison of the search costs and effective branching factors for 8-puzzle problems using breadth-first search,  $A^*$  with  $h_1$  (misplaced tiles), and  $A^*$  with  $h_2$  (Manhattan distance). Data are averaged over 100 puzzles for each solution length  $d$  from 6 to 28.

One might ask whether  $h_2$  is *always* better than  $h_1$ . The answer is “Essentially, yes.” It is easy to see from the definitions of the two heuristics that for any node  $n$ ,  $h_2(n) \geq h_1(n)$ . We thus say that  $h_2$  **dominates**  $h_1$ . Domination translates directly into efficiency:  $A^*$  using  $h_2$  will never expand more nodes than  $A^*$  using  $h_1$  (except in the case of breaking ties unluckily). The argument is simple. Recall the observation on page 108 that every node with  $f(n) < C^*$  will surely be expanded. This is the same as saying that every node with  $h(n) < C^* - g(n)$  is surely expanded when  $h$  is consistent. But because  $h_2$  is at least as big as  $h_1$  for all nodes, every node that is surely expanded by  $A^*$  search with  $h_2$  is also surely expanded with  $h_1$ , and  $h_1$  might cause other nodes to be expanded as well. Hence, it is generally better to use a heuristic function with higher values, provided it is consistent and that the computation time for the heuristic is not too long.

Domination

### 3.6.2 Generating heuristics from relaxed problems

We have seen that both  $h_1$  (misplaced tiles) and  $h_2$  (Manhattan distance) are fairly good heuristics for the 8-puzzle and that  $h_2$  is better. How might one have come up with  $h_2$ ? Is it possible for a computer to invent such a heuristic mechanically?

$h_1$  and  $h_2$  are estimates of the remaining path length for the 8-puzzle, but they are also perfectly accurate path lengths for *simplified* versions of the puzzle. If the rules of the puzzle were changed so that a tile could move anywhere instead of just to the adjacent empty square, then  $h_1$  would give the exact length of the shortest solution. Similarly, if a tile could move one square in any direction, even onto an occupied square, then  $h_2$  would give the exact length of the shortest solution. A problem with fewer restrictions on the actions is called a **relaxed problem**. The state-space graph of the relaxed problem is a *supergraph* of the original state space because the removal of restrictions creates added edges in the graph.

Relaxed problem

Because the relaxed problem adds edges to the state-space graph, any optimal solution in the original problem is, by definition, also a solution in the relaxed problem; but the relaxed

► problem may have *better* solutions if the added edges provide shortcuts. Hence, *the cost of an optimal solution to a relaxed problem is an admissible heuristic for the original problem*. Furthermore, because the derived heuristic is an exact cost for the relaxed problem, it must obey the triangle inequality and is therefore consistent (see page 106).

If a problem definition is written down in a formal language, it is possible to construct relaxed problems automatically.<sup>14</sup> For example, if the 8-puzzle actions are described as

A tile can move from square X to square Y if

X is adjacent to Y **and** Y is blank,

we can generate three relaxed problems by removing one or both of the conditions:

- (a) A tile can move from square X to square Y if X is adjacent to Y.
- (b) A tile can move from square X to square Y if Y is blank.
- (c) A tile can move from square X to square Y.

From (a), we can derive  $h_2$  (Manhattan distance). The reasoning is that  $h_2$  would be the proper score if we moved each tile in turn to its destination. The heuristic derived from (b) is discussed in Exercise 3.GASC. From (c), we can derive  $h_1$  (misplaced tiles) because it would be the proper score if tiles could move to their intended destination in one action. Notice that it is crucial that the relaxed problems generated by this technique can be solved essentially *without search*, because the relaxed rules allow the problem to be decomposed into eight independent subproblems. If the relaxed problem is hard to solve, then the values of the corresponding heuristic will be expensive to obtain.

A program called ABSOLVER can generate heuristics automatically from problem definitions, using the “relaxed problem” method and various other techniques (Prieditis, 1993). ABSOLVER generated a new heuristic for the 8-puzzle that was better than any preexisting heuristic and found the first useful heuristic for the famous Rubik’s Cube puzzle.

If a collection of admissible heuristics  $h_1 \dots h_m$  is available for a problem and none of them is clearly better than the others, which should we choose? As it turns out, we can have the best of all worlds, by defining

$$h(n) = \max\{h_1(n), \dots, h_k(n)\}.$$

This composite heuristic picks whichever function is most accurate on the node in question. Because the  $h_i$  components are admissible,  $h$  is admissible (and if  $h_i$  are all consistent,  $h$  is consistent). Furthermore,  $h$  dominates all of its component heuristics. The only drawback is that  $h(n)$  takes longer to compute. If that is an issue, an alternative is to randomly select one of the heuristics at each evaluation, or use a machine learning algorithm to predict which heuristic will be best. Doing this can result in a heuristic that is inconsistent (even if every  $h_i$  is consistent), but in practice it usually leads to faster problem solving.

### 3.6.3 Generating heuristics from subproblems: Pattern databases

#### Subproblem

Admissible heuristics can also be derived from the solution cost of a **subproblem** of a given problem. For example, Figure 3.27 shows a subproblem of the 8-puzzle instance in Figure 3.25. The subproblem involves getting tiles 1, 2, 3, 4, and the blank into their correct positions. Clearly, the cost of the optimal solution of this subproblem is a lower bound on

---

<sup>14</sup> In Chapters 8 and 11, we describe formal languages suitable for this task; with formal descriptions that can be manipulated, the construction of relaxed problems can be automated. For now, we use English.

**Figure 3.27** A subproblem of the 8-puzzle instance given in Figure 3.25. The task is to get tiles 1, 2, 3, 4, and the blank into their correct positions, without worrying about what happens to the other tiles.

the cost of the complete problem. It turns out to be more accurate than Manhattan distance in some cases.

The idea behind **pattern databases** is to store these exact solution costs for every possible subproblem instance—in our example, every possible configuration of the four tiles and the blank. (There will be  $9 \times 8 \times 7 \times 6 \times 5 = 15,120$  patterns in the database. The identities of the other four tiles are irrelevant for the purposes of solving the subproblem, but moves of those tiles do count toward the solution cost of the subproblem.) Then we compute an admissible heuristic  $h_{DB}$  for each state encountered during a search simply by looking up the corresponding subproblem configuration in the database. The database itself is constructed by searching back from the goal and recording the cost of each new pattern encountered;<sup>15</sup> the expense of this search is amortized over subsequent problem instances, and so makes sense if we expect to be asked to solve many problems.

The choice of tiles 1-2-3-4 to go with the blank is fairly arbitrary; we could also construct databases for 5-6-7-8, for 2-4-6-8, and so on. Each database yields an admissible heuristic, and these heuristics can be combined, as explained earlier, by taking the maximum value. A combined heuristic of this kind is much more accurate than the Manhattan distance; the number of nodes generated when solving random 15-puzzles can be reduced by a factor of 1000. However, with each additional database there are diminishing returns and increased memory and computation costs.

One might wonder whether the heuristics obtained from the 1-2-3-4 database and the 5-6-7-8 could be *added*, since the two subproblems seem not to overlap. Would this still give an admissible heuristic? The answer is no, because the solutions of the 1-2-3-4 subproblem and the 5-6-7-8 subproblem for a given state will almost certainly share some moves—it is unlikely that 1-2-3-4 can be moved into place without touching 5-6-7-8, and vice versa. But what if we don't count those moves—what if we don't abstract the other tiles to stars, but rather make them disappear? That is, we record not the total cost of solving the 1-2-3-4 subproblem, but just the number of moves involving 1-2-3-4. Then the sum of the two costs is still a lower bound on the cost of solving the entire problem. This is the idea behind **disjoint pattern databases**. With such databases, it is possible to solve random 15-puzzles in a few

Pattern database

Disjoint pattern databases

<sup>15</sup> By working backward from the goal, the exact solution cost of every instance encountered is immediately available. This is an example of **dynamic programming**, which we discuss further in Chapter 16.

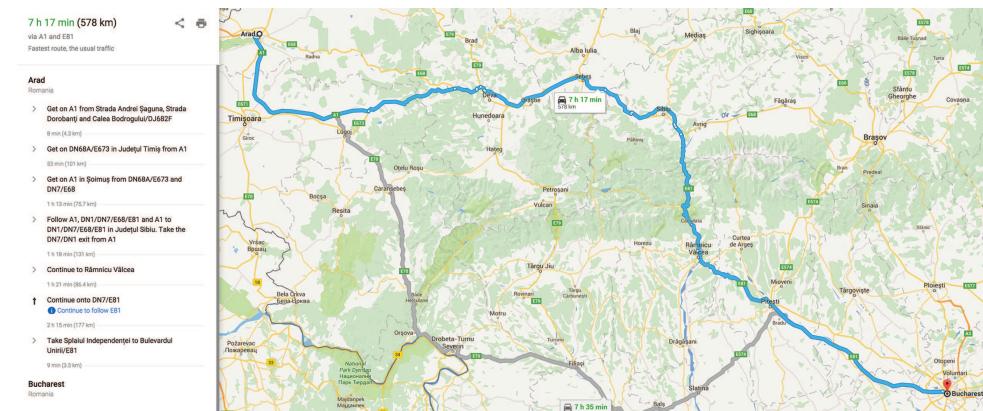

Figure 3.28 A Web service providing driving directions, computed by a search algorithm.

milliseconds—the number of nodes generated is reduced by a factor of 10,000 compared with the use of Manhattan distance. For 24-puzzles, a speedup of roughly a factor of a million can be obtained. Disjoint pattern databases work for sliding-tile puzzles because the problem can be divided up in such a way that each move affects only one subproblem—because only one tile is moved at a time.

### 3.6.4 Generating heuristics with landmarks

There are online services that host maps with tens of millions of vertices and find cost-optimal driving directions in milliseconds (Figure 3.28). How can they do that, when the best search algorithms we have considered so far are about a million times slower? There are many tricks, but the most important one is **precomputation** of some optimal path costs. Although the precomputation can be time-consuming, it need only be done once, and then can be amortized over billions of user search requests.

We could generate a perfect heuristic by precomputing and storing the cost of the optimal path between every pair of vertices. That would take  $O(|V|^2)$  space, and  $O(|E|^3)$  time—practical for graphs with 10 thousand vertices, but not 10 million.

A better approach is to choose a few (perhaps 10 or 20) **landmark points**<sup>16</sup> from the vertices. Then for each landmark  $L$  and for each other vertex  $v$  in the graph, we compute and store  $C^*(v, L)$ , the exact cost of the optimal path from  $v$  to  $L$ . (We also need  $C^*(L, v)$ ; on an undirected graph this is the same as  $C^*(v, L)$ ; on a directed graph—e.g., with one-way streets—we need to compute this separately.) Given the stored  $C^*$  tables, we can easily create an efficient (although inadmissible) heuristic: the minimum, over all landmarks, of the cost of getting from the current node to the landmark, and then to the goal:

$$h_L(n) = \min_{L \in \text{Landmarks}} C^*(n, L) + C^*(L, \text{goal})$$

If the optimal path happens to go through a landmark, this heuristic will be exact; if not it is inadmissible—it overestimates the cost to the goal. In an A\* search, if you have exact heuristics, then once you reach a node that is on an optimal path, every node you expand

<sup>16</sup> Landmark points are sometimes called “pivots” or “anchors.”

Precomputation

Landmark point

from then on will be on an optimal path. Think of the contour lines as following along this optimal path. The search will trace along the optimal path, on each iteration adding an action with cost  $c$  to get to a result state whose  $h$ -value will be  $c$  less, meaning that the total  $f = g + h$  score will remain constant at  $C^*$  all along the path.

Some route-finding algorithms save even more time by adding **shortcuts**—artificial edges in the graph that define an optimal multi-action path. For example, if there were shortcuts predefined between all the 100 biggest cities in the U.S., and we were trying to navigate from the Berkeley campus in California to NYU in New York, we could take the shortcut between Sacramento and Manhattan and cover 90% of the path in one action.

$h_L(n)$  is efficient but not admissible. But with a bit more care, we can come up with a heuristic that is both efficient and admissible:

$$h_{DH}(n) = \max_{L \in \text{Landmarks}} |C^*(n, L) - C^*(\text{goal}, L)|$$

This is called a **differential heuristic** (because of the subtraction). Think of this with a landmark that is somewhere out beyond the goal. If the goal happens to be on the optimal path from  $n$  to the landmark, then this is saying “consider the entire path from  $n$  to  $L$ , then subtract off the last part of that path, from  $\text{goal}$  to  $L$ , giving us the exact cost of the path from  $n$  to  $\text{goal}$ .” To the extent that the goal is a bit off of the optimal path to the landmark, the heuristic will be inexact, but still admissible. Landmarks that are not out beyond the goal will not be useful; a landmark that is exactly halfway between  $n$  and  $\text{goal}$  will give  $h_{DH} = 0$ , which is not helpful.

There are several ways to pick landmark points. Selecting points at random is fast, but we get better results if we take care to spread the landmarks out so they are not too close to each other. A greedy approach is to pick a first landmark at random, then find the point that is furthest from that, and add it to the set of landmarks, and continue, at each iteration adding the point that maximizes the distance to the nearest landmark. If you have logs of past search requests by your users, then you can pick landmarks that are frequently requested in searches. For the differential heuristic it is good if the landmarks are spread around the perimeter of the graph. Thus, a good technique is to find the centroid of the graph, arrange  $k$  pie-shaped wedges around the centroid, and in each wedge select the vertex that is farthest from the center.

Landmarks work especially well in route-finding problems because of the way roads are laid out in the world: a lot of traffic actually wants to travel between landmarks, so civil engineers build the widest and fastest roads along these routes; landmark search makes it easier to recover these routes.

### 3.6.5 Learning to search better

We have presented several fixed search strategies—breadth-first,  $A^*$ , and so on—that have been carefully designed and programmed by computer scientists. Could an agent *learn* how to search better? The answer is yes, and the method rests on an important concept called the **metalevel state space**. Each state in a metalevel state space captures the internal (computational) state of a program that is searching in an ordinary state space such as the map of Romania. (To keep the two concepts separate, we call the map of Romania an **object-level state space**.) For example, the internal state of the  $A^*$  algorithm consists of the current search tree. Each action in the metalevel state space is a computation step that alters the internal

Shortcuts

Differential heuristic

Metalevel state space

Object-level state space

state; for example, each computation step in A\* expands a leaf node and adds its successors to the tree. Thus, Figure 3.18, which shows a sequence of larger and larger search trees, can be seen as depicting a path in the metalevel state space where each state on the path is an object-level search tree.

Now, the path in Figure 3.18 has five steps, including one step, the expansion of Fagaras, that is not especially helpful. For harder problems, there will be many such missteps, and a **metalevel learning** algorithm can learn from these experiences to avoid exploring unpromising subtrees. The techniques used for this kind of learning are described in Chapter 23. The goal of learning is to minimize the **total cost** of problem solving, trading off computational expense and path cost.

### 3.6.6 Learning heuristics from experience

We have seen that one way to invent a heuristic is to devise a relaxed problem for which an optimal solution can be found easily. An alternative is to learn from experience. “Experience” here means solving lots of 8-puzzles, for instance. Each optimal solution to an 8-puzzle problem provides an example (goal, path) pair. From these examples, a learning algorithm can be used to construct a function  $h$  that can (with luck) approximate the true path cost for other states that arise during search. Most of these approaches learn an imperfect approximation to the heuristic function, and thus risk inadmissibility. This leads to an inevitable tradeoff between learning time, search run time, and solution cost. Techniques for machine learning are demonstrated in Chapter 19. The reinforcement learning methods described in Chapter 23 are also applicable to search.

Some machine learning techniques work better when supplied with **features** of a state that are relevant to predicting the state’s heuristic value, rather than with just the raw state description. For example, the feature “number of misplaced tiles” might be helpful in predicting the actual distance of an 8-puzzle state from the goal. Let’s call this feature  $x_1(n)$ . We could take 100 randomly generated 8-puzzle configurations and gather statistics on their actual solution costs. We might find that when  $x_1(n)$  is 5, the average solution cost is around 14, and so on. Of course, we can use multiple features. A second feature  $x_2(n)$  might be “number of pairs of adjacent tiles that are not adjacent in the goal state.” How should  $x_1(n)$  and  $x_2(n)$  be combined to predict  $h(n)$ ? A common approach is to use a linear combination:

$$h(n) = c_1x_1(n) + c_2x_2(n).$$

The constants  $c_1$  and  $c_2$  are adjusted to give the best fit to the actual data across the randomly generated configurations. One expects both  $c_1$  and  $c_2$  to be positive because misplaced tiles and incorrect adjacent pairs make the problem harder to solve. Notice that this heuristic satisfies the condition  $h(n)=0$  for goal states, but it is not necessarily admissible or consistent.

## Summary

---

This chapter has introduced search algorithms that an agent can use to select action sequences in a wide variety of environments—as long as they are episodic, single-agent, fully observable, deterministic, static, discrete, and completely known. There are tradeoffs to be made between the amount of time the search takes, the amount of memory available, and the quality of the solution. We can be more efficient if we have domain-dependent knowledge in the

form of a heuristic function that estimates how far a given state is from the goal, or if we precompute partial solutions involving patterns or landmarks.

- Before an agent can start searching, a well-defined **problem** must be formulated.
- A problem consists of five parts: the **initial state**, a set of **actions**, a **transition model** describing the results of those actions, a set of **goal states**, and an **action cost function**.
- The environment of the problem is represented by a **state space graph**. A **path** through the state space (a sequence of actions) from the initial state to a goal state is a **solution**.
- Search algorithms generally treat states and actions as **atomic**, without any internal structure (although we introduced features of states when it came time to do learning).
- Search algorithms are judged on the basis of **completeness**, **cost optimality**, **time complexity**, and **space complexity**.
- **Uninformed search** methods have access only to the problem definition. Algorithms build a search tree in an attempt to find a solution. Algorithms differ based on which node they expand first:
  - **Best-first search** selects nodes for expansion using an **evaluation function**.
  - **Breadth-first search** expands the shallowest nodes first; it is complete, optimal for unit action costs, but has exponential space complexity.
  - **Uniform-cost search** expands the node with lowest path cost,  $g(n)$ , and is optimal for general action costs.
  - **Depth-first search** expands the deepest unexpanded node first. It is neither complete nor optimal, but has linear space complexity. **Depth-limited search** adds a depth bound.
  - **Iterative deepening search** calls depth-first search with increasing depth limits until a goal is found. It is complete when full cycle checking is done, optimal for unit action costs, has time complexity comparable to breadth-first search, and has linear space complexity.
  - **Bidirectional search** expands two frontiers, one around the initial state and one around the goal, stopping when the two frontiers meet.
- **Informed search** methods have access to a **heuristic** function  $h(n)$  that estimates the cost of a solution from  $n$ . They may have access to additional information such as pattern databases with solution costs.
  - **Greedy best-first search** expands nodes with minimal  $h(n)$ . It is not optimal but is often efficient.
  - **A\* search** expands nodes with minimal  $f(n) = g(n) + h(n)$ . A\* is complete and optimal, provided that  $h(n)$  is admissible. The space complexity of A\* is still an issue for many problems.
  - **Bidirectional A\* search** is sometimes more efficient than A\* itself.
  - **IDA\*** (iterative deepening A\* search) is an iterative deepening version of A\*, and thus addresses the space complexity issue.
  - **RBFS** (recursive best-first search) and **SMA\*** (simplified memory-bounded A\*) are robust, optimal search algorithms that use limited amounts of memory; given enough time, they can solve problems for which A\* runs out of memory.

- **Beam search** puts a limit on the size of the frontier; that makes it incomplete and suboptimal, but it often finds reasonably good solutions and runs faster than complete searches.
- **Weighted A\*** search focuses the search towards a goal, expanding fewer nodes, but sacrificing optimality.
- The performance of heuristic search algorithms depends on the quality of the heuristic function. One can sometimes construct good heuristics by relaxing the problem definition, by storing precomputed solution costs for subproblems in a pattern database, by defining landmarks, or by learning from experience with the problem class.

## Bibliographical and Historical Notes

---

The topic of state-space search originated in the early years of AI. Newell and Simon’s work on the Logic Theorist (1957) and GPS (1961) led to the establishment of search algorithms as the primary tool for 1960s AI researchers and to the establishment of problem solving as the canonical AI task. Work in operations research by Richard Bellman (1957) showed the importance of additive path costs in simplifying optimization algorithms. The text by Nils Nilsson (1971) established the area on a solid theoretical footing.

The 8-puzzle is a smaller cousin of the 15-puzzle, whose history is recounted at length by Slocum and Sonneveld (2006). In 1880, the 15-puzzle attracted broad attention from the public and mathematicians (Johnson and Story, 1879; Tait, 1880). The editors of the *American Journal of Mathematics* stated, “The ‘15’ puzzle for the last few weeks has been prominently before the American public, and may safely be said to have engaged the attention of nine out of ten persons of both sexes and all ages and conditions of the community,” while the *Weekly News-Democrat* of Emporia, Kansas wrote on March 12, 1880 that “It has become literally an epidemic all over the country.”

The famous American game designer Sam Loyd falsely claimed to have invented the 15 puzzle (Loyd, 1959); actually it was invented by Noyes Chapman, a postmaster in Canastota, New York, in the mid-1870s (although a generic patent covering sliding blocks was granted to Ernest Kinsey in 1878). Ratner and Warmuth (1986) showed that the general  $n \times n$  version of the 15-puzzle belongs to the class of NP-complete problems.

Rubik’s Cube was of course invented in 1974 by Ernő Rubik, who also discovered an algorithm for finding good, but not optimal solutions. Korf (1997) found optimal solutions for some random problem instances using pattern databases and IDA\* search. Rokicki *et al.* (2014) proved that any instance can be solved in 26 moves (if you consider a 180° twist to be two moves; 20 if it counts as one). The proof consumed 35 CPU years of computation; it does not lead immediately to an efficient algorithm. Agostinelli *et al.* (2019) used reinforcement learning, deep learning networks, and Monte Carlo tree search to learn a much more efficient solver for Rubik’s cube. It is not guaranteed to find a cost-optimal solution, but does so about 60% of the time, and typical solutions times are less than a second.

Each of the real-world search problems listed in the chapter has been the subject of a good deal of research effort. Methods for selecting optimal airline flights remain proprietary for the most part, but Carl de Marcken has shown by a reduction to Diophantine decision problems that airline ticket pricing and restrictions have become so convoluted that the prob-

lem of selecting an optimal flight is formally *undecidable* (Robinson, 2002). The traveling salesperson problem (TSP) is a standard combinatorial problem in theoretical computer science (Lawler *et al.*, 1992). Karp (1972) proved the TSP decision problem to be NP-hard, but effective heuristic approximation methods were developed (Lin and Kernighan, 1973). Arora (1998) devised a fully polynomial approximation scheme for Euclidean TSPs. VLSI layout methods are surveyed by LaPaugh (2010), and many layout optimization papers appear in VLSI journals. Robotic navigation is discussed in Chapter 26. Automatic assembly sequencing was first demonstrated by FREDDY (Michie, 1972); a comprehensive review is given by (Bahubalendruni and Biswal, 2016).

Uninformed search algorithms are a central topic of computer science (Cormen *et al.*, 2009) and operations research (Dreyfus, 1969). Breadth-first search was formulated for solving mazes by Moore (1959). The method of dynamic programming (Bellman, 1957; Bellman and Dreyfus, 1962), which systematically records solutions for all subproblems of increasing lengths, can be seen as a form of breadth-first search.

Dijkstra's algorithm in the form it is usually presented in (Dijkstra, 1959) is applicable to explicit finite graphs. Nilsson (1971) introduced a version of Dijkstra's algorithm that he called uniform-cost search (because the algorithm "spreads out along contours of equal path cost") that allows for implicitly defined, infinite graphs. Nilsson's work also introduced the idea of closed and open lists, and the term "graph search." The name BEST-FIRST-SEARCH was introduced in the *Handbook of AI* (Barr and Feigenbaum, 1981). The Floyd–Warshall (Floyd, 1962) and Bellman–Ford (Bellman, 1958; Ford, 1956) algorithms allow negative step costs (as long as there are no negative cycles).

A version of iterative deepening designed to make efficient use of the chess clock was first used by Slate and Atkin (1977) in the CHESS 4.5 game-playing program. Martelli's algorithm B (1977) also includes an iterative deepening aspect. The iterative deepening technique was introduced by Bertram Raphael (1976) and came to the fore in work by Korf (1985a).

The use of heuristic information in problem solving appears in an early paper by Simon and Newell (1958), but the phrase "heuristic search" and the use of heuristic functions that estimate the distance to the goal came somewhat later (Newell and Ernst, 1965; Lin, 1965). Doran and Michie (1966) conducted extensive experimental studies of heuristic search. Although they analyzed path length and "penetrance" (the ratio of path length to the total number of nodes examined so far), they appear to have ignored the information provided by the path cost  $g(n)$ . The A\* algorithm, incorporating the current path cost into heuristic search, was developed by Hart, Nilsson, and Raphael (1968). Dechter and Pearl (1985) studied the conditions under which A\* is optimally efficient (in number of nodes expanded).

The original A\* paper (Hart *et al.*, 1968) introduced the consistency condition on heuristic functions. The monotone condition was introduced by Pohl (1977) as a simpler replacement, but Pearl (1984) showed that the two were equivalent.

Pohl (1977) pioneered the study of the relationship between the error in heuristic functions and the time complexity of A\*. Basic results were obtained for tree-like search with unit action costs and a single goal state (Pohl, 1977; Gaschnig, 1979; Huyn *et al.*, 1980; Pearl, 1984) and with multiple goal states (Dinh *et al.*, 2007). Korf and Reid (1998) showed how to predict the exact number of nodes expanded (not just an asymptotic approximation) on a variety of actual problem domains. The "effective branching factor" was proposed by Nilsson (1971) as an empirical measure of efficiency. For graph search, Helmert and Röger (2008)

noted that several well-known problems contained exponentially many nodes on optimal-cost solution paths, implying exponential time complexity for A\*.

There are many variations on the A\* algorithm. Pohl (1970) introduced weighted A\* search, and later a dynamic version (1973), where the weight changes over the depth of the tree. Ebendt and Drechsler (2009) synthesize the results and examine some applications. Hatem and Ruml (2014) show a simplified and improved version of weighted A\* that is easier to implement. Wilt and Ruml (2014) introduce speedy search as an alternative to greedy search that focuses on minimizing search time, and Wilt and Ruml (2016) show that the best heuristics for satisficing search are different from the ones for optimal search. Burns *et al.* (2012) give some implementation tricks for writing fast search code, and Felner (2018) considers how the implementation changes when using an early goal test.

Pohl (1971) introduced bidirectional search. Holte *et al.* (2016) describe the version of bidirectional search that is guaranteed to meet in the middle, making it more widely applicable. Eckerle *et al.* (2017) describe the set of surely expanded pairs of nodes, and show that no bidirectional search can be optimally efficient. The NBS algorithm (Chen *et al.*, 2017) makes explicit use of a queue of pairs of nodes.

A combination of bidirectional A\* and known landmarks was used to efficiently find driving routes for Microsoft’s online map service (Goldberg *et al.*, 2006). After caching a set of paths between landmarks, the algorithm can find an optimal-cost path between any pair of points in a 24-million-point graph of the United States, searching less than 0.1% of the graph. Korf (1987) shows how to use subgoals, macro-operators, and abstraction to achieve remarkable speedups over previous techniques. Delling *et al.* (2009) describe how to use bidirectional search, landmarks, hierarchical structure, and other tricks to find driving routes. Anderson *et al.* (2008) describe a related technique, called **coarse-to-fine search**, which can be thought of as defining landmarks at various hierarchical levels of abstraction. Korf (1987) describes conditions under which coarse-to-fine search provides an exponential speedup. Knoblock (1991) provides experimental results and analysis to quantify the advantages of hierarchical search.

#### Coarse-to-fine search

A\* and other state-space search algorithms are closely related to the **branch-and-bound** techniques that are widely used in operations research (Lawler and Wood, 1966; Rayward-Smith *et al.*, 1996). Kumar and Kanal (1988) attempt a “grand unification” of heuristic search, dynamic programming, and branch-and-bound techniques under the name of CDP—the “composite decision process.”

Because most computers in the 1960s had only a few thousand words of main memory, memory-bounded heuristic search was an early research topic. The Graph Traverser (Doran and Michie, 1966), one of the earliest search programs, commits to an action after searching best-first up to the memory limit. IDA\* (Korf, 1985b) was the first widely used length-optimal, memory-bounded heuristic search algorithm, and a large number of variants have been developed. An analysis of the efficiency of IDA\* and of its difficulties with real-valued heuristics appears in Patrick *et al.* (1992).

The original version of RBFS (Korf, 1993) is actually somewhat more complicated than the algorithm shown in Figure 3.22, which is actually closer to an independently developed algorithm called **iterative expansion** or IE (Russell, 1992). RBFS uses a lower bound as well as the upper bound; the two algorithms behave identically with admissible heuristics, but RBFS expands nodes in best-first order even with an inadmissible heuristic. The idea of

#### Branch-and-bound

#### Iterative expansion

keeping track of the best alternative path appeared earlier in Bratko's (2009) elegant Prolog implementation of A\* and in the DTA\* algorithm (Russell and Wefald, 1991). The latter work also discusses metalevel state spaces and metalevel learning.

The MA\* algorithm appeared in Chakrabarti *et al.* (1989). SMA\*, or Simplified MA\*, emerged from an attempt to implement MA\* (Russell, 1992). Kaindl and Khorsand (1994) applied SMA\* to produce a bidirectional search algorithm that was substantially faster than previous algorithms. Korf and Zhang (2000) describe a divide-and-conquer approach, and Zhou and Hansen (2002) introduce memory-bounded A\* graph search and a strategy for switching to breadth-first search to increase memory-efficiency (Zhou and Hansen, 2006).

The idea that admissible heuristics can be derived by problem relaxation appears in the seminal paper by Held and Karp (1970), who used the minimum-spanning-tree heuristic to solve the TSP. (See Exercise 3.MSTR.) The automation of the relaxation process was implemented successfully by Prieditis (1993). There is a growing literature on the application of machine learning to discover heuristic functions (Samadi *et al.*, 2008; Arfaee *et al.*, 2010; Thayer *et al.*, 2011; Lelis *et al.*, 2012).

The use of pattern databases to derive admissible heuristics is due to Gasser (1995) and Culberson and Schaeffer (1996, 1998); disjoint pattern databases are described by Korf and Felner (2002); a similar method using symbolic patterns is due to Edelkamp (2009). Felner *et al.* (2007) show how to compress pattern databases to save space. The probabilistic interpretation of heuristics was investigated by Pearl (1984) and Hansson and Mayer (1989).

Pearl's (1984) *Heuristics* and Edelkamp and Schrödl's (2012) *Heuristic Search* are influential textbooks on search. Papers about new search algorithms appear at the International Symposium on Combinatorial Search (SoCS) and the International Conference on Automated Planning and Scheduling (ICAPS), as well as in general AI conferences such as AAAI and IJCAI, and journals such as *Artificial Intelligence* and *Journal of the ACM*.

# CHAPTER 4

## SEARCH IN COMPLEX ENVIRONMENTS

*In which we relax the simplifying assumptions of the previous chapter, to get closer to the real world.*

Chapter 3 addressed problems in fully observable, deterministic, static, known environments where the solution is a sequence of actions. In this chapter, we relax those constraints. We begin with the problem of finding a good state without worrying about the path to get there, covering both discrete (Section 4.1) and continuous (Section 4.2) states. Then we relax the assumptions of determinism (Section 4.3) and observability (Section 4.4). In a nondeterministic world, the agent will need a conditional plan and carry out different actions depending on what it observes—for example, stopping if the light is red and going if it is green. With partial observability, the agent will also need to keep track of the possible states it might be in. Finally, Section 4.5 guides the agent through an unknown space that it must learn as it goes, using **online search**.

### 4.1 Local Search and Optimization Problems

In the search problems of Chapter 3 we wanted to find paths through the search space, such as a path from Arad to Bucharest. But sometimes we care only about the final state, not the path to get there. For example, in the 8-queens problem (Figure 4.3), we care only about finding a valid final configuration of 8 queens (because if you know the configuration, it is trivial to reconstruct the steps that created it). This is also true for many important applications such as integrated-circuit design, factory floor layout, job shop scheduling, automatic programming, telecommunications network optimization, crop planning, and portfolio management.

Local search

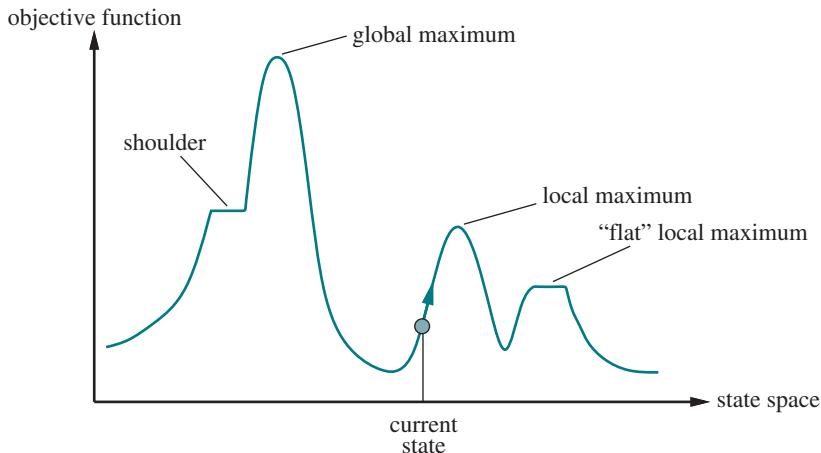

**Local search** algorithms operate by searching from a start state to neighboring states, without keeping track of the paths, nor the set of states that have been reached. That means they are not systematic—they might never explore a portion of the search space where a solution actually resides. However, they have two key advantages: (1) they use very little memory; and (2) they can often find reasonable solutions in large or infinite state spaces for which systematic algorithms are unsuitable.

Optimization problem  
Objective function

Local search algorithms can also solve **optimization problems**, in which the aim is to find the best state according to an **objective function**.

State-space landscape

To understand local search, consider the states of a problem laid out in a **state-space landscape**, as shown in Figure 4.1. Each point (state) in the landscape has an “elevation,” defined by the value of the objective function. If elevation corresponds to an objective function,

**Figure 4.1** A one-dimensional state-space landscape in which elevation corresponds to the objective function. The aim is to find the global maximum.

```

function HILL-CLIMBING(problem) returns a state that is a local maximum
  current  $\leftarrow$  problem.INITIAL
  while true do
    neighbor  $\leftarrow$  a highest-valued successor state of current
    if VALUE(neighbor)  $\leq$  VALUE(current) then return current
    current  $\leftarrow$  neighbor
  
```

**Figure 4.2** The hill-climbing search algorithm, which is the most basic local search technique. At each step the current node is replaced by the best neighbor.

then the aim is to find the highest peak—a **global maximum**—and we call the process **hill climbing**. If elevation corresponds to cost, then the aim is to find the lowest valley—a **global minimum**—and we call it **gradient descent**.

Global maximum

Global minimum

### 4.1.1 Hill-climbing search

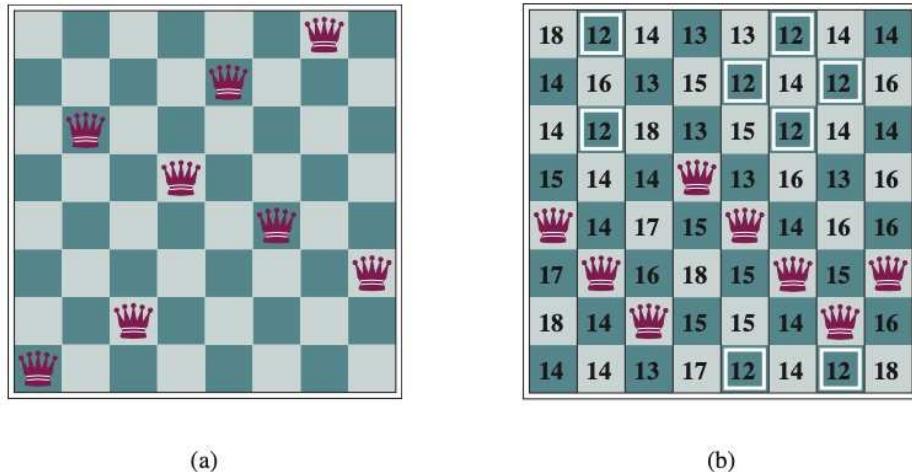

The **hill-climbing** search algorithm is shown in Figure 4.2. It keeps track of one current state and on each iteration moves to the neighboring state with highest value—that is, it heads in the direction that provides the **steepest ascent**. It terminates when it reaches a “peak” where no neighbor has a higher value. Hill climbing does not look ahead beyond the immediate neighbors of the current state. This resembles trying to find the top of Mount Everest in a thick fog while suffering from amnesia. Note that one way to use hill-climbing search is to use the negative of a heuristic cost function as the objective function; that will climb locally to the state with smallest heuristic distance to the goal.

Hill climbing

Steepest ascent

To illustrate hill climbing, we will use the **8-queens problem** (Figure 4.3). We will use a **complete-state formulation**, which means that every state has all the components of a solution, but they might not all be in the right place. In this case every state has 8 queens

Complete-state formulation

**Figure 4.3** (a) The 8-queens problem: place 8 queens on a chess board so that no queen attacks another. (A queen attacks any piece in the same row, column, or diagonal.) This position is almost a solution, except for the two queens in the fourth and seventh columns that attack each other along the diagonal. (b) An 8-queens state with heuristic cost estimate  $h=17$ . The board shows the value of  $h$  for each possible successor obtained by moving a queen within its column. There are 8 moves that are tied for best, with  $h=12$ . The hill-climbing algorithm will pick one of these.

on the board, one per column. The initial state is chosen at random, and the successors of a state are all possible states generated by moving a single queen to another square in the same column (so each state has  $8 \times 7 = 56$  successors). The heuristic cost function  $h$  is the number of pairs of queens that are attacking each other; this will be zero only for solutions. (It counts as an attack if two pieces are in the same line, even if there is an intervening piece between them.) Figure 4.3(b) shows a state that has  $h=17$ . The figure also shows the  $h$  values of all its successors.

#### Greedy local search

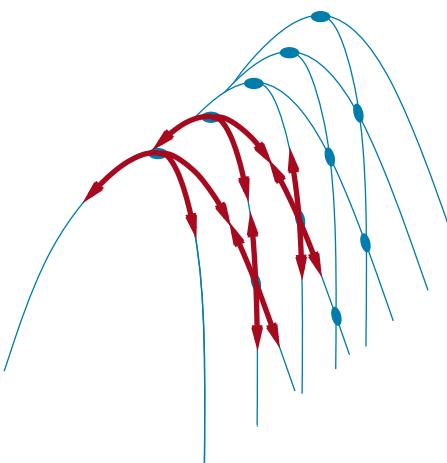

Hill climbing is sometimes called **greedy local search** because it grabs a good neighbor state without thinking ahead about where to go next. Although greed is considered one of the seven deadly sins, it turns out that greedy algorithms often perform quite well. Hill climbing can make rapid progress toward a solution because it is usually quite easy to improve a bad state. For example, from the state in Figure 4.3(b), it takes just five steps to reach the state in Figure 4.3(a), which has  $h=1$  and is very nearly a solution. Unfortunately, hill climbing can get stuck for any of the following reasons:

#### Local maximum

- **Local maxima:** A local maximum is a peak that is higher than each of its neighboring states but lower than the global maximum. Hill-climbing algorithms that reach the vicinity of a local maximum will be drawn upward toward the peak but will then be stuck with nowhere else to go. Figure 4.1 illustrates the problem schematically. More concretely, the state in Figure 4.3(a) is a local maximum (i.e., a local minimum for the cost  $h$ ); every move of a single queen makes the situation worse.

#### Ridge

- **Ridges:** A ridge is shown in Figure 4.4. Ridges result in a sequence of local maxima that is very difficult for greedy algorithms to navigate.

**Figure 4.4** Illustration of why ridges cause difficulties for hill climbing. The grid of states (dark circles) is superimposed on a ridge rising from left to right, creating a sequence of local maxima that are not directly connected to each other. From each local maximum, all the available actions point downhill. Topologies like this are common in low-dimensional state spaces, such as points in a two-dimensional plane. But in state spaces with hundreds or thousands of dimensions, this intuitive picture does not hold, and there are usually at least a few dimensions that make it possible to escape from ridges and plateaus.

- **Plateaus:** A plateau is a flat area of the state-space landscape. It can be a flat local maximum, from which no uphill exit exists, or a **shoulder**, from which progress is possible. (See Figure 4.1.) A hill-climbing search can get lost wandering on the plateau.

Plateau  
Shoulder

In each case, the algorithm reaches a point at which no progress is being made. Starting from a randomly generated 8-queens state, steepest-ascent hill climbing gets stuck 86% of the time, solving only 14% of problem instances. On the other hand, it works quickly, taking just 4 steps on average when it succeeds and 3 when it gets stuck—not bad for a state space with  $8^8 \approx 17$  million states.

How could we solve more problems? One answer is to keep going when we reach a plateau—to allow a **sideways move** in the hope that the plateau is really a shoulder, as shown in Figure 4.1. But if we are actually on a flat local maximum, then this approach will wander on the plateau forever. Therefore, we can limit the number of consecutive sideways moves, stopping after, say, 100 consecutive sideways moves. This raises the percentage of problem instances solved by hill climbing from 14% to 94%. Success comes at a cost: the algorithm averages roughly 21 steps for each successful instance and 64 for each failure.

Many variants of hill climbing have been invented. **Stochastic hill climbing** chooses at random from among the uphill moves; the probability of selection can vary with the steepness of the uphill move. This usually converges more slowly than steepest ascent, but in some state landscapes, it finds better solutions. **First-choice hill climbing** implements stochastic hill climbing by generating successors randomly until one is generated that is better than the current state. This is a good strategy when a state has many (e.g., thousands) of successors.

Another variant is **random-restart hill climbing**, which adopts the adage, “If at first you don’t succeed, try, try again.” It conducts a series of hill-climbing searches from randomly

Sideways move

Stochastic hill climbing

First-choice hill climbing

Random-restart hill climbing

generated initial states, until a goal is found. It is complete with probability 1, because it will eventually generate a goal state as the initial state. If each hill-climbing search has a probability  $p$  of success, then the expected number of restarts required is  $1/p$ . For 8-queens instances with no sideways moves allowed,  $p \approx 0.14$ , so we need roughly 7 iterations to find a goal (6 failures and 1 success). The expected number of steps is the cost of one successful iteration plus  $(1 - p)/p$  times the cost of failure, or roughly 22 steps in all. When we allow sideways moves,  $1/0.94 \approx 1.06$  iterations are needed on average and  $(1 \times 21) + (0.06/0.94) \times 64 \approx 25$  steps. For 8-queens, then, random-restart hill climbing is very effective indeed. Even for three million queens, the approach can find solutions in seconds.<sup>1</sup>

The success of hill climbing depends very much on the shape of the state-space landscape: if there are few local maxima and plateaus, random-restart hill climbing will find a good solution very quickly. On the other hand, many real problems have a landscape that looks more like a widely scattered family of balding porcupines on a flat floor, with miniature porcupines living on the tip of each porcupine needle. NP-hard problems (see Appendix A) typically have an exponential number of local maxima to get stuck on. Despite this, a reasonably good local maximum can often be found after a small number of restarts.

### 4.1.2 Simulated annealing

A hill-climbing algorithm that never makes “downhill” moves toward states with lower value (or higher cost) is always vulnerable to getting stuck in a local maximum. In contrast, a purely random walk that moves to a successor state without concern for the value will eventually stumble upon the global maximum, but will be extremely inefficient. Therefore, it seems reasonable to try to combine hill climbing with a random walk in a way that yields both efficiency and completeness.

[Simulated annealing](#)

**Simulated annealing** is such an algorithm. In metallurgy, **annealing** is the process used to temper or harden metals and glass by heating them to a high temperature and then gradually cooling them, thus allowing the material to reach a low-energy crystalline state. To explain simulated annealing, we switch our point of view from hill climbing to **gradient descent** (i.e., minimizing cost) and imagine the task of getting a ping-pong ball into the deepest crevice in a very bumpy surface. If we just let the ball roll, it will come to rest at a local minimum. If we shake the surface, we can bounce the ball out of the local minimum—perhaps into a deeper local minimum, where it will spend more time. The trick is to shake just hard enough to bounce the ball out of local minima but not hard enough to dislodge it from the global minimum. The simulated-annealing solution is to start by shaking hard (i.e., at a high temperature) and then gradually reduce the intensity of the shaking (i.e., lower the temperature).

The overall structure of the simulated-annealing algorithm (Figure 4.5) is similar to hill climbing. Instead of picking the *best* move, however, it picks a *random* move. If the move improves the situation, it is always accepted. Otherwise, the algorithm accepts the move with some probability less than 1. The probability decreases exponentially with the “badness” of the move—the amount  $\Delta E$  by which the evaluation is worsened. The probability also decreases as the “temperature”  $T$  goes down: “bad” moves are more likely to be allowed at the start when  $T$  is high, and they become more unlikely as  $T$  decreases. If the *schedule* lowers  $T$  to 0 slowly enough, then a property of the Boltzmann distribution,  $e^{\Delta E/T}$ , is that

---

<sup>1</sup> Luby *et al.* (1993) suggest restarting after a fixed number of steps and show that this can be *much* more efficient than letting each search continue indefinitely.

---

```

function SIMULATED-ANNEALING(problem, schedule) returns a solution state
  current  $\leftarrow$  problem.INITIAL
  for t = 1 to  $\infty$  do
    T  $\leftarrow$  schedule(t)
    if T = 0 then return current
    next  $\leftarrow$  a randomly selected successor of current
     $\Delta E \leftarrow \text{VALUE}(\textit{current}) - \text{VALUE}(\textit{next})$ 
    if  $\Delta E > 0$  then current  $\leftarrow$  next
    else current  $\leftarrow$  next only with probability  $e^{\Delta E/T}$ 

```

**Figure 4.5** The simulated annealing algorithm, a version of stochastic hill climbing where some downhill moves are allowed. The *schedule* input determines the value of the “temperature” *T* as a function of time.

---

all the probability is concentrated on the global maxima, which the algorithm will find with probability approaching 1.

Simulated annealing was used to solve VLSI layout problems beginning in the 1980s. It has been applied widely to factory scheduling and other large-scale optimization tasks.

### 4.1.3 Local beam search

Keeping just one node in memory might seem to be an extreme reaction to the problem of memory limitations. The **local beam search** algorithm keeps track of  $k$  states rather than just one. It begins with  $k$  randomly generated states. At each step, all the successors of all  $k$  states are generated. If any one is a goal, the algorithm halts. Otherwise, it selects the  $k$  best successors from the complete list and repeats.

At first sight, a local beam search with  $k$  states might seem to be nothing more than running  $k$  random restarts in parallel instead of in sequence. In fact, the two algorithms are quite different. In a random-restart search, each search process runs independently of the others. *In a local beam search, useful information is passed among the parallel search threads.* In effect, the states that generate the best successors say to the others, “Come over here, the grass is greener!” The algorithm quickly abandons unfruitful searches and moves its resources to where the most progress is being made.

Local beam search can suffer from a lack of diversity among the  $k$  states—they can become clustered in a small region of the state space, making the search little more than a  $k$ -times-slower version of hill climbing. A variant called **stochastic beam search**, analogous to stochastic hill climbing, helps alleviate this problem. Instead of choosing the top  $k$  successors, stochastic beam search chooses successors with probability proportional to the successor’s value, thus increasing diversity.

Local beam search

Stochastic beam search

### 4.1.4 Evolutionary algorithms

**Evolutionary algorithms** can be seen as variants of stochastic beam search that are explicitly motivated by the metaphor of natural selection in biology: there is a population of individuals (states), in which the fittest (highest value) individuals produce offspring (successor states) that populate the next generation, a process called **recombination**. There are endless forms of evolutionary algorithms, varying in the following ways:

Evolutionary algorithms

Recombination

**Figure 4.6** A genetic algorithm, illustrated for digit strings representing 8-queens states. The initial population in (a) is ranked by a fitness function in (b) resulting in pairs for mating in (c). They produce offspring in (d), which are subject to mutation in (e).

Genetic algorithm

Evolution strategies  
Genetic programming

Selection

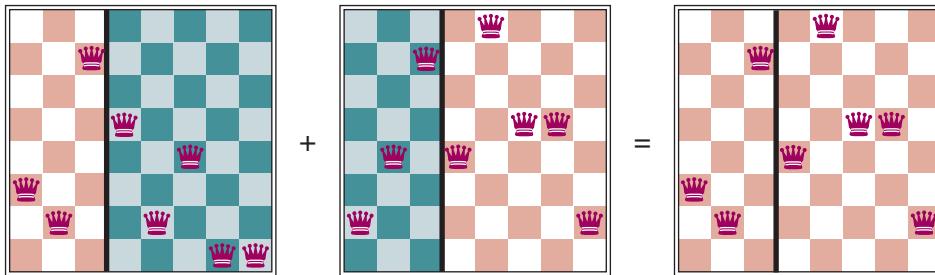

Crossover point

Mutation rate

Elitism

- The size of the population.
- The representation of each individual. In **genetic algorithms**, each individual is a string over a finite alphabet (often a Boolean string), just as DNA is a string over the alphabet ACGT. In **evolution strategies**, an individual is a sequence of real numbers, and in **genetic programming** an individual is a computer program.
- The mixing number,  $\rho$ , which is the number of parents that come together to form offspring. The most common case is  $\rho = 2$ : two parents combine their “genes” (parts of their representation) to form offspring. When  $\rho = 1$  we have stochastic beam search (which can be seen as asexual reproduction). It is possible to have  $\rho > 2$ , which occurs only rarely in nature but is easy enough to simulate on computers.
- The **selection** process for selecting the individuals who will become the parents of the next generation: one possibility is to select from all individuals with probability proportional to their fitness score. Another possibility is to randomly select  $n$  individuals ( $n > \rho$ ), and then select the  $\rho$  most fit ones as parents.
- The recombination procedure. One common approach (assuming  $\rho = 2$ ), is to randomly select a **crossover point** to split each of the parent strings, and recombine the parts to form two children, one with the first part of parent 1 and the second part of parent 2; the other with the second part of parent 1 and the first part of parent 2.
- The **mutation rate**, which determines how often offspring have random mutations to their representation. Once an offspring has been generated, every bit in its composition is flipped with probability equal to the mutation rate.
- The makeup of the next generation. This can be just the newly formed offspring, or it can include a few top-scoring parents from the previous generation (a practice called **elitism**, which guarantees that overall fitness will never decrease over time). The practice of **culling**, in which all individuals below a given threshold are discarded, can lead to a speedup (Baum *et al.*, 1995).

Figure 4.6(a) shows a population of four 8-digit strings, each representing a state of the 8-queens puzzle: the  $c$ -th digit represents the row number of the queen in column  $c$ . In (b), each state is rated by the fitness function. Higher fitness values are better, so for the 8-queens

**Figure 4.7** The 8-queens states corresponding to the first two parents in Figure 4.6(c) and the first offspring in Figure 4.6(d). The green columns are lost in the crossover step and the red columns are retained. (To interpret the numbers in Figure 4.6: row 1 is the bottom row, and 8 is the top row.)

problem we use the number of *nonattacking* pairs of queens, which has a value of  $8 \times 7 / 2 = 28$  for a solution. The values of the four states in (b) are 24, 23, 20, and 11. The fitness scores are then normalized to probabilities, and the resulting values are shown next to the fitness values in (b).

In (c), two pairs of parents are selected, in accordance with the probabilities in (b). Notice that one individual is selected twice and one not at all. For each selected pair, a crossover point (dotted line) is chosen randomly. In (d), we cross over the parent strings at the crossover points, yielding new offspring. For example, the first child of the first pair gets the first three digits (327) from the first parent and the remaining digits (48552) from the second parent. The 8-queens states involved in this recombination step are shown in Figure 4.7.

Finally, in (e), each location in each string is subject to random mutation with a small independent probability. One digit was mutated in the first, third, and fourth offspring. In the 8-queens problem, this corresponds to choosing a queen at random and moving it to a random square in its column. It is often the case that the population is diverse early on in the process, so crossover frequently takes large steps in the state space early in the search process (as in simulated annealing). After many generations of selection towards higher fitness, the population becomes less diverse, and smaller steps are typical. Figure 4.8 describes an algorithm that implements all these steps.

Genetic algorithms are similar to stochastic beam search, but with the addition of the crossover operation. This is advantageous if there are blocks that perform useful functions. For example, it could be that putting the first three queens in positions 2, 4, and 6 (where they do not attack each other) constitutes a useful block that can be combined with other useful blocks that appear in other individuals to construct a solution. It can be shown mathematically that, if the blocks do not serve a purpose—for example if the positions of the genetic code are randomly permuted—then crossover conveys no advantage.

The theory of genetic algorithms explains how this works using the idea of a **schema**, which is a substring in which some of the positions can be left unspecified. For example, the schema 246\*\*\*\*\* describes all 8-queens states in which the first three queens are in positions 2, 4, and 6, respectively. Strings that match the schema (such as 24613578) are called **instances** of the schema. It can be shown that if the average fitness of the instances of a schema is above the mean, then the number of instances of the schema will grow over time.

Schema

Instance

## Evolution and Search

The theory of **evolution** was developed by Charles Darwin in *On the Origin of Species by Means of Natural Selection* (1859) and independently by Alfred Russel Wallace (1858). The central idea is simple: variations occur in reproduction and will be preserved in successive generations approximately in proportion to their effect on reproductive fitness.

Darwin's theory was developed with no knowledge of how the traits of organisms can be inherited and modified. The probabilistic laws governing these processes were first identified by Gregor Mendel (1866), a monk who experimented with sweet peas. Much later, Watson and Crick (1953) identified the structure of the DNA molecule and its alphabet, AGTC (adenine, guanine, thymine, cytosine). In the standard model, variation occurs both by point mutations in the letter sequence and by "crossover" (in which the DNA of an offspring is generated by combining long sections of DNA from each parent).

The analogy to local search algorithms has already been described; the principal difference between stochastic beam search and evolution is the use of *sexual* reproduction, wherein successors are generated from *multiple* individuals rather than just one. The actual mechanisms of evolution are, however, far richer than most genetic algorithms allow. For example, mutations can involve reversals, duplications, and movement of large chunks of DNA; some viruses borrow DNA from one organism and insert it into another; and there are transposable genes that do nothing but copy themselves many thousands of times within the genome.

There are even genes that poison cells from potential mates that do not carry the gene, thereby increasing their own chances of replication. Most important is the fact that the *genes themselves encode the mechanisms* whereby the genome is reproduced and translated into an organism. In genetic algorithms, those mechanisms are a separate program that is not represented within the strings being manipulated.

Darwinian evolution may appear inefficient, having generated blindly some  $10^{43}$  or so organisms without improving its search heuristics one iota. But learning does play a role in evolution. Although the otherwise great French naturalist Jean Lamarck (1809) was wrong to propose that traits acquired by adaptation during an organism's lifetime would be passed on to its offspring, James Baldwin's (1896) superficially similar theory is correct: learning can effectively relax the fitness landscape, leading to an acceleration in the rate of evolution. An organism that has a trait that is not quite adaptive for its environment will pass on the trait if it also has enough plasticity to learn to adapt to the environment in a way that is beneficial. Computer simulations (Hinton and Nowlan, 1987) confirm that this **Baldwin effect** is real, and that a consequence is that things that are hard to learn end up in the genome, but things that are easy to learn need not reside there (Morgan and Griffiths, 2015).

---

Clearly, this effect is unlikely to be significant if adjacent bits are totally unrelated to each other, because then there will be few contiguous blocks that provide a consistent benefit. Genetic algorithms work best when schemas correspond to meaningful components of a solution. For example, if the string is a representation of an antenna, then the schemas may represent components of the antenna, such as reflectors and deflectors. A good component is likely to be good in a variety of different designs. This suggests that successful use of genetic algorithms requires careful engineering of the representation.

In practice, genetic algorithms have their place within the broad landscape of optimization methods (Marler and Arora, 2004), particularly for complex structured problems such as circuit layout or job-shop scheduling, and more recently for evolving the architecture of deep neural networks (Miikkulainen *et al.*, 2019). It is not clear how much of the appeal of genetic algorithms arises from their superiority on specific tasks, and how much from the appealing metaphor of evolution.

## 4.2 Local Search in Continuous Spaces

---

In Chapter 2, we explained the distinction between discrete and continuous environments, pointing out that most real-world environments are continuous. A continuous action space has an infinite branching factor, and thus can't be handled by most of the algorithms we have covered so far (with the exception of first-choice hill climbing and simulated annealing).

This section provides a *very brief* introduction to some local search techniques for continuous spaces. The literature on this topic is vast; many of the basic techniques originated

in the 17th century, after the development of calculus by Newton and Leibniz.<sup>2</sup> We find uses for these techniques in several places in this book, including the chapters on learning, vision, and robotics.

We begin with an example. Suppose we want to place three new airports anywhere in Romania, such that the sum of squared straight-line distances from each city on the map to its nearest airport is minimized. (See Figure 3.1 for the map of Romania.) The state space is then defined by the coordinates of the three airports:  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$ . This is a *six-dimensional* space; we also say that states are defined by six **variables**. In general, states are defined by an  $n$ -dimensional vector of variables,  $\mathbf{x}$ . Moving around in this space corresponds to moving one or more of the airports on the map. The objective function  $f(\mathbf{x}) = f(x_1, y_1, x_2, y_2, x_3, y_3)$  is relatively easy to compute for any particular state once we compute the closest cities. Let  $C_i$  be the set of cities whose closest airport (in the state  $\mathbf{x}$ ) is airport  $i$ . Then, we have

$$f(\mathbf{x}) = f(x_1, y_1, x_2, y_2, x_3, y_3) = \sum_{i=1}^3 \sum_{c \in C_i} (x_i - x_c)^2 + (y_i - y_c)^2. \quad (4.1)$$

This equation is correct not only for the state  $\mathbf{x}$  but also for states in the local neighborhood of  $\mathbf{x}$ . However, it is not correct globally; if we stray too far from  $x$  (by altering the location of one or more of the airports by a large amount) then the set of closest cities for that airport changes, and we need to recompute  $C_i$ .

#### Discretization

One way to deal with a continuous state space is to **discretize** it. For example, instead of allowing the  $(x_i, y_i)$  locations to be any point in continuous two-dimensional space, we could limit them to fixed points on a rectangular grid with spacing of size  $\delta$  (delta). Then instead of having an infinite number of successors, each state in the space would have only 12 successors, corresponding to incrementing one of the 6 variables by  $\pm\delta$ . We can then apply any of our local search algorithms to this discrete space. Alternatively, we could make the branching factor finite by sampling successor states randomly, moving in a random direction by a small amount,  $\delta$ . Methods that measure progress by the change in the value of the objective function between two nearby points are called **empirical gradient** methods. Empirical gradient search is the same as steepest-ascent hill climbing in a discretized version of the state space. Reducing the value of  $\delta$  over time can give a more accurate solution, but does not necessarily converge to a global optimum in the limit.

#### Empirical gradient

#### Gradient

Often we have an objective function expressed in a mathematical form such that we can use calculus to solve the problem analytically rather than empirically. Many methods attempt to use the **gradient** of the landscape to find a maximum. The gradient of the objective function is a vector  $\nabla f$  that gives the magnitude and direction of the steepest slope. For our problem, we have

$$\nabla f = \left( \frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial y_1}, \frac{\partial f}{\partial x_2}, \frac{\partial f}{\partial y_2}, \frac{\partial f}{\partial x_3}, \frac{\partial f}{\partial y_3} \right).$$

In some cases, we can find a maximum by solving the equation  $\nabla f = 0$ . (This could be done, for example, if we were placing just one airport; the solution is the arithmetic mean of all the cities' coordinates.) In many cases, however, this equation cannot be solved in closed form. For example, with three airports, the expression for the gradient depends on what cities are

<sup>2</sup> Knowledge of vectors, matrices, and derivatives is useful for this section (see Appendix A).

closest to each airport in the current state. This means we can compute the gradient *locally* (but not *globally*); for example,

$$\frac{\partial f}{\partial x_1} = 2 \sum_{c \in C_1} (x_1 - x_c). \quad (4.2)$$

Given a locally correct expression for the gradient, we can perform steepest-ascent hill climbing by updating the current state according to the formula

$$\mathbf{x} \leftarrow \mathbf{x} + \alpha \nabla f(\mathbf{x}),$$

where  $\alpha$  (alpha) is a small constant often called the **step size**. There exist a huge variety of methods for adjusting  $\alpha$ . The basic problem is that if  $\alpha$  is too small, too many steps are needed; if  $\alpha$  is too large, the search could overshoot the maximum. The technique of **line search** tries to overcome this dilemma by extending the current gradient direction—usually by repeatedly doubling  $\alpha$ —until  $f$  starts to decrease again. The point at which this occurs becomes the new current state. There are several schools of thought about how the new direction should be chosen at this point.

For many problems, the most effective algorithm is the venerable **Newton–Raphson** method. This is a general technique for finding roots of functions—that is, solving equations of the form  $g(x)=0$ . It works by computing a new estimate for the root  $x$  according to Newton’s formula

$$x \leftarrow x - g(x)/g'(x).$$

To find a maximum or minimum of  $f$ , we need to find  $\mathbf{x}$  such that the *gradient* is a zero vector (i.e.,  $\nabla f(\mathbf{x})=\mathbf{0}$ ). Thus,  $g(x)$  in Newton’s formula becomes  $\nabla f(\mathbf{x})$ , and the update equation can be written in matrix–vector form as

$$\mathbf{x} \leftarrow \mathbf{x} - \mathbf{H}_f^{-1}(\mathbf{x}) \nabla f(\mathbf{x}),$$

where  $\mathbf{H}_f(\mathbf{x})$  is the **Hessian** matrix of second derivatives, whose elements  $H_{ij}$  are given by  $\partial^2 f / \partial x_i \partial x_j$ . For our airport example, we can see from Equation (4.2) that  $\mathbf{H}_f(\mathbf{x})$  is particularly simple: the off-diagonal elements are zero and the diagonal elements for airport  $i$  are just twice the number of cities in  $C_i$ . A moment’s calculation shows that one step of the update moves airport  $i$  directly to the centroid of  $C_i$ , which is the minimum of the local expression for  $f$  from Equation (4.1).<sup>3</sup> For high-dimensional problems, however, computing the  $n^2$  entries of the Hessian and inverting it may be expensive, so many approximate versions of the Newton–Raphson method have been developed.

Local search methods suffer from local maxima, ridges, and plateaus in continuous state spaces just as much as in discrete spaces. Random restarts and simulated annealing are often helpful. High-dimensional continuous spaces are, however, big places in which it is very easy to get lost.

A final topic is **constrained optimization**. An optimization problem is constrained if solutions must satisfy some hard constraints on the values of the variables. For example, in our airport-siting problem, we might constrain sites to be inside Romania and on dry land (rather than in the middle of lakes). The difficulty of constrained optimization problems depends on the nature of the constraints and the objective function. The best-known category is that of **linear programming** problems, in which constraints must be linear inequalities

<sup>3</sup> In general, the Newton–Raphson update can be seen as fitting a quadratic surface to  $f$  at  $\mathbf{x}$  and then moving directly to the minimum of that surface—which is also the minimum of  $f$  if  $f$  is quadratic.

forming a **convex set**<sup>4</sup> and the objective function is also linear. The time complexity of linear programming is polynomial in the number of variables.

Linear programming is probably the most widely studied and broadly useful method for optimization. It is a special case of the more general problem of **convex optimization**, which allows the constraint region to be any convex region and the objective to be any function that is convex within the constraint region. Under certain conditions, convex optimization problems are also polynomially solvable and may be feasible in practice with thousands of variables. Several important problems in machine learning and control theory can be formulated as convex optimization problems (see Chapter 21).

## 4.3 Search with Nondeterministic Actions

In Chapter 3, we assumed a fully observable, deterministic, known environment. Therefore, an agent can observe the initial state, calculate a sequence of actions that reach the goal, and execute the actions with its “eyes closed,” never having to use its percepts.

When the environment is partially observable, however, the agent doesn’t know for sure what state it is in; and when the environment is nondeterministic, the agent doesn’t know what state it transitions to after taking an action. That means that rather than thinking “I’m in state  $s_1$  and if I do action  $a$  I’ll end up in state  $s_2$ ,” an agent will now be thinking “I’m either in state  $s_1$  or  $s_3$ , and if I do action  $a$  I’ll end up in state  $s_2, s_4$  or  $s_5$ .” We call a set of physical states that the agent believes are possible a **belief state**.

In partially observable and nondeterministic environments, the solution to a problem is no longer a sequence, but rather a **conditional plan** (sometimes called a contingency plan or a strategy) that specifies what to do depending on what percepts agent receives while executing the plan. We examine nondeterminism in this section and partial observability in the next.

### 4.3.1 The erratic vacuum world

The vacuum world from Chapter 2 has eight states, as shown in Figure 4.9. There are three actions—*Right*, *Left*, and *Suck*—and the goal is to clean up all the dirt (states 7 and 8). If the environment is fully observable, deterministic, and completely known, then the problem is easy to solve with any of the algorithms in Chapter 3, and the solution is an action sequence. For example, if the initial state is 1, then the action sequence [*Suck*, *Right*, *Suck*] will reach a goal state, 8.

Now suppose that we introduce nondeterminism in the form of a powerful but erratic vacuum cleaner. In the **erratic vacuum world**, the *Suck* action works as follows:

- When applied to a dirty square the action cleans the square and sometimes cleans up dirt in an adjacent square, too.
- When applied to a clean square the action sometimes deposits dirt on the carpet.<sup>5</sup>

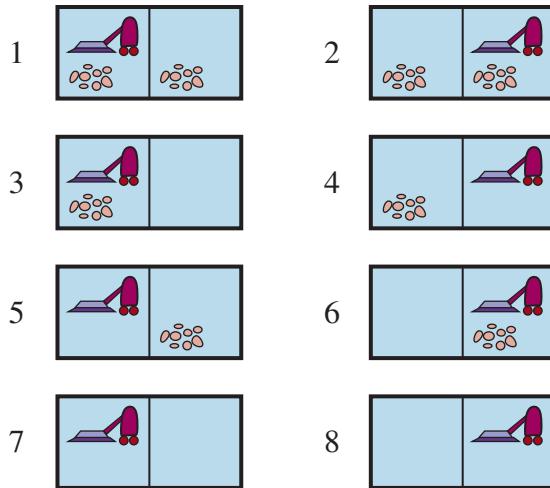

To provide a precise formulation of this problem, we need to generalize the notion of a **transition model** from Chapter 3. Instead of defining the transition model by a **RESULT** function

<sup>4</sup> A set of points  $\mathcal{S}$  is convex if the line joining any two points in  $\mathcal{S}$  is also contained in  $\mathcal{S}$ . A **convex function** is one for which the space “above” it forms a convex set; by definition, convex functions have no local (as opposed to global) minima.

<sup>5</sup> We assume that most readers face similar problems and can sympathize with our agent. We apologize to owners of modern, efficient cleaning appliances who cannot take advantage of this pedagogical device.

Belief state

Conditional plan

**Figure 4.9** The eight possible states of the vacuum world; states 7 and 8 are goal states.

that returns a single outcome state, we use a `RESULTS` function that returns a set of possible outcome states. For example, in the erratic vacuum world, the *Suck* action in state 1 cleans up either just the current location, or both locations:

$$\text{RESULTS}(1, \text{Suck}) = \{5, 7\}$$

If we start in state 1, no single *sequence* of actions solves the problem, but the following **conditional plan** does:

$$[\text{Suck}, \text{if } \text{State} = 5 \text{ then } [\text{Right}, \text{Suck}] \text{ else } []]. \quad (4.3)$$

Here we see that a conditional plan can contain **if–then–else** steps; this means that solutions are *trees* rather than sequences. Here the conditional in the **if** statement tests to see what the current state is; this is something the agent will be able to observe at runtime, but doesn't know at planning time. Alternatively, we could have had a formulation that tests the percept rather than the state. Many problems in the real, physical world are contingency problems, because exact prediction of the future is impossible. For this reason, many people keep their eyes open while walking around.

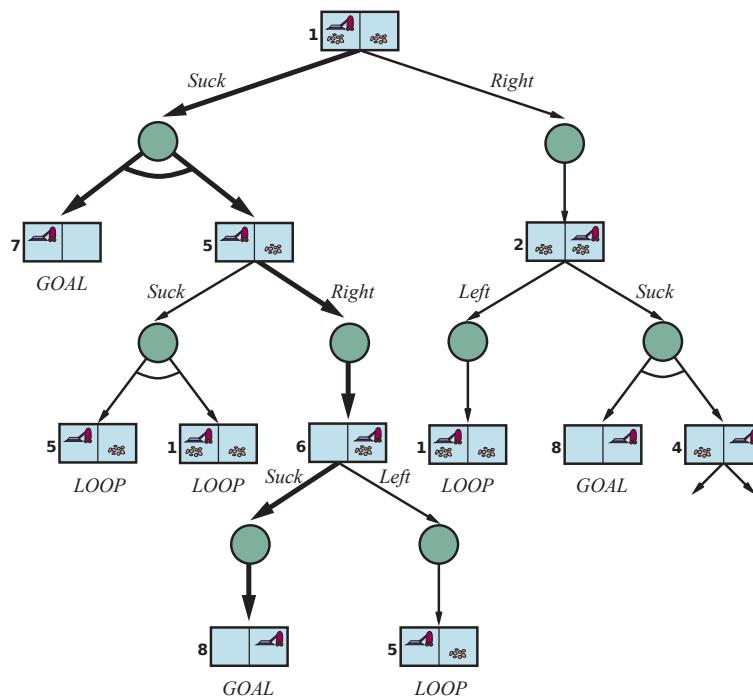

### 4.3.2 AND–OR search trees

How do we find these contingent solutions to nondeterministic problems? As in Chapter 3, we begin by constructing search trees, but here the trees have a different character. In a deterministic environment, the only branching is introduced by the agent's own choices in each state: I can do this action or that action. We call these nodes **OR nodes**. In the vacuum world, for example, at an OR node the agent chooses *Left* or *Right* or *Suck*. In a nondeterministic environment, branching is also introduced by the *environment's* choice of outcome for each action. We call these nodes **AND nodes**. For example, the *Suck* action in state 1 results in the belief state  $\{5, 7\}$ , so the agent would need to find a plan for state 5 *and* for state 7. These two kinds of nodes alternate, leading to an **AND–OR tree** as illustrated in Figure 4.10.

Or node

And node

And-or tree

**Figure 4.10** The first two levels of the search tree for the erratic vacuum world. State nodes are OR nodes where some action must be chosen. At the AND nodes, shown as circles, every outcome must be handled, as indicated by the arc linking the outgoing branches. The solution found is shown in bold lines.

A solution for an AND–OR search problem is a subtree of the complete search tree that (1) has a goal node at every leaf, (2) specifies one action at each of its OR nodes, and (3) includes every outcome branch at each of its AND nodes. The solution is shown in bold lines in the figure; it corresponds to the plan given in Equation (4.3).

Figure 4.11 gives a recursive, depth-first algorithm for AND–OR graph search. One key aspect of the algorithm is the way in which it deals with cycles, which often arise in nondeterministic problems (e.g., if an action sometimes has no effect or if an unintended effect can be corrected). If the current state is identical to a state on the path from the root, then it returns with failure. This doesn't mean that there is *no* solution from the current state; it simply means that if there *is* a noncyclic solution, it must be reachable from the earlier incarnation of the current state, so the new incarnation can be discarded. With this check, we ensure that the algorithm terminates in every finite state space, because every path must reach a goal, a dead end, or a repeated state. Notice that the algorithm does not check whether the current state is a repetition of a state on some *other* path from the root, which is important for efficiency.

AND–OR graphs can be explored either breadth-first or best-first. The concept of a heuristic function must be modified to estimate the cost of a contingent solution rather than a sequence, but the notion of admissibility carries over and there is an analog of the A\* algorithm for finding optimal solutions. (See the bibliographical notes at the end of the chapter.)

---

```

function AND-OR-SEARCH(problem) returns a conditional plan, or failure
  return OR-SEARCH(problem, problem.INITIAL, [])

function OR-SEARCH(problem, state, path) returns a conditional plan, or failure
  if problem.IS-GOAL(state) then return the empty plan
  if IS-CYCLE(state, path) then return failure
  for each action in problem.ACTIONS(state) do
    plan  $\leftarrow$  AND-SEARCH(problem, RESULTS(state, action), [state] + [path])
    if plan  $\neq$  failure then return [action] + [plan]
  return failure

function AND-SEARCH(problem, states, path) returns a conditional plan, or failure
  for each si in states do
    plani  $\leftarrow$  OR-SEARCH(problem, si, path)
    if plani = failure then return failure
  return [if s1 then plan1 else if s2 then plan2 else ... if sn-1 then plann-1 else plann]

```

---

### 4.3.3 Try, try again

Consider a *slippery* vacuum world, which is identical to the ordinary (non-erratic) vacuum world except that movement actions sometimes fail, leaving the agent in the same location. For example, moving *Right* in state 1 leads to the belief state {1,2}. Figure 4.12 shows part of the search graph; clearly, there are no longer any acyclic solutions from state 1, and AND-OR-SEARCH would return with failure. There is, however, a **cyclic solution**, which is to keep trying *Right* until it works. We can express this with a new **while** construct:

[*Suck*, **while** *State*=5 **do** *Right*, *Suck*]

or by adding a **label** to denote some portion of the plan and referring to that label later:

[*Suck*, *L<sub>1</sub>* : *Right*, **if** *State*=5 **then** *L<sub>1</sub>* **else** *Suck*].

When is a cyclic plan a solution? A minimum condition is that every leaf is a goal state and that a leaf is reachable from every point in the plan. In addition to that, we need to consider the cause of the nondeterminism. If it is really the case that the vacuum robot’s drive mechanism works some of the time, but randomly and independently slips on other occasions, then the agent can be confident that if the action is repeated enough times, eventually it will work and the plan will succeed. But if the nondeterminism is due to some unobserved fact about the robot or environment—perhaps a drive belt has snapped and the robot will never move—then repeating the action will not help.

One way to understand this decision is to say that the initial problem formulation (fully observable, nondeterministic) is abandoned in favor of a different formulation (partially observable, deterministic) where the failure of the cyclic plan is attributed to an unobserved property of the drive belt. In Chapter 12 we discuss how to decide which of several uncertain possibilities is more likely.

Cyclic solution

**Figure 4.12** Part of the search graph for a slippery vacuum world, where we have shown (some) cycles explicitly. All solutions for this problem are cyclic plans because there is no way to move reliably.

## 4.4 Search in Partially Observable Environments

We now turn to the problem of partial observability, where the agent's percepts are not enough to pin down the exact state. That means that some of the agent's actions will be aimed at reducing uncertainty about the current state.

### 4.4.1 Searching with no observation

Sensorless  
Conformant

When the agent's percepts provide *no information at all*, we have what is called a **sensorless** problem (or a **conformant** problem). At first, you might think the sensorless agent has no hope of solving a problem if it has no idea what state it starts in, but sensorless solutions are surprisingly common and useful, primarily because they *don't* rely on sensors working properly. In manufacturing systems, for example, many ingenious methods have been developed for orienting parts correctly from an unknown initial position by using a sequence of actions with no sensing at all. Sometimes a sensorless plan is better even when a conditional plan with sensing is available. For example, doctors often prescribe a broad-spectrum antibiotic rather than using the conditional plan of doing a blood test, then waiting for the results to come back, and then prescribing a more specific antibiotic. The sensorless plan saves time and money, and avoids the risk of the infection worsening before the test results are available.

Consider a sensorless version of the (deterministic) vacuum world. Assume that the agent knows the geography of its world, but not its own location or the distribution of dirt. In that case, its initial belief state is  $\{1, 2, 3, 4, 5, 6, 7, 8\}$  (see Figure 4.9). Now, if the agent moves *Right* it will be in one of the states  $\{2, 4, 6, 8\}$ —the agent has gained information without perceiving anything! After  $[Right, Suck]$  the agent will always end up in one of the states  $\{4, 8\}$ . Finally, after  $[Right, Suck, Left, Suck]$  the agent is guaranteed to reach the goal state 7, no matter what the start state. We say that the agent can **coerce** the world into state 7.

Coercion

The solution to a sensorless problem is a sequence of actions, not a conditional plan (because there is no perceiving). But we search in the space of belief states rather than physical states.<sup>6</sup> In belief-state space, the problem is *fully observable* because the agent always knows its own belief state. Furthermore, the solution (if any) for a sensorless problem is always a sequence of actions. This is because, as in the ordinary problems of Chapter 3, the percepts received after each action are completely predictable—they’re always empty! So there are no contingencies to plan for. This is true *even if the environment is nondeterministic*.

We could introduce new algorithms for sensorless search problems. But instead, we can use the existing algorithms from Chapter 3 if we transform the underlying physical problem into a belief-state problem, in which we search over belief states rather than physical states. The original problem,  $P$ , has components  $\text{Actions}_P, \text{Result}_P$  etc., and the belief-state problem has the following components:

- **States:** The belief-state space contains every possible subset of the physical states. If  $P$  has  $N$  states, then the belief-state problem has  $2^N$  belief states, although many of those may be unreachable from the initial state.
- **Initial state:** Typically the belief state consisting of all states in  $P$ , although in some cases the agent will have more knowledge than this.
- **Actions:** This is slightly tricky. Suppose the agent is in belief state  $b = \{s_1, s_2\}$ , but  $\text{ACTIONS}_P(s_1) \neq \text{ACTIONS}_P(s_2)$ ; then the agent is unsure of which actions are legal. If we assume that illegal actions have no effect on the environment, then it is safe to take the *union* of all the actions in any of the physical states in the current belief state  $b$ :

$$\text{ACTIONS}(b) = \bigcup_{s \in b} \text{ACTIONS}_P(s).$$

On the other hand, if an illegal action might lead to catastrophe, it is safer to allow only the *intersection*, that is, the set of actions legal in *all* the states. For the vacuum world, every state has the same legal actions, so both methods give the same result.

- **Transition model:** For deterministic actions, the new belief state has one result state for each of the current possible states (although some result states may be the same):

$$b' = \text{RESULT}(b, a) = \{s' : s' = \text{RESULT}_P(s, a) \text{ and } s \in b\}. \quad (4.4)$$

With nondeterminism, the new belief state consists of all the possible results of applying the action to any of the states in the current belief state:

$$\begin{aligned} b' = \text{RESULT}(b, a) &= \{s' : s' \in \text{RESULT}_P(s, a) \text{ and } s \in b\} \\ &= \bigcup_{s \in b} \text{RESULT}_P(s, a), \end{aligned}$$

The size of  $b'$  will be the same or smaller than  $b$  for deterministic actions, but may be larger than  $b$  with nondeterministic actions (see Figure 4.13).

- **Goal test:** The agent *possibly* achieves the goal if *any* state  $s$  in the belief state satisfies the goal test of the underlying problem,  $\text{IS-GOAL}_P(s)$ . The agent *necessarily* achieves the goal if *every* state satisfies  $\text{IS-GOAL}_P(s)$ . We aim to necessarily achieve the goal.
- **Action cost:** This is also tricky. If the same action can have different costs in different states, then the cost of taking an action in a given belief state could be one of

---

<sup>6</sup> In a fully observable environment, each belief state contains one physical state. Thus, we can view the algorithms in Chapter 3 as searching in a belief-state space of singleton belief states.

**Figure 4.13** (a) Predicting the next belief state for the sensorless vacuum world with the deterministic action, *Right*. (b) Prediction for the same belief state and action in the slippery version of the sensorless vacuum world.

several values. (This gives rise to a new class of problems, which we explore in Exercise 4.MVAL.) For now we assume that the cost of an action is the same in all states and so can be transferred directly from the underlying physical problem.

Figure 4.14 shows the reachable belief-state space for the deterministic, sensorless vacuum world. There are only 12 reachable belief states out of  $2^8 = 256$  possible belief states.

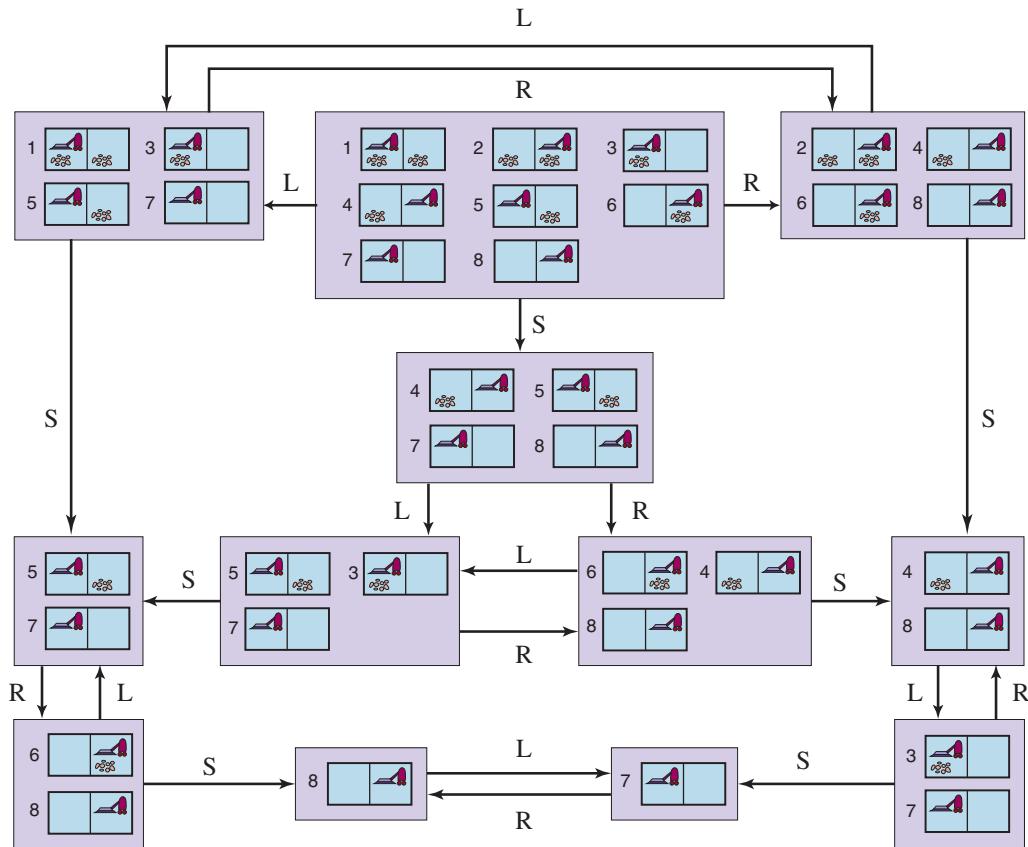

The preceding definitions enable the automatic construction of the belief-state problem formulation from the definition of the underlying physical problem. Once this is done, we can solve sensorless problems with any of the ordinary search algorithms of Chapter 3.

In ordinary graph search, newly reached states are tested to see if they were previously reached. This works for belief states, too; for example, in Figure 4.14, the action sequence *[Suck,Left,Suck]* starting at the initial state reaches the same belief state as *[Right,Left,Suck]*, namely, {5, 7}. Now, consider the belief state reached by *[Left]*, namely, {1, 3, 5, 7}. Obviously, this is not identical to {5, 7}, but it is a *superset*. We can discard (prune) any such superset belief state. Why? Because a solution from {1, 3, 5, 7} must be a solution for each of the individual states 1, 3, 5, and 7, and thus it is a solution for any combination of these individual states, such as {5, 7}; therefore we don't need to try to solve {1, 3, 5, 7}, we can concentrate on trying to solve the strictly easier belief state {5, 7}.

Conversely, if {1, 3, 5, 7} has already been generated and found to be solvable, then any *subset*, such as {5, 7}, is guaranteed to be solvable. (If I have a solution that works when I'm very confused about what state I'm in, it will still work when I'm less confused.) This extra level of pruning may dramatically improve the efficiency of sensorless problem solving.

Even with this improvement, however, sensorless problem-solving as we have described it is seldom feasible in practice. One issue is the vastness of the belief-state space—we saw in the previous chapter that often a search space of size  $N$  is too large, and now we have search spaces of size  $2^N$ . Furthermore, each element of the search space is a set of up to  $N$  elements. For large  $N$ , we won't be able to represent even a single belief state without running out of memory space.

One solution is to represent the belief state by some more compact description. In English, we could say the agent knows “Nothing” in the initial state; after moving *Left*, we could

**Figure 4.14** The reachable portion of the belief-state space for the deterministic, sensorless vacuum world. Each rectangular box corresponds to a single belief state. At any given point, the agent has a belief state but does not know which physical state it is in. The initial belief state (complete ignorance) is the top center box.

say, “Not in the rightmost column,” and so on. Chapter 7 explains how to do this in a formal representation scheme.

Another approach is to avoid the standard search algorithms, which treat belief states as black boxes just like any other problem state. Instead, we can look *inside* the belief states and develop **incremental belief-state search** algorithms that build up the solution one physical state at a time. For example, in the sensorless vacuum world, the initial belief state is  $\{1, 2, 3, 4, 5, 6, 7, 8\}$ , and we have to find an action sequence that works in all 8 states. We can do this by first finding a solution that works for state 1; then we check if it works for state 2; if not, go back and find a different solution for state 1, and so on.

Just as an AND–OR search has to find a solution for every branch at an AND node, this algorithm has to find a solution for every state in the belief state; the difference is that AND–OR search can find a different solution for each branch, whereas an incremental belief-state search has to find *one* solution that works for *all* the states.

The main advantage of the incremental approach is that it is typically able to detect failure quickly—when a belief state is unsolvable, it is usually the case that a small subset of the

Incremental  
belief-state search

belief state, consisting of the first few states examined, is also unsolvable. In some cases, this leads to a speedup proportional to the size of the belief states, which may themselves be as large as the physical state space itself.

#### 4.4.2 Searching in partially observable environments

Many problems cannot be solved without sensing. For example, the sensorless 8-puzzle is impossible. On the other hand, a little bit of sensing can go a long way: we can solve 8-puzzles if we can see just the upper-left corner square. The solution involves moving each tile in turn into the observable square and keeping track of its location from then on.

For a partially observable problem, the problem specification will specify a  $\text{PERCEPT}(s)$  function that returns the percept received by the agent in a given state. If sensing is nondeterministic, then we can use a  $\text{PERCEPTS}$  function that returns a set of possible percepts. For fully observable problems,  $\text{PERCEPT}(s) = s$  for every state  $s$ , and for sensorless problems  $\text{PERCEPT}(s) = \text{null}$ .

Consider a local-sensing vacuum world, in which the agent has a position sensor that yields the percept  $L$  in the left square, and  $R$  in the right square, and a dirt sensor that yields *Dirty* when the current square is dirty and *Clean* when it is clean. Thus, the  $\text{PERCEPT}$  in state 1 is  $[L, \text{Dirty}]$ . With partial observability, it will usually be the case that several states produce the same percept; state 3 will also produce  $[L, \text{Dirty}]$ . Hence, given this initial percept, the initial belief state will be  $\{1, 3\}$ . We can think of the transition model between belief states for partially observable problems as occurring in three stages, as shown in Figure 4.15:

- The **prediction** stage computes the belief state resulting from the action,  $\text{RESULT}(b, a)$ , exactly as we did with sensorless problems. To emphasize that this is a prediction, we use the notation  $\hat{b} = \text{RESULT}(b, a)$ , where the “hat” over the  $b$  means “estimated,” and we also use  $\text{PREDICT}(b, a)$  as a synonym for  $\text{RESULT}(b, a)$ .
- The **possible percepts** stage computes the set of percepts that could be observed in the predicted belief state (using the letter  $o$  for observation):

$$\text{POSSIBLE-PERCEPTS}(\hat{b}) = \{o : o = \text{PERCEPT}(s) \text{ and } s \in \hat{b}\}.$$

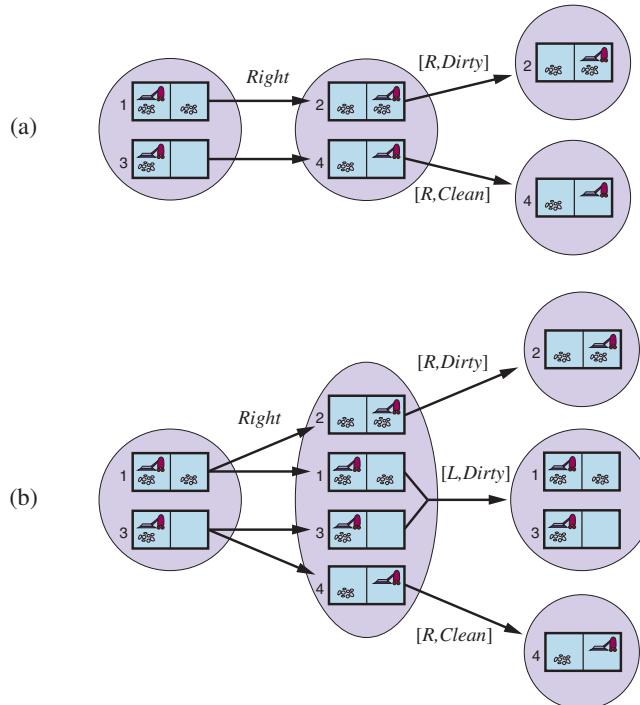

- The **update** stage computes, for each possible percept, the belief state that would result from the percept. The updated belief state  $b_o$  is the set of states in  $\hat{b}$  that could have produced the percept:

$$b_o = \text{UPDATE}(\hat{b}, o) = \{s : o = \text{PERCEPT}(s) \text{ and } s \in \hat{b}\}.$$

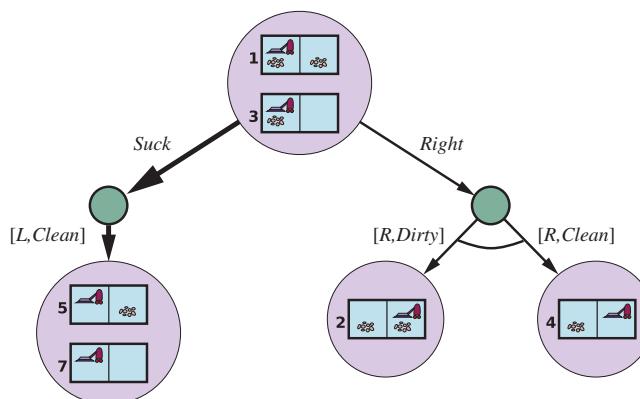

The agent needs to deal with *possible* percepts at planning time, because it won’t know the *actual* percepts until it executes the plan. Notice that nondeterminism in the physical environment can enlarge the belief state in the prediction stage, but each updated belief state  $b_o$  can be no larger than the predicted belief state  $\hat{b}$ ; observations can only help reduce uncertainty. Moreover, for deterministic sensing, the belief states for the different possible percepts will be disjoint, forming a *partition* of the original predicted belief state.

Putting these three stages together, we obtain the possible belief states resulting from a given action and the subsequent possible percepts:

$$\begin{aligned} \text{RESULTS}(b, a) = \{b_o : b_o &= \text{UPDATE}(\text{PREDICT}(b, a), o) \text{ and} \\ o &\in \text{POSSIBLE-PERCEPTS}(\text{PREDICT}(b, a))\}. \end{aligned} \quad (4.5)$$

**Figure 4.15** Two examples of transitions in local-sensing vacuum worlds. (a) In the deterministic world, *Right* is applied in the initial belief state, resulting in a new predicted belief state with two possible physical states; for those states, the possible percepts are  $[R, \text{Dirty}]$  and  $[R, \text{Clean}]$ , leading to two belief states, each of which is a singleton. (b) In the slippery world, *Right* is applied in the initial belief state, giving a new belief state with four physical states; for those states, the possible percepts are  $[L, \text{Dirty}]$ ,  $[R, \text{Dirty}]$ , and  $[R, \text{Clean}]$ , leading to three belief states as shown.

**Figure 4.16** The first level of the AND-OR search tree for a problem in the local-sensing vacuum world; *Suck* is the first action in the solution.

### 4.4.3 Solving partially observable problems

The preceding section showed how to derive the RESULTS function for a nondeterministic belief-state problem from an underlying physical problem, given the PERCEPT function. With this formulation, the AND–OR search algorithm of Figure 4.11 can be applied directly to derive a solution. Figure 4.16 shows part of the search tree for the local-sensing vacuum world, assuming an initial percept  $[L, \text{Dirty}]$ . The solution is the conditional plan

$$[\text{Suck}, \text{Right}, \mathbf{if} \ R\text{state} = \{6\} \ \mathbf{then} \ \text{Suck} \ \mathbf{else} \ []].$$

Notice that, because we supplied a belief-state problem to the AND–OR search algorithm, it returned a conditional plan that tests the belief state rather than the actual state. This is as it should be: in a partially observable environment the agent won’t know the actual state.

As in the case of standard search algorithms applied to sensorless problems, the AND–OR search algorithm treats belief states as black boxes, just like any other states. One can improve on this by checking for previously generated belief states that are subsets or supersets of the current state, just as for sensorless problems. One can also derive incremental search algorithms, analogous to those described for sensorless problems, that provide substantial speedups over the black-box approach.

### 4.4.4 An agent for partially observable environments

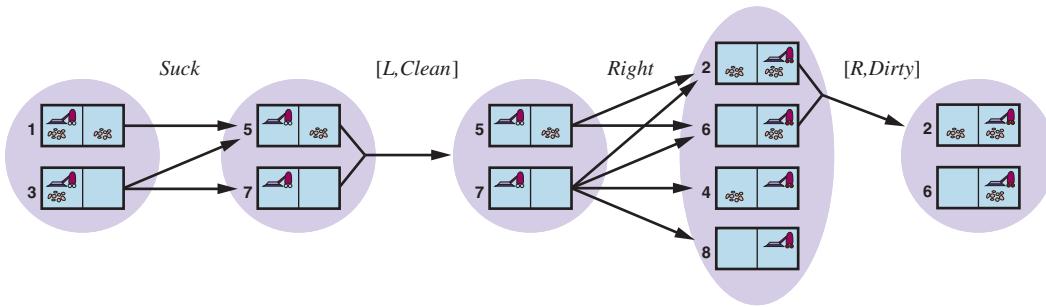

An agent for partially observable environments formulates a problem, calls a search algorithm (such as AND-OR-SEARCH) to solve it, and executes the solution. There are two main differences between this agent and the one for fully observable deterministic environments. First, the solution will be a conditional plan rather than a sequence; to execute an if–then–else expression, the agent will need to test the condition and execute the appropriate branch of the conditional. Second, the agent will need to maintain its belief state as it performs actions and receives percepts. This process resembles the prediction–observation–update process in Equation (4.5) but is actually simpler because the percept is given by the environment rather than calculated by the agent. Given an initial belief state  $b$ , an action  $a$ , and a percept  $o$ , the new belief state is:

$$b' = \text{UPDATE}(\text{PREDICT}(b, a), o). \quad (4.6)$$

Consider a *kindergarten* vacuum world wherein agents sense only the state of their current square, and any square may become dirty at any time unless the agent is actively cleaning it at that moment.<sup>7</sup> Figure 4.17 shows the belief state being maintained in this environment.

In partially observable environments—which include the vast majority of real-world environments—maintaining one’s belief state is a core function of any intelligent system. This function goes under various names, including **monitoring**, **filtering**, and **state estimation**. Equation (4.6) is called a recursive state estimator because it computes the new belief state from the previous one rather than by examining the entire percept sequence. If the agent is not to “fall behind,” the computation has to happen as fast as percepts are coming in. As the environment becomes more complex, the agent will only have time to compute an approximate belief state, perhaps focusing on the implications of the percept for the aspects of the environment that are of current interest. Most work on this problem has been done for

<sup>7</sup> The usual apologies to those who are unfamiliar with the effect of small children on the environment.

**Figure 4.17** Two prediction–update cycles of belief-state maintenance in the kindergarten vacuum world with local sensing.

stochastic, continuous-state environments with the tools of probability theory, as explained in Chapter 14.

In this section we will show an example in a discrete environment with deterministic sensors and nondeterministic actions. The example concerns a robot with a particular state estimation task called **localization**: working out where it is, given a map of the world and a sequence of percepts and actions. Our robot is placed in the maze-like environment of Figure 4.18. The robot is equipped with four sonar sensors that tell whether there is an obstacle—the outer wall or a dark shaded square in the figure—in each of the four compass directions. The percept is in the form of a bit vector, one bit for each of the directions north, east, south, and west in that order, so 1011 means there are obstacles to the north, south, and west, but not east.

We assume that the sensors give perfectly correct data, and that the robot has a correct map of the environment. But unfortunately, the robot’s navigational system is broken, so when it executes a *Right* action, it moves randomly to one of the adjacent squares. The robot’s task is to determine its current location.

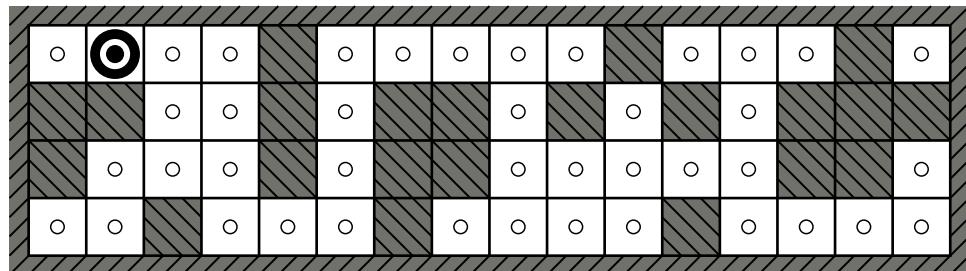

Suppose the robot has just been switched on, and it does not know where it is—its initial belief state  $b$  consists of the set of all locations. The robot then receives the percept 1011 and does an update using the equation  $b_o = \text{UPDATE}(1011)$ , yielding the 4 locations shown in Figure 4.18(a). You can inspect the maze to see that those are the only four locations that yield the percept 1011.

Next the robot executes a *Right* action, but the result is nondeterministic. The new belief state,  $b_a = \text{PREDICT}(b_o, \text{Right})$ , contains all the locations that are one step away from the locations in  $b_o$ . When the second percept, 1010, arrives, the robot does  $\text{UPDATE}(b_a, 1010)$  and finds that the belief state has collapsed down to the single location shown in Figure 4.18(b). That’s the only location that could be the result of

$$\text{UPDATE}(\text{PREDICT}(\text{UPDATE}(b, 1011), \text{Right}), 1010).$$

With nondeterministic actions the PREDICT step grows the belief state, but the UPDATE step shrinks it back down—as long as the percepts provide some useful identifying information. Sometimes the percepts don’t help much for localization: If there were one or more long east-west corridors, then a robot could receive a long sequence of 1010 percepts, but never know

Localization

(a) Possible locations of robot after  $E_1 = 1011$ (b) Possible locations of robot after  $E_1 = 1011, E_2 = 1010$ 

**Figure 4.18** Possible positions of the robot,  $\odot$ , (a) after one observation,  $E_1 = 1011$ , and (b) after moving one square and making a second observation,  $E_2 = 1010$ . When sensors are noiseless and the transition model is accurate, there is only one possible location for the robot consistent with this sequence of two observations.

where in the corridor(s) it was. But for environments with reasonable variation in geography, localization often converges quickly to a single point, even when actions are nondeterministic.

What happens if the sensors are faulty? If we can reason only with Boolean logic, then we have to treat every sensor bit as being either correct or incorrect, which is the same as having no perceptual information at all. But we will see that probabilistic reasoning (Chapter 12), allows us to extract useful information from a faulty sensor as long as it is wrong less than half the time.

## 4.5 Online Search Agents and Unknown Environments

Offline search  
Online search

So far we have concentrated on agents that use **offline search** algorithms. They compute a complete solution before taking their first action. In contrast, an **online search**<sup>8</sup> agent interleaves computation and action: first it takes an action, then it observes the environment and computes the next action. Online search is a good idea in dynamic or semi-dynamic environments, where there is a penalty for sitting around and computing too long. Online

<sup>8</sup> The term “online” here refers to algorithms that must process input as it is received rather than waiting for the entire input data set to become available. This usage of “online” is unrelated to the concept of “having an Internet connection.”

search is also helpful in nondeterministic domains because it allows the agent to focus its computational efforts on the contingencies that actually arise rather than those that *might* happen but probably won't.

Of course, there is a tradeoff: the more an agent plans ahead, the less often it will find itself up the creek without a paddle. In unknown environments, where the agent does not know what states exist or what its actions do, the agent must use its actions as experiments in order to learn about the environment.

A canonical example of online search is the **mapping problem**: a robot is placed in an unknown building and must explore to build a map that can later be used for getting from *A* to *B*. Methods for escaping from labyrinths—required knowledge for aspiring heroes of antiquity—are also examples of online search algorithms. Spatial exploration is not the only form of online exploration, however. Consider a newborn baby: it has many possible actions but knows the outcomes of none of them, and it has experienced only a few of the possible states that it can reach.

Mapping problem

### 4.5.1 Online search problems

An online search problem is solved by interleaving computation, sensing, and acting. We'll start by assuming a deterministic and fully observable environment (Chapter 16 relaxes these assumptions) and stipulate that the agent knows only the following:

- $\text{ACTIONS}(s)$ , the legal actions in state  $s$ ;
- $c(s, a, s')$ , the cost of applying action  $a$  in state  $s$  to arrive at state  $s'$ . Note that this cannot be used until the agent knows that  $s'$  is the outcome.
- $\text{Is-GOAL}(s)$ , the goal test.

Note in particular that the agent *cannot* determine  $\text{RESULT}(s, a)$  except by actually being in  $s$  and doing  $a$ . For example, in the maze problem shown in Figure 4.19, the agent does not know that going *Up* from (1,1) leads to (1,2); nor, having done that, does it know that going *Down* will take it back to (1,1). This degree of ignorance can be reduced in some applications—for example, a robot explorer might know how its movement actions work and be ignorant only of the locations of obstacles.

Finally, the agent might have access to an admissible heuristic function  $h(s)$  that estimates the distance from the current state to a goal state. For example, in Figure 4.19, the agent might know the location of the goal and be able to use the Manhattan-distance heuristic (page 116).

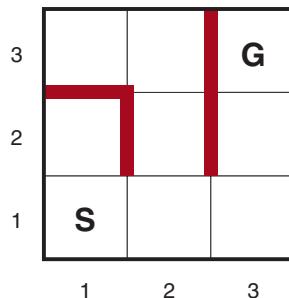

Typically, the agent's objective is to reach a goal state while minimizing cost. (Another possible objective is simply to explore the entire environment.) The cost is the total path cost that the agent incurs as it travels. It is common to compare this cost with the path cost the agent would incur *if it knew the search space in advance*—that is, the optimal path in the known environment. In the language of online algorithms, this comparison is called the **competitive ratio**; we would like it to be as small as possible.

Online explorers are vulnerable to **dead ends**: states from which no goal state is reachable. If the agent doesn't know what each action does, it might execute the “jump into bottomless pit” action, and thus never reach the goal. In general, *no algorithm can avoid dead ends in all state spaces*. Consider the two dead-end state spaces in Figure 4.20(a). An online search algorithm that has visited states *S* and *A* cannot tell if it is in the top state space or the bottom one; the two look identical based on what the agent has seen. Therefore, there

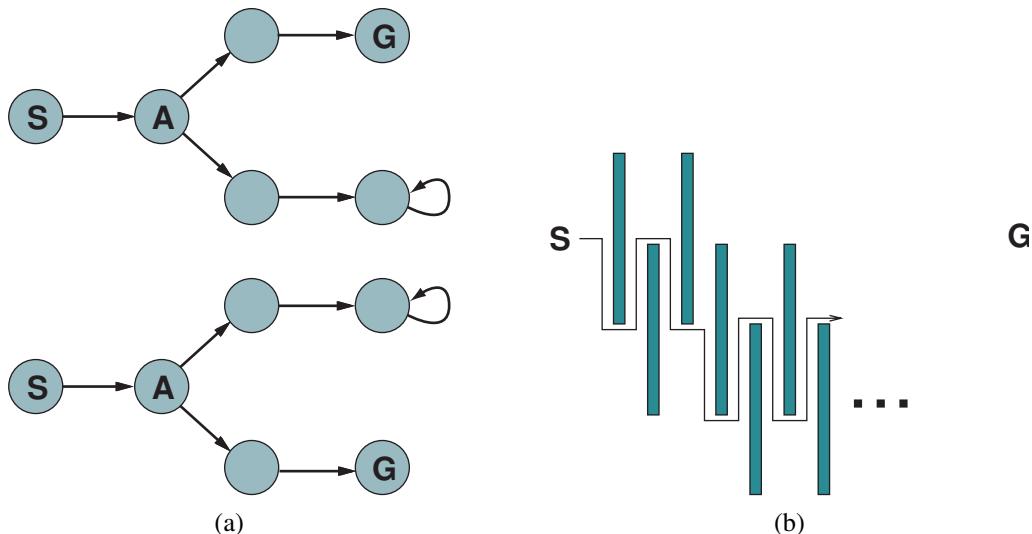

Competitive ratio

Dead end

**Figure 4.19** A simple maze problem. The agent starts at  $S$  and must reach  $G$  but knows nothing of the environment.

**Figure 4.20** (a) Two state spaces that might lead an online search agent into a dead end. Any given agent will fail in at least one of these spaces. (b) A two-dimensional environment that can cause an online search agent to follow an arbitrarily inefficient route to the goal. Whichever choice the agent makes, the adversary blocks that route with another long, thin wall, so that the path followed is much longer than the best possible path.

Adversary argument

is no way it could know how to choose the correct action in both state spaces. This is an example of an **adversary argument**—we can imagine an adversary constructing the state space while the agent explores it and putting the goals and dead ends wherever it chooses, as in Figure 4.20(b).

Irreversible action

Safely explorable

Dead ends are a real difficulty for robot exploration—staircases, ramps, cliffs, one-way streets, and even natural terrain all present states from which some actions are **irreversible**—there is no way to return to the previous state. The exploration algorithm we will present is only guaranteed to work in state spaces that are **safely explorable**—that is, some goal state is reachable from every reachable state. State spaces with only reversible actions, such as

---

```

function ONLINE-DFS-AGENT(problem,  $s'$ ) returns an action
     $s, a$ , the previous state and action, initially null
    result, a table mapping  $(s, a)$  to  $s'$ , initially empty
    untried, a table mapping  $s$  to a list of untried actions
    unbacktracked, a table mapping  $s$  to a list of states never backtracked to

    if problem.IS-GOAL( $s'$ ) then return stop
    if  $s'$  is a new state (not in untried) then untried[ $s'$ ]  $\leftarrow$  problem.ACTIONS( $s'$ )
    if  $s$  is not null then
        result[ $s, a$ ]  $\leftarrow s'$ 
        add  $s$  to the front of unbacktracked[ $s'$ ]
    if untried[ $s'$ ] is empty then
        if unbacktracked[ $s'$ ] is empty then return stop
         $a \leftarrow$  an action  $b$  such that result[ $s', b$ ] = POP(unbacktracked[ $s'$ ])
         $s' \leftarrow$  null
    else  $a \leftarrow$  POP(untried[ $s'$ ]))
     $s \leftarrow s'$ 
    return  $a$ 

```

**Figure 4.21** An online search agent that uses depth-first exploration. The agent can safely explore only in state spaces in which every action can be “undone” by some other action.

---

mazes and 8-puzzles, are clearly safely explorable (if they have any solution at all). We will cover the subject of safe exploration in more depth in Section 23.3.2.

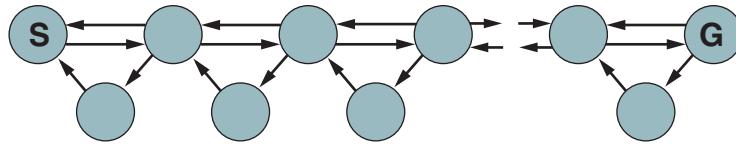

Even in safely explorable environments, no bounded competitive ratio can be guaranteed if there are paths of unbounded cost. This is easy to show in environments with irreversible actions, but in fact it remains true for the reversible case as well, as Figure 4.20(b) shows. For this reason, it is common to characterize the performance of online search algorithms in terms of the size of the entire state space rather than just the depth of the shallowest goal.

### 4.5.2 Online search agents

After each action, an online agent in an observable environment receives a percept telling it what state it has reached; from this information, it can augment its map of the environment. The updated map is then used to plan where to go next. This interleaving of planning and action means that online search algorithms are quite different from the offline search algorithms we have seen previously: offline algorithms explore their *model* of the state space, while online algorithms explore the real world. For example, A\* can expand a node in one part of the space and then immediately expand a node in a distant part of the space, because node expansion involves simulated rather than real actions.

An online algorithm, on the other hand, can discover successors only for a state that it physically occupies. To avoid traveling all the way to a distant state to expand the next node, it seems better to expand nodes in a *local* order. Depth-first search has exactly this property because (except when the algorithm is backtracking) the next node expanded is a child of the previous node expanded.

An online depth-first exploration agent (for deterministic but unknown actions) is shown in Figure 4.21. This agent stores its map in a table, *result*[ $s, a$ ], that records the state resulting from executing action  $a$  in state  $s$ . (For nondeterministic actions, the agent could record a set

**Figure 4.22** An environment in which a random walk will take exponentially many steps to find the goal.

of states under  $results[s, a]$ .) Whenever the current state has unexplored actions, the agent tries one of those actions. The difficulty comes when the agent has tried all the actions in a state. In offline depth-first search, the state is simply dropped from the queue; in an online search, the agent has to backtrack in the physical world. In depth-first search, this means going back to the state from which the agent most recently entered the current state. To achieve that, the algorithm keeps another table that lists, for each state, the predecessor states to which the agent has not yet backtracked. If the agent has run out of states to which it can backtrack, then its search is complete.

We recommend that the reader trace through the progress of ONLINE-DFS-AGENT when applied to the maze given in Figure 4.19. It is fairly easy to see that the agent will, in the worst case, end up traversing every link in the state space exactly twice. For exploration, this is optimal; for finding a goal, on the other hand, the agent's competitive ratio could be arbitrarily bad if it goes off on a long excursion when there is a goal right next to the initial state. An online variant of iterative deepening solves this problem; for an environment that is a uniform tree, the competitive ratio of such an agent is a small constant.

Because of its method of backtracking, ONLINE-DFS-AGENT works only in state spaces where the actions are reversible. There are slightly more complex algorithms that work in general state spaces, but no such algorithm has a bounded competitive ratio.

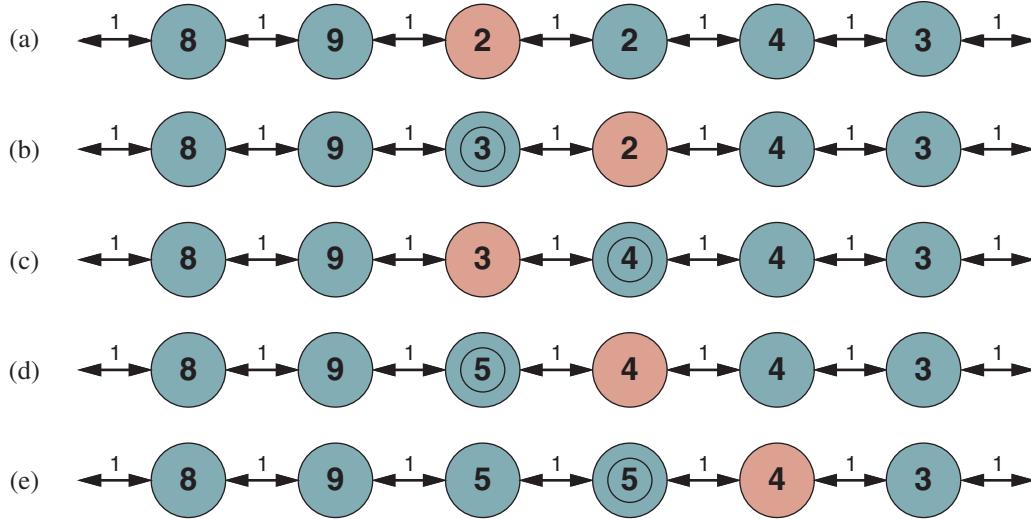

### 4.5.3 Online local search

Like depth-first search, **hill-climbing search** has the property of locality in its node expansions. In fact, because it keeps just one current state in memory, hill-climbing search is *already* an online search algorithm! Unfortunately, the basic algorithm is not very good for exploration because it leaves the agent sitting at local maxima with nowhere to go. Moreover, random restarts cannot be used, because the agent cannot teleport itself to a new start state.

Random walk

Instead of random restarts, one might consider using a **random walk** to explore the environment. A random walk simply selects at random one of the available actions from the current state; preference can be given to actions that have not yet been tried. It is easy to prove that a random walk will *eventually* find a goal or complete its exploration, provided that the space is finite and safely exploratory.<sup>9</sup> On the other hand, the process can be very slow. Figure 4.22 shows an environment in which a random walk will take exponentially many steps to find the goal, because, for each state in the top row except S, backward progress is twice as likely as forward progress. The example is contrived, of course, but there are many real-world state spaces whose topology causes these kinds of “traps” for random walks.

<sup>9</sup> Random walks are complete on infinite one-dimensional and two-dimensional grids. On a three-dimensional grid, the probability that the walk ever returns to the starting point is only about 0.3405 (Hughes, 1995).

**Figure 4.23** Five iterations of LRTA\* on a one-dimensional state space. Each state is labeled with  $H(s)$ , the current cost estimate to reach a goal, and every link has an action cost of 1. The red state marks the location of the agent, and the updated cost estimates at each iteration have a double circle.

Augmenting hill climbing with *memory* rather than randomness turns out to be a more effective approach. The basic idea is to store a “current best estimate”  $H(s)$  of the cost to reach the goal from each state that has been visited.  $H(s)$  starts out being just the heuristic estimate  $h(s)$  and is updated as the agent gains experience in the state space.

Figure 4.23 shows a simple example in a one-dimensional state space. In (a), the agent seems to be stuck in a flat local minimum at the red state. Rather than staying where it is, the agent should follow what seems to be the best path to the goal given the current cost estimates for its neighbors. The estimated cost to reach the goal through a neighbor  $s'$  is the cost to get to  $s'$  plus the estimated cost to get to a goal from there—that is,  $c(s, a, s') + H(s')$ . In the example, there are two actions, with estimated costs 1 + 9 to the left and 1 + 2 to the right, so it seems best to move right.

In (b) it is clear that the cost estimate of 2 for the red state in (a) was overly optimistic. Since the best move cost 1 and led to a state that is at least 2 steps from a goal, the red state must be at least 3 steps from a goal, so its  $H$  should be updated accordingly, as shown in Figure 4.23(b). Continuing this process, the agent will move back and forth twice more, updating  $H$  each time and “flattening out” the local minimum until it escapes to the right.

An agent implementing this scheme, which is called learning real-time A\* (**LRTA\***), is shown in Figure 4.24. Like ONLINE-DFS-AGENT, it builds a map of the environment in the *result* table. It updates the cost estimate for the state it has just left and then chooses the “apparently best” move according to its current cost estimates. One important detail is that actions that have not yet been tried in a state  $s$  are always assumed to lead immediately to the goal with the least possible cost, namely  $h(s)$ . This **optimism under uncertainty** encourages the agent to explore new, possibly promising paths.

---

```

function LRTA*-AGENT(problem, s', h) returns an action
    s, a, the previous state and action, initially null
    result, a table mapping (s, a) to s', initially empty
    H, a table mapping s to a cost estimate, initially empty

    if IS-GOAL(s') then return stop
    if s' is a new state (not in H) then H[s']  $\leftarrow$  h(s')
    if s is not null then
        result[s, a]  $\leftarrow$  s'
         $H[s] \leftarrow \min_{b \in \text{ACTIONS}(s)} \text{LRTA}^*-\text{COST}(\text{problem}, s, b, \text{result}[s, b], H)$ 
         $a \leftarrow \operatorname{argmin}_{b \in \text{ACTIONS}(s)} \text{LRTA}^*-\text{COST}(\text{problem}, s', b, \text{result}[s', b], H)$ 
        s  $\leftarrow$  s'
    return a

function LRTA*-COST(problem, s, a, s', H) returns a cost estimate
    if s' is undefined then return h(s)
    else return problem.ACTION-COST(s, a, s') + H[s']

```

**Figure 4.24** LRTA\*-AGENT selects an action according to the values of neighboring states, which are updated as the agent moves about the state space.

---

An LRTA\* agent is guaranteed to find a goal in any finite, safely explorable environment. Unlike A\*, however, it is not complete for infinite state spaces—there are cases where it can be led infinitely astray. It can explore an environment of  $n$  states in  $O(n^2)$  steps in the worst case, but often does much better. The LRTA\* agent is just one of a large family of online agents that one can define by specifying the action selection rule and the update rule in different ways. We discuss this family, developed originally for stochastic environments, in Chapter 23.

#### 4.5.4 Learning in online search

The initial ignorance of online search agents provides several opportunities for learning. First, the agents learn a “map” of the environment—more precisely, the outcome of each action in each state—simply by recording each of their experiences. Second, the local search agents acquire more accurate estimates of the cost of each state by using local updating rules, as in LRTA\*. In Chapter 23, we show that these updates eventually converge to *exact* values for every state, provided that the agent explores the state space in the right way. Once exact values are known, optimal decisions can be taken simply by moving to the lowest-cost successor—that is, pure hill climbing is then an optimal strategy.

If you followed our suggestion to trace the behavior of ONLINE-DFS-AGENT in the environment of Figure 4.19, you will have noticed that the agent is not very bright. For example, after it has seen that the *Up* action goes from (1,1) to (1,2), the agent still has no idea that the *Down* action goes back to (1,1) or that the *Up* action also goes from (2,1) to (2,2), from (2,2) to (2,3), and so on. In general, we would like the agent to learn that *Up* increases the *y*-coordinate unless there is a wall in the way, that *Down* reduces it, and so on.

For this to happen, we need two things. First, we need a formal and explicitly manipulable representation for these kinds of general rules; so far, we have hidden the information inside

the black box called the RESULT function. Chapters 8 to 11 are devoted to this issue. Second, we need algorithms that can construct suitable general rules from the specific observations made by the agent. These are covered in Chapter 19.

If we anticipate that we will be called upon to solve multiple similar problems in the future then it makes sense to invest time (and memory) to make those future searches easier. There are several ways to do this, all falling under the heading of **incremental search**. We could keep the search tree in memory and reuse the parts of it that are unchanged in the new problem. We could keep the heuristic  $h$  values and update them as we gain new information—either because the world has changed or because we have computed a better estimate. Or we could keep the best-path  $g$  values, using them to piece together a new solution, and updating them when the world changes.

Incremental search

## Summary

---

This chapter has examined search algorithms for problems in partially observable, nondeterministic, unknown, and continuous environments.

- Local search methods such as **hill climbing** keep only a small number of states in memory. They have been applied to optimization problems, where the idea is to find a high-scoring state, without worrying about the path to the state. Several stochastic local search algorithms have been developed, including **simulated annealing**, which returns optimal solutions when given an appropriate cooling schedule.
- Many local search methods apply also to problems in continuous spaces. **Linear programming** and **convex optimization** problems obey certain restrictions on the shape of the state space and the nature of the objective function, and admit polynomial-time algorithms that are often extremely efficient in practice. For some mathematically well-formed problems, we can find the maximum using calculus to find where the gradient is zero; for other problems we have to make do with the empirical gradient, which measures the difference in fitness between two nearby points.
- An **evolutionary algorithm** is a stochastic hill-climbing search in which a population of states is maintained. New states are generated by **mutation** and by **crossover**, which combines pairs of states.
- In **nondeterministic** environments, agents can apply AND–OR search to generate **contingent** plans that reach the goal regardless of which outcomes occur during execution.
- When the environment is partially observable, the **belief state** represents the set of possible states that the agent might be in.
- Standard search algorithms can be applied directly to belief-state space to solve **sensorless problems**, and belief-state AND–OR search can solve general partially observable problems. Incremental algorithms that construct solutions state by state within a belief state are often more efficient.
- **Exploration problems** arise when the agent has no idea about the states and actions of its environment. For safely exploratory environments, **online search** agents can build a map and find a goal if one exists. Updating heuristic estimates from experience provides an effective method to escape from local minima.

## Bibliographical and Historical Notes

---

Local search techniques have a long history in mathematics and computer science. Indeed, the Newton–Raphson method (Newton, 1671; Raphson, 1690) can be seen as a very efficient local search method for continuous spaces in which gradient information is available. Brent (1973) is a classic reference for optimization algorithms that do not require such information. Beam search, which we have presented as a local search algorithm, originated as a bounded-width variant of dynamic programming for speech recognition in the HARPY system (Lowerre, 1976). A related algorithm is analyzed in depth by Pearl (1984, Ch. 5).

The topic of local search was reinvigorated in the early 1990s by surprisingly good results for large constraint-satisfaction problems such as  $n$ -queens (Minton *et al.*, 1992) and Boolean satisfiability (Selman *et al.*, 1992) and by the incorporation of randomness, multiple simultaneous searches, and other improvements. This renaissance of what Christos Papadimitriou has called “New Age” algorithms also sparked increased interest among theoretical computer scientists (Koutsoupias and Papadimitriou, 1992; Aldous and Vazirani, 1994).

### Tabu search

In the field of operations research, a variant of hill climbing called **tabu search** has gained popularity (Glover and Laguna, 1997). This algorithm maintains a tabu list of  $k$  previously visited states that cannot be revisited; as well as improving efficiency when searching graphs, this list can allow the algorithm to escape from some local minima.

### Heavy-tailed distribution

Another useful improvement on hill climbing is the STAGE algorithm (Boyan and Moore, 1998). The idea is to use the local maxima found by random-restart hill climbing to get an idea of the overall shape of the landscape. The algorithm fits a smooth quadratic surface to the set of local maxima and then calculates the global maximum of that surface analytically. This becomes the new restart point. Gomes *et al.* (1998) showed that the run times of systematic backtracking algorithms often have a **heavy-tailed distribution**, which means that the probability of a very long run time is more than would be predicted if the run times were exponentially distributed. When the run time distribution is heavy-tailed, random restarts find a solution faster, on average, than a single run to completion. Hoos and Stützle (2004) provide a book-length coverage of the topic.

Simulated annealing was first described by Kirkpatrick *et al.* (1983), who borrowed directly from the **Metropolis algorithm** (which is used to simulate complex systems in physics (Metropolis *et al.*, 1953) and was supposedly invented at a Los Alamos dinner party). Simulated annealing is now a field in itself, with hundreds of papers published every year.

Finding optimal solutions in continuous spaces is the subject matter of several fields, including **optimization theory**, **optimal control theory**, and the **calculus of variations**. The basic techniques are explained well by Bishop (1995); Press *et al.* (2007) cover a wide range of algorithms and provide working software.

Researchers have taken inspiration for search and optimization algorithms from a wide variety of fields of study: metallurgy (simulated annealing); biology (genetic algorithms); neuroscience (neural networks); mountaineering (hill climbing); economics (market-based algorithms (Dias *et al.*, 2006)); physics (particle swarms (Li and Yao, 2012) and spin glasses (Mézard *et al.*, 1987)); animal behavior (reinforcement learning, grey wolf optimizers (Mirjalili and Lewis, 2014)); ornithology (Cuckoo search (Yang and Deb, 2014)); entomology (ant colony (Dorigo *et al.*, 2008), bee colony (Karaboga and Basturk, 2007), firefly (Yang, 2009) and glowworm (Krishnanand and Ghose, 2009) optimization); and others.

**Linear programming** (LP) was first studied systematically by the mathematician Leonid Kantorovich (1939). It was one of the first applications of computers; the **simplex algorithm** (Dantzig, 1949) is still used despite worst-case exponential complexity. Karmarkar (1984) developed the far more efficient family of **interior-point** methods, which was shown to have polynomial complexity for the more general class of convex optimization problems by Nesterov and Nemirovski (1994). Excellent introductions to convex optimization are provided by Ben-Tal and Nemirovski (2001) and Boyd and Vandenberghe (2004).

Work by Sewall Wright (1931) on the concept of a **fitness landscape** was an important precursor to the development of genetic algorithms. In the 1950s, several statisticians, including Box (1957) and Friedman (1959), used evolutionary techniques for optimization problems, but it wasn't until Rechenberg (1965) introduced **evolution strategies** to solve optimization problems for airfoils that the approach gained popularity. In the 1960s and 1970s, John Holland (1975) championed genetic algorithms, both as a useful optimization tool and as a method to expand our understanding of adaptation (Holland, 1995).

The **artificial life** movement (Langton, 1995) took this idea one step further, viewing the products of genetic algorithms as *organisms* rather than solutions to problems. The Baldwin effect discussed in the chapter was proposed roughly simultaneously by Conwy Lloyd Morgan (1896) and James (Baldwin, 1896). Computer simulations have helped to clarify its implications (Hinton and Nowlan, 1987; Ackley and Littman, 1991; Morgan and Griffiths, 2015). Smith and Szathmáry (1999), Ridley (2004), and Carroll (2007) provide general background on evolution.

Most comparisons of genetic algorithms to other approaches (especially stochastic hill climbing) have found that the genetic algorithms are slower to converge (O'Reilly and Oppacher, 1994; Mitchell *et al.*, 1996; Juels and Wattenberg, 1996; Baluja, 1997). Such findings are not universally popular within the GA community, but recent attempts within that community to understand population-based search as an approximate form of Bayesian learning (see Chapter 21) might help close the gap between the field and its critics (Pelikan *et al.*, 1999). The theory of **quadratic dynamical systems** may also explain the performance of GAs (Rabani *et al.*, 1998). There are some impressive practical applications of GAs, in areas as diverse as antenna design (Lohn *et al.*, 2001), computer-aided design (Renner and Ekart, 2003), climate models (Stanislawska *et al.*, 2015), medicine (Ghaheri *et al.*, 2015), and designing deep neural networks (Miikkulainen *et al.*, 2019).

The field of **genetic programming** is a subfield of genetic algorithms in which the representations are programs rather than bit strings. The programs are represented in the form of syntax trees, either in a standard programming language or in specially designed formats to represent electronic circuits, robot controllers, and so on. Crossover involves splicing together subtrees in such a way that the offspring are guaranteed to be well-formed expressions.

Interest in genetic programming was spurred by the work of John Koza (1992, 1994), but it goes back at least to early experiments with machine code by Friedberg (1958) and with finite-state automata by Fogel *et al.* (1966). As with genetic algorithms, there is debate about the effectiveness of the technique. Koza *et al.* (1999) describe experiments in the use of genetic programming to design circuit devices.

The journals *Evolutionary Computation* and *IEEE Transactions on Evolutionary Computation* cover evolutionary algorithms; articles are also found in *Complex Systems*, *Adaptive Behavior*, and *Artificial Life*. The main conference is the *Genetic and Evolutionary Com-*

putation Conference (GECCO). Good overview texts on genetic algorithms include those by Mitchell (1996), Fogel (2000), Langdon and Poli (2002), and Poli *et al.* (2008).

The unpredictability and partial observability of real environments were recognized early on in robotics projects that used planning techniques, including Shakey (Fikes *et al.*, 1972) and FREDDY (Michie, 1972). The problems received more attention after the publication of McDermott's (1978a) influential article *Planning and Acting*.

The first work to make explicit use of AND–OR trees seems to have been Slagle's SAINT program for symbolic integration, mentioned in Chapter 1. Amarel (1967) applied the idea to propositional theorem proving, a topic discussed in Chapter 7, and introduced a search algorithm similar to AND–OR–GRAPH–SEARCH. The algorithm was further developed by Nilsson (1971), who also described AO\*—which, as its name suggests, finds optimal solutions. AO\* was further improved by Martelli and Montanari (1973).

AO\* is a top-down algorithm; a bottom-up generalization of A\* is A\*LD, for A\* Lightest Derivation (Felzenszwalb and McAllester, 2007). Interest in AND–OR search underwent a revival in the early 2000s, with new algorithms for finding cyclic solutions (Jimenez and Torras, 2000; Hansen and Zilberstein, 2001) and new techniques inspired by dynamic programming (Bonet and Geffner, 2005).

The idea of transforming partially observable problems into belief-state problems originated with Astrom (1965) for the much more complex case of probabilistic uncertainty (see Chapter 16). Erdmann and Mason (1988) studied the problem of robotic manipulation without sensors, using a continuous form of belief-state search. They showed that it was possible to orient a part on a table from an arbitrary initial position by a well-designed sequence of tilting actions. More practical methods, based on a series of precisely oriented diagonal barriers across a conveyor belt, use the same algorithmic insights (Wiegley *et al.*, 1996).

The belief-state approach was reinvented in the context of sensorless and partially observable search problems by Genesereth and Nourbakhsh (1993). Additional work was done on sensorless problems in the logic-based planning community (Goldman and Boddy, 1996; Smith and Weld, 1998). This work has emphasized concise representations for belief states, as explained in Chapter 11. Bonet and Geffner (2000) introduced the first effective heuristics for belief-state search; these were refined by Bryce *et al.* (2006). The incremental approach to belief-state search, in which solutions are constructed incrementally for subsets of states within each belief state, was studied in the planning literature by Kurien *et al.* (2002); several new incremental algorithms were introduced for nondeterministic, partially observable problems by Russell and Wolfe (2005). Additional references for planning in stochastic, partially observable environments appear in Chapter 16.

Algorithms for exploring unknown state spaces have been of interest for many centuries. Depth-first search in a reversible maze can be implemented by keeping one's left hand on the wall; loops can be avoided by marking each junction. The more general problem of exploring **Eulerian graphs** (i.e., graphs in which each node has equal numbers of incoming and outgoing edges) was solved by an algorithm due to Hierholzer (1873).

The first thorough algorithmic study of the exploration problem for arbitrary graphs was carried out by Deng and Papadimitriou (1990), who developed a completely general algorithm but showed that no bounded competitive ratio is possible for exploring a general graph. Papadimitriou and Yannakakis (1991) examined the question of finding paths to a goal in geometric path-planning environments (where all actions are reversible). They showed that

a small competitive ratio is achievable with square obstacles, but with general rectangular obstacles no bounded ratio can be achieved. (See Figure 4.20.)

In a dynamic environment, the state of the world can spontaneously change without any action by the agent. For example, the agent can plan an optimal driving route from *A* to *B*, but an accident or unusually bad rush hour traffic can spoil the plan. Incremental search algorithms such as Lifelong Planning A\* (Koenig *et al.*, 2004) and D\* Lite (Koenig and Likhachev, 2002) deal with this situation.

The LRTA\* algorithm was developed by Korf (1990) as part of an investigation into **real-time search** for environments in which the agent must act after searching for only a fixed amount of time (a common situation in two-player games). LRTA\* is in fact a special case of reinforcement learning algorithms for stochastic environments (Barto *et al.*, 1995). Its policy of optimism under uncertainty—always head for the closest unvisited state—can result in an exploration pattern that is less efficient in the uninformed case than simple depth-first search (Koenig, 2000). Dasgupta *et al.* (1994) show that online iterative deepening search is optimally efficient for finding a goal in a uniform tree with no heuristic information.

Several informed variants on the LRTA\* theme have been developed with different methods for searching and updating within the known portion of the graph (Pemberton and Korf, 1992). As yet, there is no good theoretical understanding of how to find goals with optimal efficiency when using heuristic information. Sturtevant and Bulitko (2016) provide an analysis of some pitfalls that occur in practice.

# CHAPTER 5

## CONSTRAINT SATISFACTION PROBLEMS

*In which we see how treating states as more than just little black boxes leads to new search methods and a deeper understanding of problem structure.*

Chapters 3 and 4 explored the idea that problems can be solved by searching the state space: a graph where the nodes are states and the edges between them are actions. We saw that domain-specific heuristics could estimate the cost of reaching the goal from a given state, but that from the point of view of the search algorithm, each state is atomic, or indivisible—a black box with no internal structure. For each problem we need domain-specific code to describe the transitions between states.

In this chapter we break open the black box by using a **factored representation** for each state: a set of **variables**, each of which has a **value**. A problem is solved when each variable has a value that satisfies all the constraints on the variable. A problem described this way is called a **constraint satisfaction problem**, or **CSP**.

CSP search algorithms take advantage of the structure of states and use *general* rather than domain-specific heuristics to enable the solution of complex problems. The main idea is to eliminate large portions of the search space all at once by identifying variable/value combinations that violate the constraints. CSPs have the additional advantage that the actions and transition model can be deduced from the problem description.

Constraint satisfaction problem

Relation

### 5.1 Defining Constraint Satisfaction Problems

A constraint satisfaction problem consists of three components,  $\mathcal{X}$ ,  $\mathcal{D}$ , and  $\mathcal{C}$ :

$\mathcal{X}$  is a set of variables,  $\{X_1, \dots, X_n\}$ .

$\mathcal{D}$  is a set of domains,  $\{D_1, \dots, D_n\}$ , one for each variable.

$\mathcal{C}$  is a set of constraints that specify allowable combinations of values.

A domain,  $D_i$ , consists of a set of allowable values,  $\{v_1, \dots, v_k\}$ , for variable  $X_i$ . For example, a Boolean variable would have the domain  $\{\text{true}, \text{false}\}$ . Different variables can have different domains of different sizes. Each constraint  $C_j$  consists of a pair  $\langle \text{scope}, \text{rel} \rangle$ , where *scope* is a tuple of variables that participate in the constraint and *rel* is a **relation** that defines the values that those variables can take on. A relation can be represented as an explicit set of all tuples of values that satisfy the constraint, or as a function that can compute whether a tuple is a member of the relation. For example, if  $X_1$  and  $X_2$  both have the domain  $\{1, 2, 3\}$ , then the constraint saying that  $X_1$  must be greater than  $X_2$  can be written as  $\langle (X_1, X_2), \{(3, 1), (3, 2), (2, 1)\} \rangle$  or as  $\langle (X_1, X_2), X_1 > X_2 \rangle$ .

CSPs deal with **assignments** of values to variables,  $\{X_i = v_i, X_j = v_j, \dots\}$ . An assignment that does not violate any constraints is called a **consistent** or legal assignment. A **complete assignment** is one in which every variable is assigned a value, and a **solution** to a CSP is a consistent, complete assignment. A **partial assignment** is one that leaves some variables unassigned, and a **partial solution** is a partial assignment that is consistent. Solving a CSP is an NP-complete problem in general, although there are important subclasses of CSPs that can be solved very efficiently.

Partial solution

### 5.1.1 Example problem: Map coloring

Suppose that, having tired of Romania, we are looking at a map of Australia showing each of its states and territories (Figure 5.1(a)). We are given the task of coloring each region either red, green, or blue in such a way that no two neighboring regions have the same color. To formulate this as a CSP, we define the variables to be the regions:

$$\mathcal{X} = \{WA, NT, Q, NSW, V, SA, T\}.$$

The domain of every variable is the set  $D_i = \{\text{red}, \text{green}, \text{blue}\}$ . The constraints require neighboring regions to have distinct colors. Since there are nine places where regions border, there are nine constraints:

$$\mathcal{C} = \{SA \neq WA, SA \neq NT, SA \neq Q, SA \neq NSW, SA \neq V, \\ WA \neq NT, NT \neq Q, Q \neq NSW, NSW \neq V\}.$$

Here we are using abbreviations;  $SA \neq WA$  is a shortcut for  $\langle(SA, WA), SA \neq WA\rangle$ , where  $SA \neq WA$  can be fully enumerated in turn as

$$\{(red, green), (red, blue), (green, red), (green, blue), (blue, red), (blue, green)\}.$$

There are many possible solutions to this problem, such as

$$\{WA = \text{red}, NT = \text{green}, Q = \text{red}, NSW = \text{green}, V = \text{red}, SA = \text{blue}, T = \text{red}\}.$$

It can be helpful to visualize a CSP as a **constraint graph**, as shown in Figure 5.1(b). The nodes of the graph correspond to variables of the problem, and an edge connects any two variables that participate in a constraint.

Constraint graph

Why formulate a problem as a CSP? One reason is that the CSPs yield a natural representation for a wide variety of problems; it is often easy to formulate a problem as a CSP. Another is that years of development work have gone into making CSP solvers fast and efficient. A third is that a CSP solver can quickly prune large swathes of the search space that an atomic state-space searcher cannot. For example, once we have chosen  $\{SA = \text{blue}\}$  in the Australia problem, we can conclude that none of the five neighboring variables can take on the value *blue*. A search procedure that does not use constraints would have to consider  $3^5 = 243$  assignments for the five neighboring variables; with constraints we have only  $2^5 = 32$  assignments to consider, a reduction of 87%.

In atomic state-space search we can only ask: is this specific state a goal? No? What about this one? With CSPs, once we find out that a partial assignment violates a constraint, we can immediately discard further refinements of the partial assignment. Furthermore, we can see *why* the assignment is not a solution—we see which variables violate a constraint—so we can focus attention on the variables that matter. As a result, many problems that are intractable for atomic state-space search can be solved quickly when formulated as a CSP.

**Figure 5.1** (a) The principal states and territories of Australia. Coloring this map can be viewed as a constraint satisfaction problem (CSP). The goal is to assign colors to each region so that no neighboring regions have the same color. (b) The map-coloring problem represented as a constraint graph.

### 5.1.2 Example problem: Job-shop scheduling

Factories have the problem of scheduling a day's worth of jobs, subject to various constraints. In practice, many of these problems are solved with CSP techniques. Consider the problem of scheduling the assembly of a car. The whole job is composed of tasks, and we can model each task as a variable, where the value of each variable is the time that the task starts, expressed as an integer number of minutes. Constraints can assert that one task must occur before another—for example, a wheel must be installed before the hubcap is put on—and that only so many tasks can go on at once. Constraints can also specify that a task takes a certain amount of time to complete.

We consider a small part of the car assembly, consisting of 15 tasks: install axles (front and back), affix all four wheels (right and left, front and back), tighten nuts for each wheel, affix hubcaps, and inspect the final assembly. We can represent the tasks with 15 variables:

$$\mathcal{X} = \{Axe_F, Axe_B, Wheel_{RF}, Wheel_{LF}, Wheel_{RB}, Wheel_{LB}, Nuts_{RF}, Nuts_{LF}, Nuts_{RB}, Nuts_{LB}, Cap_{RF}, Cap_{LF}, Cap_{RB}, Cap_{LB}, Inspect\}.$$

## Precedence constraint

Next, we represent **precedence constraints** between individual tasks. Whenever a task  $T_1$  must occur before task  $T_2$ , and task  $T_1$  takes duration  $d_1$  to complete, we add an arithmetic constraint of the form

$$T_1 + d_1 < T_2.$$

In our example, the axles have to be in place before the wheels are put on, and it takes 10 minutes to install an axle, so we write

$$Axe_F + 10 \leq Wheel_{RF}; \quad Axe_F + 10 \leq Wheel_{LF}; \\ Axe_B + 10 \leq Wheel_{RB}; \quad Axe_B + 10 \leq Wheel_{LB}.$$

Next we say that for each wheel, we must affix the wheel (which takes 1 minute), then tighten the nuts (2 minutes), and finally attach the hubcap (1 minute, but not represented yet):

$$\begin{aligned} Wheel_{RF} + 1 &\leq Nuts_{RF}; \quad Nuts_{RF} + 2 \leq Cap_{RF}; \\ Wheel_{LF} + 1 &\leq Nuts_{LF}; \quad Nuts_{LF} + 2 \leq Cap_{LF}; \\ Wheel_{RB} + 1 &\leq Nuts_{RB}; \quad Nuts_{RB} + 2 \leq Cap_{RB}; \\ Wheel_{LB} + 1 &\leq Nuts_{LB}; \quad Nuts_{LB} + 2 \leq Cap_{LB}. \end{aligned}$$

Suppose we have four workers to install wheels, but they have to share one tool that helps put the axle in place. We need a **disjunctive constraint** to say that  $Axle_F$  and  $Axle_B$  must not overlap in time; either one comes first or the other does:

$$(Axle_F + 10 \leq Axle_B) \quad \text{or} \quad (Axle_B + 10 \leq Axle_F).$$

This looks like a more complicated constraint, combining arithmetic and logic. But it still reduces to a set of pairs of values that  $Axle_F$  and  $Axle_B$  can take on.

We also need to assert that the inspection comes last and takes 3 minutes. For every variable except *Inspect* we add a constraint of the form  $X + d_X \leq Inspect$ . Finally, suppose there is a requirement to get the whole assembly done in 30 minutes. We can achieve that by limiting the domain of all variables:

$$D_i = \{0, 1, 2, 3, \dots, 30\}.$$

This particular problem is trivial to solve, but CSPs have been successfully applied to job-shop scheduling problems like this with thousands of variables.

### 5.1.3 Variations on the CSP formalism

The simplest kind of CSP involves variables that have **discrete, finite domains**. Map-coloring problems and scheduling with time limits are both of this kind. The 8-queens problem (Figure 4.3) can also be viewed as a finite-domain CSP, where the variables  $Q_1, \dots, Q_8$  correspond to the queens in columns 1 to 8, and the domain of each variable specifies the possible row numbers for the queen in that column,  $D_i = \{1, 2, 3, 4, 5, 6, 7, 8\}$ . The constraints say that no two queens can be in the same row or diagonal.

A discrete domain can be **infinite**, such as the set of integers or strings. (If we didn't put a deadline on the job-scheduling problem, there would be an infinite number of start times for each variable.) With infinite domains, we must use implicit constraints like  $T_1 + d_1 \leq T_2$  rather than explicit tuples of values. Special solution algorithms (which we do not discuss here) exist for **linear constraints** on integer variables—that is, constraints, such as the one just given, in which each variable appears only in linear form. It can be shown that no algorithm exists for solving general **nonlinear constraints** on integer variables—the problem is undecidable.

Constraint satisfaction problems with **continuous domains** are common in the real world and are widely studied in the field of operations research. For example, the scheduling of experiments on the Hubble Space Telescope requires very precise timing of observations; the start and finish of each observation and maneuver are continuous-valued variables that must obey a variety of astronomical, precedence, and power constraints. The best-known category of continuous-domain CSPs is that of **linear programming** problems, where constraints must be linear equalities or inequalities. Linear programming problems can be solved in time polynomial in the number of variables. Problems with different types of constraints and objective functions have also been studied—quadratic programming, second-order conic programming, and so on. These problems constitute an important area of applied mathematics.

**Continuous domains**

Unary constraint

Binary constraint

Binary CSP

Global constraint

Cryptarithmetic

Constraint hypergraph

Dual graph

In addition to examining the types of variables that can appear in CSPs, it is useful to look at the types of constraints. The simplest type is the **unary constraint**, which restricts the value of a single variable. For example, in the map-coloring problem it could be the case that South Australians won't tolerate the color green; we can express that with the unary constraint  $\langle (SA), SA \neq \text{green} \rangle$ . (The initial specification of the domain of a variable can also be seen as a unary constraint.)

A **binary constraint** relates two variables. For example,  $SA \neq NSW$  is a binary constraint. A **binary CSP** is one with only unary and binary constraints; it can be represented as a constraint graph, as in Figure 5.1(b).

We can also define higher-order constraints. The ternary constraint  $\text{Between}(X, Y, Z)$ , for example, can be defined as  $\langle (X, Y, Z), X < Y < Z \text{ or } X > Y > Z \rangle$ .

A constraint involving an arbitrary number of variables is called a **global constraint**. (The name is traditional but confusing because a global constraint need not involve *all* the variables in a problem). One of the most common global constraints is *Alldiff*, which says that all of the variables involved in the constraint must have different values. In Sudoku problems (see Section 5.2.6), all variables in a row, column, or  $3 \times 3$  box must satisfy an *Alldiff* constraint.

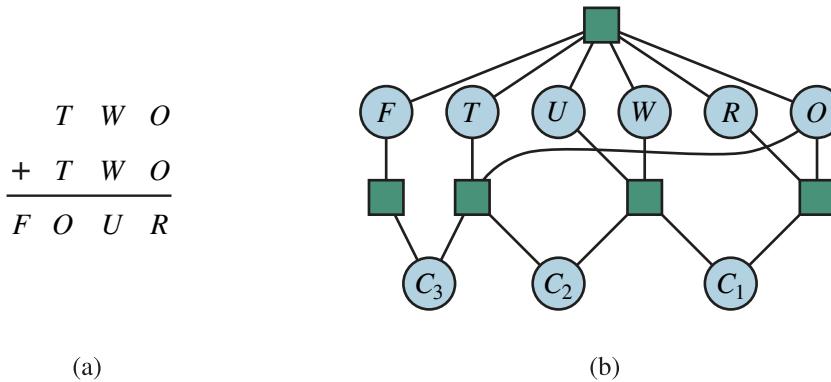

Another example is provided by **cryptarithmetic** puzzles (Figure 5.2(a)). Each letter in a cryptarithmetic puzzle represents a different digit. For the case in Figure 5.2(a), this would be represented as the global constraint *Alldiff*( $F, T, U, W, R, O$ ). The addition constraints on the four columns of the puzzle can be written as the following  $n$ -ary constraints:

$$\begin{aligned} O + O &= R + 10 \cdot C_1 \\ C_1 + W + W &= U + 10 \cdot C_2 \\ C_2 + T + T &= O + 10 \cdot C_3 \\ C_3 &= F, \end{aligned}$$

where  $C_1$ ,  $C_2$ , and  $C_3$  are auxiliary variables representing the digit carried over into the tens, hundreds, or thousands column. These constraints can be represented in a **constraint hypergraph**, such as the one shown in Figure 5.2(b). A hypergraph consists of ordinary nodes (the circles in the figure) and hypernodes (the squares), which represent  $n$ -ary constraints—constraints involving  $n$  variables.

Alternatively, as Exercise 5.NARY asks you to prove, every finite-domain constraint can be reduced to a set of binary constraints if enough auxiliary variables are introduced. This means that we could transform any CSP into one with only binary constraints—which certainly makes the life of the algorithm designer simpler. Another way to convert an  $n$ -ary CSP to a binary one is the **dual graph** transformation: create a new graph in which there will be one variable for each constraint in the original graph, and one binary constraint for each pair of constraints in the original graph that share variables.

For example, consider a CSP with the variables  $\mathcal{X} = \{X, Y, Z\}$ , each with the domain  $\{1, 2, 3, 4, 5\}$ , and with the two constraints  $C_1 : \langle (X, Y, Z), X + Y = Z \rangle$  and  $C_2 : \langle (X, Y), X + 1 = Y \rangle$ . Then the dual graph would have the variables  $\mathcal{X} = \{C_1, C_2\}$ , where the domain of the  $C_1$  variable in the dual graph is the set of  $\{(x_i, y_j, z_k)\}$  tuples from the  $C_1$  constraint in the original problem, and similarly the domain of  $C_2$  is the set of  $\{(x_i, y_j)\}$  tuples. The dual graph has the binary constraint  $\langle (C_1, C_2), R_1 \rangle$ , where  $R_1$  is a new relation that defines the constraint between  $C_1$  and  $C_2$ ; in this case it would be  $R_1 = \{((1, 2, 3), (1, 2)), ((2, 3, 5), (2, 3))\}$ .

**Figure 5.2** (a) A cryptarithmic problem. Each letter stands for a distinct digit; the aim is to find a substitution of digits for letters such that the resulting sum is arithmetically correct, with the added restriction that no leading zeroes are allowed. (b) The constraint hypergraph for the cryptarithmic problem, showing the *Alldiff* constraint (square box at the top) as well as the column addition constraints (four square boxes in the middle). The variables  $C_1$ ,  $C_2$ , and  $C_3$  represent the carry digits for the three columns from right to left.

There are however two reasons why we might prefer a global constraint such as *Alldiff* rather than a set of binary constraints. First, it is easier and less error-prone to write the problem description using *Alldiff*. Second, it is possible to design special-purpose inference algorithms for global constraints that are more efficient than operating with primitive constraints. We describe these inference algorithms in Section 5.2.5.

The constraints we have described so far have all been absolute constraints, violation of which rules out a potential solution. Many real-world CSPs include **preference constraints** indicating which solutions are preferred. For example, in a university class-scheduling problem there are absolute constraints that no professor can teach two classes at the same time. But we also may allow preference constraints: Prof. R might prefer teaching in the morning, whereas Prof. N prefers teaching in the afternoon. A schedule that has Prof. R teaching at 2 p.m. would still be an allowable solution (unless Prof. R happens to be the department chair) but would not be an optimal one.

Preference constraints can often be encoded as costs on individual variable assignments—for example, assigning an afternoon slot for Prof. R costs 2 points against the overall objective function, whereas a morning slot costs 1. With this formulation, CSPs with preferences can be solved with optimization search methods, either path-based or local. We call such a problem a **constrained optimization problem**, or COP. Linear programs are one class of COPs.

Preference constraints

Constrained optimization problem

## 5.2 Constraint Propagation: Inference in CSPs

An atomic state-space search algorithm makes progress in only one way: by expanding a node to visit the successors. A CSP algorithm has choices. It can generate successors by choosing a new variable assignment, or it can do a specific type of inference called **constraint propagation**: using the constraints to reduce the number of legal values for a variable, which

Constraint propagation

in turn can reduce the legal values for another variable, and so on. The idea is that this will leave fewer choices to consider when we make the next choice of a variable assignment. Constraint propagation may be intertwined with search, or it may be done as a preprocessing step, before search starts. Sometimes this preprocessing can solve the whole problem, so no search is required at all.

#### Local consistency

The key idea is **local consistency**. If we treat each variable as a node in a graph (see Figure 5.1(b)) and each binary constraint as an edge, then the process of enforcing local consistency in each part of the graph causes inconsistent values to be eliminated throughout the graph. There are different types of local consistency, which we now cover in turn.

#### Node consistency

A single variable (corresponding to a node in the CSP graph) is **node-consistent** if all the values in the variable's domain satisfy the variable's unary constraints. For example, in the variant of the Australia map-coloring problem (Figure 5.1) where South Australians dislike green, the variable *SA* starts with domain  $\{red, green, blue\}$ , and we can make it node consistent by eliminating *green*, leaving *SA* with the reduced domain  $\{red, blue\}$ . We say that a graph is node-consistent if every variable in the graph is node-consistent.

It is easy to eliminate all the unary constraints in a CSP by reducing the domain of variables with unary constraints at the start of the solving process. As mentioned earlier, it is also possible to transform all  $n$ -ary constraints into binary ones. Because of this, some CSP solvers work with only binary constraints, expecting the user to eliminate the other constraints ahead of time. We make that assumption for the rest of this chapter, except where noted.

#### Arc consistency

#### Arc consistency

A variable in a CSP is **arc-consistent**<sup>1</sup> if every value in its domain satisfies the variable's binary constraints. More formally,  $X_i$  is arc-consistent with respect to another variable  $X_j$  if for every value in the current domain  $D_i$  there is some value in the domain  $D_j$  that satisfies the binary constraint on the arc  $(X_i, X_j)$ . A graph is arc-consistent if every variable is arc-consistent with every other variable. For example, consider the constraint  $Y = X^2$  where the domain of both  $X$  and  $Y$  is the set of decimal digits. We can write this constraint explicitly as

$$\langle (X, Y), \{(0, 0), (1, 1), (2, 4), (3, 9)\} \rangle.$$

To make  $X$  arc-consistent with respect to  $Y$ , we reduce  $X$ 's domain to  $\{0, 1, 2, 3\}$ . If we also make  $Y$  arc-consistent with respect to  $X$ , then  $Y$ 's domain becomes  $\{0, 1, 4, 9\}$ , and the whole CSP is arc-consistent. On the other hand, arc consistency can do nothing for the Australia map-coloring problem. Consider the following inequality constraint on  $(SA, WA)$ :

$$\{(red, green), (red, blue), (green, red), (green, blue), (blue, red), (blue, green)\}.$$

No matter what value you choose for *SA* (or for *WA*), there is a valid value for the other variable. So applying arc consistency has no effect on the domains of either variable.

The most popular algorithm for enforcing arc consistency is called AC-3 (see Figure 5.3). To make every variable arc-consistent, the AC-3 algorithm maintains a queue of arcs to consider. Initially, the queue contains all the arcs in the CSP. (Each binary constraint becomes two arcs, one in each direction.) AC-3 then pops off an arbitrary arc  $(X_i, X_j)$  from the queue

---

<sup>1</sup> We have been using the term “edge” rather than “arc,” so it would make more sense to call this “edge-consistent,” but the name “arc-consistent” is historical.

---

```

function AC-3(csp) returns false if an inconsistency is found and true otherwise
  queue  $\leftarrow$  a queue of arcs, initially all the arcs in csp

  while queue is not empty do
     $(X_i, X_j) \leftarrow \text{POP}(\text{queue})$ 
    if REVISE(csp,  $X_i$ ,  $X_j$ ) then
      if size of  $D_i = 0$  then return false
      for each  $X_k$  in  $X_i.\text{NEIGHBORS} - \{X_j\}$  do
        add  $(X_k, X_i)$  to queue
    return true

function REVISE(csp,  $X_i$ ,  $X_j$ ) returns true iff we revise the domain of  $X_i$ 
  revised  $\leftarrow$  false
  for each  $x$  in  $D_i$  do
    if no value  $y$  in  $D_j$  allows  $(x, y)$  to satisfy the constraint between  $X_i$  and  $X_j$  then
      delete  $x$  from  $D_i$ 
      revised  $\leftarrow$  true
  return revised

```

**Figure 5.3** The arc-consistency algorithm AC-3. After applying AC-3, either every arc is arc-consistent, or some variable has an empty domain, indicating that the CSP cannot be solved. The name “AC-3” was used by the algorithm’s inventor (Mackworth, 1977) because it was the third version developed in the paper.

---

and makes  $X_i$  arc-consistent with respect to  $X_j$ . If this leaves  $D_i$  unchanged, the algorithm just moves on to the next arc. But if this revises  $D_i$  (makes the domain smaller), then we add to the queue all arcs  $(X_k, X_i)$  where  $X_k$  is a neighbor of  $X_i$ . We need to do that because the change in  $D_i$  might enable further reductions in  $D_k$ , even if we have previously considered  $X_k$ . If  $D_i$  is revised down to nothing, then we know the whole CSP has no consistent solution, and AC-3 can immediately return failure. Otherwise, we keep checking, trying to remove values from the domains of variables until no more arcs are in the queue. At that point, we are left with a CSP that is equivalent to the original CSP—they both have the same solutions—but the arc-consistent CSP will be faster to search because its variables have smaller domains. In some cases, it solves the problem completely (by reducing every domain to size 1) and in others it proves that no solution exists (by reducing some domain to size 0).

The complexity of AC-3 can be analyzed as follows. Assume a CSP with  $n$  variables, each with domain size at most  $d$ , and with  $c$  binary constraints (arcs). Each arc  $(X_k, X_i)$  can be inserted in the queue only  $d$  times because  $X_i$  has at most  $d$  values to delete. Checking consistency of an arc can be done in  $O(d^2)$  time, so we get  $O(cd^3)$  total worst-case time.

### 5.2.3 Path consistency

Suppose we are to color the map of Australia with just two colors, red and blue. Arc consistency does nothing because every constraint can be satisfied individually with red at one end and blue at the other. But clearly there is no solution to the problem: because Western Australia, Northern Territory, and South Australia all touch each other, we need at least three colors for them alone.

## Path consistency

Arc consistency tightens down the domains (unary constraints) using the arcs (binary constraints). To make progress on problems like map coloring, we need a stronger notion of consistency. **Path consistency** tightens the binary constraints by using implicit constraints that are inferred by looking at triples of variables.

A two-variable set  $\{X_i, X_j\}$  is path-consistent with respect to a third variable  $X_m$  if, for every assignment  $\{X_i = a, X_j = b\}$  consistent with the constraints (if any) on  $\{X_i, X_j\}$ , there is an assignment to  $X_m$  that satisfies the constraints on  $\{X_i, X_m\}$  and  $\{X_m, X_j\}$ . The name refers to the overall consistency of the path from  $X_i$  to  $X_j$  with  $X_m$  in the middle.

Let's see how path consistency fares in coloring the Australia map with two colors. We will make the set  $\{WA, SA\}$  path-consistent with respect to  $NT$ . We start by enumerating the consistent assignments to the set. In this case, there are only two:  $\{WA = red, SA = blue\}$  and  $\{WA = blue, SA = red\}$ . We can see that with both of these assignments  $NT$  can be neither *red* nor *blue* (because it would conflict with either *WA* or *SA*). Because there is no valid choice for  $NT$ , we eliminate both assignments, and we end up with no valid assignments for  $\{WA, SA\}$ . Therefore, we know that there can be no solution to this problem.

## K-consistency

## Strongly k-consistent

Stronger forms of propagation can be defined with the notion of  **$k$ -consistency**. A CSP is  $k$ -consistent if, for any set of  $k - 1$  variables and for any consistent assignment to those variables, a consistent value can always be assigned to any  $k$ th variable. 1-consistency says that, given the empty set, we can make any set of one variable consistent: this is what we called node consistency. 2-consistency is the same as arc consistency. For binary constraint graphs, 3-consistency is the same as path consistency.

A CSP is **strongly  $k$ -consistent** if it is  $k$ -consistent and is also  $(k - 1)$ -consistent,  $(k - 2)$ -consistent, ... all the way down to 1-consistent. Now suppose we have a CSP with  $n$  nodes and make it strongly  $n$ -consistent (i.e., strongly  $k$ -consistent for  $k = n$ ). We can then solve the problem as follows: First, we choose a consistent value for  $X_1$ . We are then guaranteed to be able to choose a value for  $X_2$  because the graph is 2-consistent, for  $X_3$  because it is 3-consistent, and so on. For each variable  $X_i$ , we need only search through the  $d$  values in the domain to find a value consistent with  $X_1, \dots, X_{i-1}$ . The total run time is only  $O(n^2 d)$ .

Of course, there is no free lunch: constraint satisfaction is NP-complete in general, and any algorithm for establishing  $n$ -consistency must take time exponential in  $n$  in the worst case. Worse,  $n$ -consistency also requires space that is exponential in  $n$ . In practice, determining the appropriate level of consistency checking is mostly an empirical science. Computing 2-consistency is common, and 3-consistency less common.

## 5.2.5 Global constraints

Remember that a **global constraint** is one involving an arbitrary number of variables (but not necessarily all variables). Global constraints occur frequently in real problems and can be handled by special-purpose algorithms that are more efficient than the general-purpose methods described so far. For example, the *Alldiff* constraint says that all the variables involved must have distinct values (as in the cryptarithmetic problem above and Sudoku puzzles below). One simple form of inconsistency detection for *Alldiff* constraints works as follows: if  $m$  variables are involved in the constraint, and if they have  $n$  possible distinct values altogether, and  $m > n$ , then the constraint cannot be satisfied.

This leads to the following simple algorithm: First, remove any variable in the constraint that has a singleton domain, and delete that variable's value from the domains of the remaining variables. Repeat as long as there are singleton variables. If at any point an empty domain is produced or there are more variables than domain values left, then an inconsistency has been detected.

This method can detect the inconsistency in the assignment  $\{WA = red, NSW = red\}$  for Figure 5.1. Notice that the variables  $SA$ ,  $NT$ , and  $Q$  are effectively connected by an *Alldiff* constraint because each pair must have two different colors. After applying AC-3 with the partial assignment, the domains of  $SA$ ,  $NT$ , and  $Q$  are all reduced to  $\{green, blue\}$ . That is, we have three variables and only two colors, so the *Alldiff* constraint is violated. Thus, a simple consistency procedure for a higher-order constraint is sometimes more effective than applying arc consistency to an equivalent set of binary constraints.

Another important higher-order constraint is the **resource constraint**, sometimes called the *Atmost* constraint. For example, in a scheduling problem, let  $P_1, \dots, P_4$  denote the numbers of personnel assigned to each of four tasks. The constraint that no more than 10 personnel are assigned in total is written as  $Atmost(10, P_1, P_2, P_3, P_4)$ . We can detect an inconsistency simply by checking the sum of the minimum values of the current domains; for example, if each variable has the domain  $\{3, 4, 5, 6\}$ , the *Atmost* constraint cannot be satisfied. We can also enforce consistency by deleting the maximum value of any domain if it is not consistent with the minimum values of the other domains. Thus, if each variable in our example has the domain  $\{2, 3, 4, 5, 6\}$ , the values 5 and 6 can be deleted from each domain.

For large resource-limited problems with integer values—such as logistical problems involving moving thousands of people in hundreds of vehicles—it is usually not possible to represent the domain of each variable as a large set of integers and gradually reduce that set by consistency-checking methods. Instead, domains are represented by upper and lower bounds and are managed by **bounds propagation**. For example, in an airline-scheduling problem, let's suppose there are two flights,  $F_1$  and  $F_2$ , for which the planes have capacities 165 and 385, respectively. The initial domains for the numbers of passengers on flights  $F_1$  and  $F_2$  are then

$$D_1 = [0, 165] \quad \text{and} \quad D_2 = [0, 385].$$

Now suppose we have the additional constraint that the two flights together must carry 420 people:  $F_1 + F_2 = 420$ . Propagating bounds constraints, we reduce the domains to

$$D_1 = [35, 165] \quad \text{and} \quad D_2 = [255, 385].$$

We say that a CSP is **bounds-consistent** if for every variable  $X$ , and for both the lower-bound and upper-bound values of  $X$ , there exists some value of  $Y$  that satisfies the constraint between  $X$  and  $Y$  for every variable  $Y$ . This kind of bounds propagation is widely used in practical constraint problems.

## 5.2.6 Sudoku

The popular **Sudoku** puzzle has introduced millions of people to constraint satisfaction problems, although they may not realize it. A Sudoku board consists of 81 squares, some of which are initially filled with digits from 1 to 9. The puzzle is to fill in all the remaining squares such that no digit appears twice in any row, column, or  $3 \times 3$  box (see Figure 5.4). A row, column, or box is called a **unit**.

**Resource constraint**

H	8	1	4	2	5	3	7	6	9
I	6	9	5	4	1	7	3	8	2

(b)

**Figure 5.4** (a) A Sudoku puzzle and (b) its solution.

The Sudoku puzzles that appear in newspapers and puzzle books have the property that there is exactly one solution. Although some can be tricky to solve by hand, taking tens of minutes, a CSP solver can handle thousands of puzzles per second.

A Sudoku puzzle can be considered a CSP with 81 variables, one for each square. We use the variable names  $A1$  through  $A9$  for the top row (left to right), down to  $I1$  through  $I9$  for the bottom row. The empty squares have the domain  $\{1, 2, 3, 4, 5, 6, 7, 8, 9\}$  and the pre-filled squares have a domain consisting of a single value. In addition, there are 27 different  $AllDiff$  constraints, one for each unit (row, column, and box of 9 squares):

$$\begin{aligned}
 &AllDiff(A1, A2, A3, A4, A5, A6, A7, A8, A9) \\
 &AllDiff(B1, B2, B3, B4, B5, B6, B7, B8, B9) \\
 &\dots \\
 &AllDiff(A1, B1, C1, D1, E1, F1, G1, H1, I1) \\
 &AllDiff(A2, B2, C2, D2, E2, F2, G2, H2, I2) \\
 &\dots \\
 &AllDiff(A1, A2, A3, B1, B2, B3, C1, C2, C3) \\
 &AllDiff(A4, A5, A6, B4, B5, B6, C4, C5, C6) \\
 &\dots
 \end{aligned}$$

Let us see how far arc consistency can take us. Assume that the  $AllDiff$  constraints have been expanded into binary constraints (such as  $A1 \neq A2$ ) so that we can apply the AC-3 algorithm directly. Consider variable  $E6$  from Figure 5.4(a)—the empty square between the 2 and the 8 in the middle box. From the constraints in the box, we can remove 1, 2, 7, and 8 from  $E6$ 's domain. From the constraints in its column, we can eliminate 5, 6, 2, 8, 9, and 3 (although 2 and 8 were already removed). That leaves  $E6$  with a domain of  $\{4\}$ ; in other words, we know the answer for  $E6$ . Now consider variable  $I6$ —the square in the bottom middle box surrounded by 1, 3, and 3. Applying arc consistency in its column, we eliminate 5, 6, 2, 4 (since we now know  $E6$  must be 4), 8, 9, and 3. We eliminate 1 by arc consistency with  $I5$ ,

and we are left with only the value 7 in the domain of  $I6$ . Now there are 8 known values in column 6, so arc consistency can infer that  $A6$  must be 1. Inference continues along these lines, and eventually, AC-3 can solve the entire puzzle—all the variables have their domains reduced to a single value, as shown in Figure 5.4(b).

Of course, Sudoku would soon lose its appeal if every puzzle could be solved by a mechanical application of AC-3, and indeed AC-3 works only for the easiest Sudoku puzzles. Slightly harder ones can be solved by PC-2, but at a greater computational cost: there are 255,960 different path constraints to consider in a Sudoku puzzle. To solve the hardest puzzles and to make efficient progress, we will have to be more clever.

Indeed, the appeal of Sudoku puzzles for the human solver is the need to be resourceful in applying more complex inference strategies. Aficionados give them colorful names, such as “naked triples.” That strategy works as follows: in any unit (row, column or box), find three squares that each have a domain that contains the same three numbers or a subset of those numbers. For example, the three domains might be  $\{1, 8\}$ ,  $\{3, 8\}$ , and  $\{1, 3, 8\}$ . From that we don’t know which square contains 1, 3, or 8, but we do know that the three numbers must be distributed among the three squares. Therefore we can remove 1, 3, and 8 from the domains of every *other* square in the unit.

It is interesting to note how far we can go without saying much that is specific to Sudoku. We do of course have to say that there are 81 variables, that their domains are the digits 1 to 9, and that there are 27 *Alldiff* constraints. But beyond that, all the strategies—arc consistency, path consistency, and so on—apply generally to all CSPs, not just to Sudoku problems. Even naked triples is really a strategy for enforcing consistency of *Alldiff* constraints and is not specific to Sudoku *per se*. This is the power of the CSP formalism: for each new problem area, we only need to define the problem in terms of constraints; then the general constraint-solving mechanisms can take over.

## 5.3 Backtracking Search for CSPs

---

Sometimes we can finish the constraint propagation process and still have variables with multiple possible values. In that case we have to **search** for a solution. In this section we cover backtracking search algorithms that work on partial assignments; in the next section we look at local search algorithms over complete assignments.

Consider how a standard depth-limited search (from Chapter 3) could solve CSPs. A state would be a partial assignment, and an action would extend the assignment, adding, say,  $NSW = \text{red}$  or  $SA = \text{blue}$  for the Australia map-coloring problem. For a CSP with  $n$  variables of domain size  $d$  we would end up with a search tree where all the complete assignments (and thus all the solutions) are leaf nodes at depth  $n$ . But notice that the branching factor at the top level would be  $nd$  because any of  $d$  values can be assigned to any of  $n$  variables. At the next level, the branching factor is  $(n - 1)d$ , and so on for  $n$  levels. So the tree has  $n! \cdot d^n$  leaves, even though there are only  $d^n$  possible complete assignments!

We can get back that factor of  $n!$  by recognizing a crucial property of CSPs: **commutativity**. A problem is commutative if the order of application of any given set of actions does not matter. In CSPs, it makes no difference if we first assign  $NSW = \text{red}$  and then  $SA = \text{blue}$ , or the other way around. Therefore, we need only consider a *single* variable at each node in the search tree. At the root we might make a choice between  $SA = \text{red}$ ,  $SA = \text{green}$ , and

Commutativity

```

function BACKTRACKING-SEARCH(csp) returns a solution or failure
  return BACKTRACK(csp, {})

function BACKTRACK(csp, assignment) returns a solution or failure
  if assignment is complete then return assignment
  var  $\leftarrow$  SELECT-UNASSIGNED-VARIABLE(csp, assignment)
  for each value in ORDER-DOMAIN-VALUES(csp, var, assignment) do
    if value is consistent with assignment then
      add {var = value} to assignment
      inferences  $\leftarrow$  INFERENCE(csp, var, assignment)
      if inferences  $\neq$  failure then
        add inferences to csp
        result  $\leftarrow$  BACKTRACK(csp, assignment)
        if result  $\neq$  failure then return result
        remove inferences from csp
        remove {var = value} from assignment
  return failure

```

**Figure 5.5** A simple backtracking algorithm for constraint satisfaction problems. The algorithm is modeled on the recursive depth-first search of Chapter 3. The functions SELECT-UNASSIGNED-VARIABLE and ORDER-DOMAIN-VALUES implement the general-purpose heuristics discussed in Section 5.3.1. The INFERENCE function can optionally impose arc-, path-, or *k*-consistency, as desired. If a value choice leads to failure (noticed either by INFERENCE or by BACKTRACK), then value assignments (including those made by INFERENCE) are retracted and a new value is tried.

---

$SA = blue$ , but we would never choose between  $NSW = red$  and  $SA = blue$ . With this restriction, the number of leaves is  $d^n$ , as we would hope. At each level of the tree we do have to choose which variable we will deal with, but we never have to backtrack over that choice.

Figure 5.5 shows a backtracking search procedure for CSPs. It repeatedly chooses an unassigned variable, and then tries all values in the domain of that variable in turn, trying to extend each one into a solution via a recursive call. If the call succeeds, the solution is returned, and if it fails, the assignment is restored to the previous state, and we try the next value. If no value works then we return failure. Part of the search tree for the Australia problem is shown in Figure 5.6, where we have assigned variables in the order  $WA, NT, Q, \dots$

Notice that BACKTRACKING-SEARCH keeps only a single representation of a state (*assignment*) and alters that representation rather than creating new ones (see page 98).

Whereas the uninformed search algorithms of Chapter 3 could be improved only by supplying them with *domain-specific* heuristics, it turns out that backtracking search can be improved using *domain-independent* heuristics that take advantage of the factored representation of CSPs. In the following four sections we show how this is done:

- (5.3.1) Which variable should be assigned next (SELECT-UNASSIGNED-VARIABLE), and in what order should its values be tried (ORDER-DOMAIN-VALUES)?
- (5.3.2) What inferences should be performed at each step in the search (INFERENCE)?
- (5.3.3) Can we BACKTRACK more than one step when appropriate?
- (5.3.4) Can we save and reuse partial results from the search?

**Figure 5.6** Part of the search tree for the map-coloring problem in Figure 5.1.

### 5.3.1 Variable and value ordering

The backtracking algorithm contains the line

```
var ← SELECT-UNASSIGNED-VARIABLE(csp, assignment) .
```

The simplest strategy for SELECT-UNASSIGNED-VARIABLE is static ordering: choose the variables in order,  $\{X_1, X_2, \dots\}$ . The next simplest is to choose randomly. Neither strategy is optimal. For example, after the assignments for  $WA = \text{red}$  and  $NT = \text{green}$  in Figure 5.6, there is only one possible value for  $SA$ , so it makes sense to assign  $SA = \text{blue}$  next rather than assigning  $Q$ . In fact, after  $SA$  is assigned, the choices for  $Q, NSW$ , and  $V$  are all forced.

This intuitive idea—choosing the variable with the fewest “legal” values—is called the **minimum-remaining-values** (MRV) heuristic. It also has been called the “most constrained variable” or “fail-first” heuristic, the latter because it picks a variable that is most likely to cause a failure soon, thereby pruning the search tree. If some variable  $X$  has no legal values left, the MRV heuristic will select  $X$  and failure will be detected immediately—avoiding pointless searches through other variables. The MRV heuristic usually performs better than a random or static ordering, sometimes by orders of magnitude, although the results vary depending on the problem.

The MRV heuristic doesn’t help at all in choosing the first region to color in Australia, because initially every region has three legal colors. In this case, the **degree heuristic** comes in handy. It attempts to reduce the branching factor on future choices by selecting the variable that is involved in the largest number of constraints on other unassigned variables. In Figure 5.1,  $SA$  is the variable with highest degree, 5; the other variables have degree 2 or 3, except for  $T$ , which has degree 0. If we assign the  $SA$  first, we can then go around the five mainland regions in clockwise or counterclockwise order and assign each one a color that is different than  $SA$  and different than the previous region. The minimum-remaining-values heuristic is usually a more powerful guide, but the degree heuristic can be useful as a tie-breaker.

Once a variable has been selected, the algorithm must decide on the order in which to examine its values. The **least-constraining-value** heuristic is effective for this. It prefers the value that rules out the fewest choices for the neighboring variables in the constraint

Minimum-remaining-values

Degree heuristic

Least-constraining-value

graph. For example, suppose that in Figure 5.1 we have generated the partial assignment with  $WA = \text{red}$  and  $NT = \text{green}$  and that our next choice is for  $Q$ . Blue would be a bad choice because it eliminates the last legal value left for  $Q$ 's neighbor,  $SA$ . The least-constraining-value heuristic therefore prefers red to blue. In general, the heuristic is trying to leave the maximum flexibility for subsequent variable assignments.

Why should variable selection be fail-first, but value selection be fail-last? Every variable has to be assigned eventually, so by choosing the ones that are likely to fail first, we will on average have fewer successful assignments to backtrack over. For value ordering, the trick is that we only need one solution; therefore it makes sense to look for the most likely values first. If we wanted to enumerate all solutions rather than just find one, then value ordering would be irrelevant.

### 5.3.2 Interleaving search and inference

We saw how AC-3 can reduce the domains of variables *before* we begin the search. But inference can be even more powerful *during* the course of a search: every time we make a choice of a value for a variable, we have a brand-new opportunity to infer new domain reductions on the neighboring variables.

#### Forward checking

One of the simplest forms of inference is called **forward checking**. Whenever a variable  $X$  is assigned, the forward-checking process establishes arc consistency for it: for each unassigned variable  $Y$  that is connected to  $X$  by a constraint, delete from  $Y$ 's domain any value that is inconsistent with the value chosen for  $X$ .

Figure 5.7 shows the progress of backtracking search on the Australia CSP with forward checking. There are two important points to notice about this example. First, notice that after  $WA = \text{red}$  and  $Q = \text{green}$  are assigned, the domains of  $NT$  and  $SA$  are reduced to a single value; we have eliminated branching on these variables altogether by propagating information from  $WA$  and  $Q$ . A second point to notice is that after  $V = \text{blue}$ , the domain of  $SA$  is empty. Hence, forward checking has detected that the partial assignment  $\{WA = \text{red}, Q = \text{green}, V = \text{blue}\}$  is inconsistent with the constraints of the problem, and the algorithm backtracks immediately.

For many problems the search will be more effective if we combine the MRV heuristic with forward checking. Consider Figure 5.7 after assigning  $\{WA = \text{red}\}$ . Intuitively, it seems that that assignment constrains its neighbors,  $NT$  and  $SA$ , so we should handle those variables next, and then all the other variables will fall into place. That's exactly what happens with MRV:  $NT$  and  $SA$  each have two values, so one of them is chosen first, then the other, then  $Q$ ,  $NSW$ , and  $V$  in order. Finally  $T$  still has three values, and any one of them works. We can view forward checking as an efficient way to incrementally compute the information that the MRV heuristic needs to do its job.

Although forward checking detects many inconsistencies, it does not detect all of them. The problem is that it doesn't look ahead far enough. For example, consider the  $Q = \text{green}$  row of Figure 5.7. We've made  $WA$  and  $Q$  arc-consistent, but we've left both  $NT$  and  $SA$  with blue as their only possible value, which is an inconsistency, since they are neighbors.

#### Maintaining Arc Consistency

The algorithm called MAC (for **Maintaining Arc Consistency**) detects inconsistencies like this. After a variable  $X_i$  is assigned a value, the INFERENCE procedure calls AC-3, but instead of a queue of all arcs in the CSP, we start with only the arcs  $(X_j, X_i)$  for all  $X_j$  that are unassigned variables that are neighbors of  $X_i$ . From there, AC-3 does constraint propagation in the usual way, and if any variable has its domain reduced to the empty set, the call to AC-3

	<i>WA</i>	<i>NT</i>	<i>Q</i>	<i>NSW</i>	<i>V</i>	<i>SA</i>	<i>T</i>
Initial domains	red green blue						
After <i>WA</i> =red	red	green blue	red green blue	red green blue	red green blue	green blue	red green blue
After <i>Q</i> =green	red	blue	green	red blue	red blue	blue	red green blue
After <i>V</i> =blue	red	blue	green	red	blue		red green

**Figure 5.7** The progress of a map-coloring search with forward checking. *WA*=red is assigned first; then forward checking deletes red from the domains of the neighboring variables *NT* and *SA*. After *Q*=green is assigned, green is deleted from the domains of *NT*, *SA*, and *NSW*. After *V*=blue is assigned, blue is deleted from the domains of *NSW* and *SA*, leaving *SA* with no legal values.

fails and we know to backtrack immediately. We can see that MAC is strictly more powerful than forward checking because forward checking does the same thing as MAC on the initial arcs in MAC’s queue; but unlike MAC, forward checking does not recursively propagate constraints when changes are made to the domains of variables.

### 5.3.3 Intelligent backtracking: Looking backward

The BACKTRACKING-SEARCH algorithm in Figure 5.5 has a very simple policy for what to do when a branch of the search fails: back up to the preceding variable and try a different value for it. This is called **chronological backtracking** because the *most recent* decision point is revisited. In this subsection, we consider better possibilities.

Consider what happens when we apply simple backtracking in Figure 5.1 with a fixed variable ordering *Q*, *NSW*, *V*, *T*, *SA*, *WA*, *NT*. Suppose we have generated the partial assignment  $\{Q=\text{red}, \text{NSW}=\text{green}, V=\text{blue}, T=\text{red}\}$ . When we try the next variable, *SA*, we see that every value violates a constraint. We back up to *T* and try a new color for Tasmania! Obviously this is silly—recoloring Tasmania cannot possibly help in resolving the problem with South Australia.

A more intelligent approach is to backtrack to a variable that might fix the problem—a variable that was responsible for making one of the possible values of *SA* impossible. To do this, we will keep track of a set of assignments that are in conflict with some value for *SA*. The set (in this case  $\{Q=\text{red}, \text{NSW}=\text{green}, V=\text{blue}\}$ ), is called the **conflict set** for *SA*. The **backjumping** method backtracks to the *most recent* assignment in the conflict set; in this case, backjumping would jump over Tasmania and try a new value for *V*. This method is easily implemented by a modification to BACKTRACK such that it accumulates the conflict set while checking for a legal value to assign. If no legal value is found, the algorithm should return the most recent element of the conflict set along with the failure indicator.

The sharp-eyed reader may have noticed that forward checking can supply the conflict set with no extra work: whenever forward checking based on an assignment  $X=x$  deletes a value from  $Y$ ’s domain, it should add  $X=x$  to  $Y$ ’s conflict set. If the last value is deleted from  $Y$ ’s domain, then the assignments in the conflict set of  $Y$  are added to the conflict set of  $X$ . That is, we now know that  $X=x$  leads to a contradiction (in  $Y$ ), and thus a different assignment should be tried for  $X$ .

Chronological backtracking

Conflict set  
Backjumping

The eagle-eyed reader may have noticed something odd: backjumping occurs when every value in a domain is in conflict with the current assignment; but forward checking detects this event and prevents the search from ever reaching such a node! In fact, it can be shown that *every* branch pruned by backjumping is also pruned by forward checking. Hence, simple backjumping is redundant in a forward-checking search or, indeed, in a search that uses stronger consistency checking, such as MAC—you need only do one or the other.

Despite the observations of the preceding paragraph, the idea behind backjumping remains a good one: to backtrack based on the reasons for failure. Backjumping notices failure when a variable’s domain becomes empty, but in many cases a branch is doomed long before this occurs. Consider again the partial assignment  $\{WA = red, NSW = red\}$  (which, from our earlier discussion, is inconsistent). Suppose we try  $T = red$  next and then assign  $NT, Q, V, SA$ . We know that no assignment can work for these last four variables, so eventually we run out of values to try at  $NT$ . Now, the question is, where to backtrack? Backjumping cannot work, because  $NT$  *does* have values consistent with the preceding assigned variables— $NT$  doesn’t have a complete conflict set of preceding variables that caused it to fail. We know, however, that the four variables  $NT, Q, V$ , and  $SA$ , *taken together*, failed because of a set of preceding variables, which must be those variables that directly conflict with the four.

This leads to a different—and deeper—notion of the conflict set for a variable such as  $NT$ : it is that set of preceding variables that caused  $NT$ , *together with any subsequent variables*, to have no consistent solution. In this case, the set is  $WA$  and  $NSW$ , so the algorithm should backtrack to  $NSW$  and skip over Tasmania. A backjumping algorithm that uses conflict sets defined in this way is called **conflict-directed backjumping**.

We must now explain how these new conflict sets are computed. The method is in fact quite simple. The “terminal” failure of a branch of the search always occurs because a variable’s domain becomes empty; that variable has a standard conflict set. In our example,  $SA$  fails, and its conflict set is (say)  $\{WA, NT, Q\}$ . We backjump to  $Q$ , and  $Q$  *absorbs* the conflict set from  $SA$  (minus  $Q$  itself, of course) into its own direct conflict set, which is  $\{NT, NSW\}$ ; the new conflict set is  $\{WA, NT, NSW\}$ . That is, there is no solution from  $Q$  onward, given the preceding assignment to  $\{WA, NT, NSW\}$ . Therefore, we backtrack to  $NT$ , the most recent of these.  $NT$  absorbs  $\{WA, NT, NSW\} - \{NT\}$  into its own direct conflict set  $\{WA\}$ , giving  $\{WA, NSW\}$  (as stated in the previous paragraph). Now the algorithm backjumps to  $NSW$ , as we would hope. To summarize: let  $X_j$  be the current variable, and let  $conf(X_j)$  be its conflict set. If every possible value for  $X_j$  fails, backjump to the most recent variable  $X_i$  in  $conf(X_j)$  and recompute the conflict set for  $X_i$  as follows:

$$conf(X_i) \leftarrow conf(X_i) \cup conf(X_j) - \{X_i\}.$$

### 5.3.4 Constraint learning

When we reach a contradiction, backjumping can tell us how far to back up, so we don’t waste time changing variables that won’t fix the problem. But we would also like to avoid running into the same problem again. When the search arrives at a contradiction, we know that some subset of the conflict set is responsible for the problem. **Constraint learning** is the idea of finding a minimum set of variables from the conflict set that causes the problem. This set of variables, along with their corresponding values, is called a **no-good**. We then record the no-good, either by adding a new constraint to the CSP to forbid this combination of assignments or by keeping a separate cache of no-goods.

Conflict-directed  
backjumping

Constraint learning

No-good

For example, consider the state  $\{WA = red, NT = green, Q = blue\}$  in the bottom row of Figure 5.6. Forward checking can tell us this state is a no-good because there is no valid assignment to  $SA$ . In this particular case, recording the no-good would not help, because once we prune this branch from the search tree, we will never encounter this combination again. But suppose that the search tree in Figure 5.6 were actually part of a larger search tree that started by first assigning values for  $V$  and  $T$ . Then it would be worthwhile to record  $\{WA = red, NT = green, Q = blue\}$  as a no-good because we are going to run into the same problem again for each possible set of assignments to  $V$  and  $T$ .

No-goods can be effectively used by forward checking or by backjumping. Constraint learning is one of the most important techniques used by modern CSP solvers to achieve efficiency on complex problems.

## 5.4 Local Search for CSPs

Local search algorithms (see Section 4.1) turn out to be very effective in solving many CSPs. They use a complete-state formulation (as introduced in Section 4.1.1) where each state assigns a value to every variable, and the search changes the value of one variable at a time. As an example, we'll use the 8-queens problem, as defined as a CSP on page 167. In Figure 5.8 we start on the left with a complete assignment to the 8 variables; typically this will violate several constraints. We then randomly choose a conflicted variable, which turns out to be  $Q_8$ , the rightmost column. We'd like to change the value to something that brings us closer to a solution; the most obvious approach is to select the value that results in the minimum number of conflicts with other variables—the **min-conflicts** heuristic.

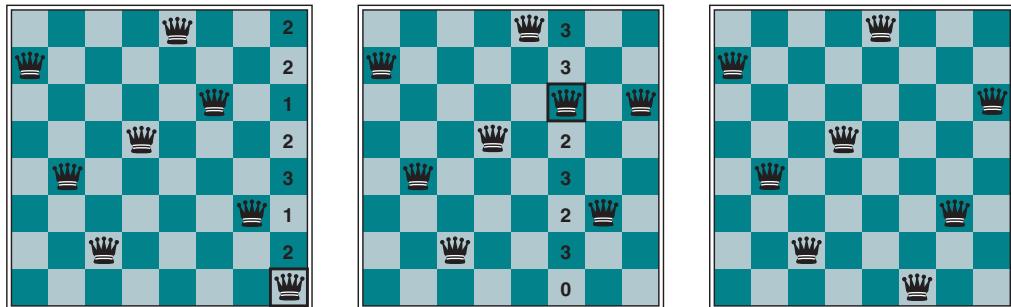

In the figure we see there are two rows that only violate one constraint; we pick  $Q_8 = 3$  (that is, we move the queen to the 8th column, 3rd row). On the next iteration, in the middle board of the figure, we select  $Q_6$  as the variable to change, and note that moving the queen to the 8th row results in no conflicts. At this point there are no more conflicted variables, so we have a solution. The algorithm is shown in Figure 5.9.<sup>2</sup>

Min-conflicts is surprisingly effective for many CSPs. Amazingly, on the  $n$ -queens problem, if you don't count the initial placement of queens, the run time of min-conflicts is roughly *independent of problem size*. It solves even the *million*-queens problem in an average of 50 steps (after the initial assignment). This remarkable observation was the stimulus leading to a great deal of research in the 1990s on local search and the distinction between easy and hard problems, which we take up in Section 7.6.3. Roughly speaking,  $n$ -queens is easy for local search because solutions are densely distributed throughout the state space. Min-conflicts also works well for hard problems. For example, it has been used to schedule observations for the Hubble Space Telescope, reducing the time taken to schedule a week of observations from three weeks (!) to around 10 minutes.

All the local search techniques from Section 4.1 are candidates for application to CSPs, and some of those have proved especially effective. The landscape of a CSP under the min-conflicts heuristic usually has a series of plateaus. There may be millions of variable assignments that are only one conflict away from a solution. Plateau search—allowing sideways moves to another state with the same score—can help local search find its way off this

Min-conflicts

<sup>2</sup> Local search can easily be extended to constrained optimization problems (COPs). In that case, all the techniques for hill climbing and simulated annealing can be applied to optimize the objective function.

**Figure 5.8** A two-step solution using min-conflicts for an 8-queens problem. At each stage, a queen is chosen for reassignment in its column. The number of conflicts (in this case, the number of attacking queens) is shown in each square. The algorithm moves the queen to the min-conflicts square, breaking ties randomly.

```

function MIN-CONFLICTS(csp, max_steps) returns a solution or failure
  inputs: csp, a constraint satisfaction problem
           max_steps, the number of steps allowed before giving up
  current  $\leftarrow$  an initial complete assignment for csp
  for i = 1 to max_steps do
    if current is a solution for csp then return current
    var  $\leftarrow$  a randomly chosen conflicted variable from csp.VARIABLES
    value  $\leftarrow$  the value v for var that minimizes CONFLICTS(csp, var, v, current)
    set var = value in current
  return failure

```

**Figure 5.9** The MIN-CONFLICTS local search algorithm for CSPs. The initial state may be chosen randomly or by a greedy assignment process that chooses a minimal-conflict value for each variable in turn. The CONFLICTS function counts the number of constraints violated by a particular value, given the rest of the current assignment.

plateau. This wandering on the plateau can be directed with a technique called **tabu search**: keeping a small list of recently visited states and forbidding the algorithm to return to those states. Simulated annealing can also be used to escape from plateaus.

#### Constraint weighting

Another technique called **constraint weighting** aims to concentrate the search on the important constraints. Each constraint is given a numeric weight, initially all 1. At each step of the search, the algorithm chooses a variable/value pair to change that will result in the lowest total weight of all violated constraints. The weights are then adjusted by incrementing the weight of each constraint that is violated by the current assignment. This has two benefits: it adds topography to plateaus, making sure that it is possible to improve from the current state, and it also adds learning: over time the difficult constraints are assigned higher weights.

Another advantage of local search is that it can be used in an online setting (see Section 4.5) when the problem changes. Consider a scheduling problem for an airline's weekly flights. The schedule may involve thousands of flights and tens of thousands of personnel

assignments, but bad weather at one airport can render the schedule infeasible. We would like to repair the schedule with a minimum number of changes. This can be easily done with a local search algorithm starting from the current schedule. A backtracking search with the new set of constraints usually requires much more time and might find a solution with many changes from the current schedule.

## 5.5 The Structure of Problems

In this section, we examine ways in which the *structure* of the problem, as represented by the constraint graph, can be used to find solutions quickly. Most of the approaches here also apply to other problems besides CSPs, such as probabilistic reasoning.

The only way we can possibly hope to deal with the vast real world is to decompose it into subproblems. Looking again at the constraint graph for Australia (Figure 5.1(b), repeated as Figure 5.12(a)), one fact stands out: Tasmania is not connected to the mainland.<sup>3</sup> Intuitively, it is obvious that coloring Tasmania and coloring the mainland are **independent subproblems**—any solution for the mainland combined with any solution for Tasmania yields a solution for the whole map.

Independence can be ascertained simply by finding **connected components** of the constraint graph. Each component corresponds to a subproblem  $CSP_i$ . If assignment  $S_i$  is a solution of  $CSP_i$ , then  $\bigcup_i S_i$  is a solution of  $\bigcup_i CSP_i$ . Why is this important? Suppose each  $CSP_i$  has  $c$  variables from the total of  $n$  variables, where  $c$  is a constant. Then there are  $n/c$  subproblems, each of which takes at most  $d^c$  work to solve, where  $d$  is the size of the domain. Hence, the total work is  $O(d^c n/c)$ , which is *linear* in  $n$ ; without the decomposition, the total work is  $O(d^n)$ , which is exponential in  $n$ . Let's make this more concrete: dividing a Boolean CSP with 100 variables into four subproblems reduces the worst-case solution time from the lifetime of the universe down to less than a second.

Completely independent subproblems are delicious, then, but rare. Fortunately, some other graph structures are also easy to solve. For example, a constraint graph is a **tree** when any two variables are connected by only one path. We will show that *any tree-structured CSP can be solved in time linear in the number of variables*.<sup>4</sup> The key is a new notion of consistency, called **directional arc consistency** or DAC. A CSP is defined to be directional arc-consistent under an ordering of variables  $X_1, X_2, \dots, X_n$  if and only if every  $X_i$  is arc-consistent with each  $X_j$  for  $j > i$ .

To solve a tree-structured CSP, first pick any variable to be the root of the tree, and choose an ordering of the variables such that each variable appears after its parent in the tree. Such an ordering is called a **topological sort**. Figure 5.10(a) shows a sample tree and (b) shows one possible ordering. Any tree with  $n$  nodes has  $n - 1$  edges, so we can make this graph directed arc-consistent in  $O(n)$  steps, each of which must compare up to  $d$  possible domain values for two variables, for a total time of  $O(nd^2)$ . Once we have a directed arc-consistent graph, we can just march down the list of variables and choose any remaining value. Since each edge from a parent to its child is arc-consistent, we know that for any value we choose for the parent, there will be a valid value left to choose for the child. That means we won't

Independent subproblems

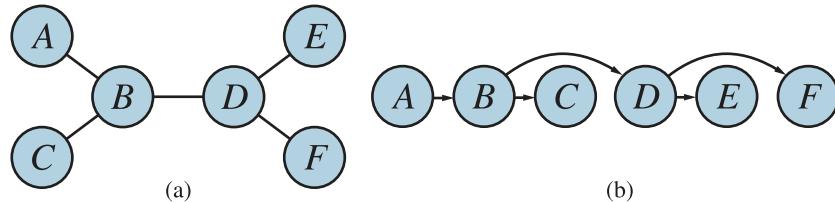

Connected component

Directional arc consistency

Topological sort

<sup>3</sup> A careful cartographer or patriotic Tasmanian might object that Tasmania should not be colored the same as its nearest mainland neighbor, to avoid the impression that it *might* be part of that state.

<sup>4</sup> Sadly, very few regions of the world have tree-structured maps, although Sulawesi comes close.

**Figure 5.10** (a) The constraint graph of a tree-structured CSP. (b) A linear ordering of the variables consistent with the tree with  $A$  as the root. This is known as a **topological sort** of the variables.

---

```

function TREE-CSP-SOLVER(csp) returns a solution, or failure
  inputs: csp, a CSP with components  $X$ ,  $D$ ,  $C$ 

   $n \leftarrow$  number of variables in  $X$ 
  assignment  $\leftarrow$  an empty assignment
  root  $\leftarrow$  any variable in  $X$ 
   $X \leftarrow \text{TOPOLOGICALSORT}(X, \text{root})$ 
  for  $j = n$  down to 2 do
    MAKE-ARC-CONSISTENT(PARENT( $X_j$ ),  $X_j$ )
    if it cannot be made consistent then return failure
  for  $i = 1$  to  $n$  do
    assignment[ $X_i$ ]  $\leftarrow$  any consistent value from  $D_i$ 
    if there is no consistent value then return failure
  return assignment

```

---

**Figure 5.11** The TREE-CSP-SOLVER algorithm for solving tree-structured CSPs. If the CSP has a solution, we will find it in linear time; if not, we will detect a contradiction.

have to backtrack; we can move linearly through the variables. The complete algorithm is shown in Figure 5.11.

Now that we have an efficient algorithm for trees, we can consider whether more general constraint graphs can be *reduced* to trees somehow. There are two ways to do this: by removing nodes (Section 5.5.1) or by collapsing nodes together (Section 5.5.2).

### 5.5.1 Cutset conditioning

The first way to reduce a constraint graph to a tree involves assigning values to some variables so that the remaining variables form a tree. Consider the constraint graph for Australia, shown again in Figure 5.12(a). Without South Australia, the graph would become a tree, as in (b). Fortunately, we can delete South Australia (in the graph, not the country) by fixing a value for SA and deleting from the domains of the other variables any values that are inconsistent with the value chosen for SA.

Now, any solution for the CSP after SA and its constraints are removed will be consistent with the value chosen for SA. (This works for binary CSPs; the situation is more complicated with higher-order constraints.) Therefore, we can solve the remaining tree with the algorithm

**Figure 5.12** (a) The original constraint graph from Figure 5.1. (b) After the removal of SA, the constraint graph becomes a forest of two trees.

given above and thus solve the whole problem. Of course, in the general case (as opposed to map coloring), the value chosen for *SA* could be the wrong one, so we would need to try each possible value. The general algorithm is as follows:

1. Choose a subset  $S$  of the CSP's variables such that the constraint graph becomes a tree after removal of  $S$ .  $S$  is called a **cycle cutset**. Cycle cutset
2. For each possible assignment to the variables in  $S$  that satisfies all constraints on  $S$ ,
  - (a) remove from the domains of the remaining variables any values that are inconsistent with the assignment for  $S$ , and
  - (b) if the remaining CSP has a solution, return it together with the assignment for  $S$ .

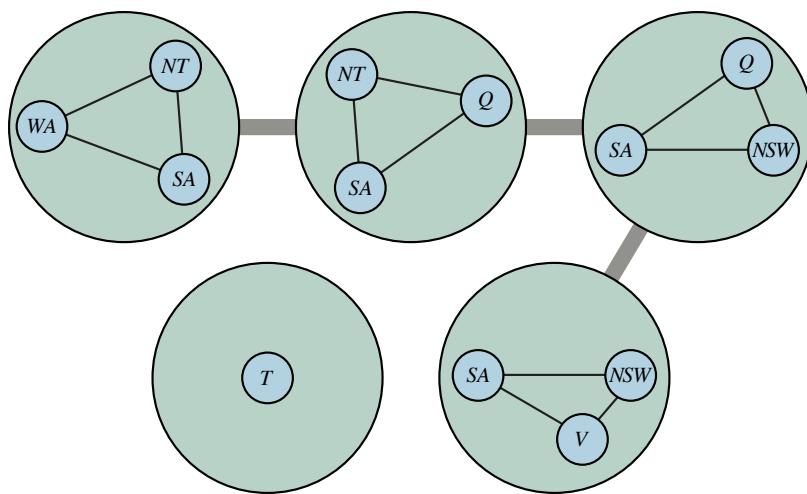

If the cycle cutset has size  $c$ , then the total run time is  $O(d^c \cdot (n - c)d^2)$ : we have to try each of the  $d^c$  combinations of values for the variables in  $S$ , and for each combination we must solve a tree problem of size  $n - c$ . If the graph is “nearly a tree,” then  $c$  will be small and the savings over straight backtracking will be huge—for our 100-Boolean-variable example, if we could find a cutset of size  $c = 20$ , this would get us down from the lifetime of the Universe to a few minutes. In the worst case, however,  $c$  can be as large as  $(n - 2)$ . Finding the *smallest* cycle cutset is NP-hard, but several efficient approximation algorithms are known. The overall algorithmic approach is called **cutset conditioning**; it comes up again in Chapter 13, where it is used for reasoning about probabilities. Cutset conditioning

### 5.5.2 Tree decomposition

The second way to reduce a constraint graph to a tree is based on constructing a **tree decomposition** of the constraint graph: a transformation of the original graph into a tree where each node in the tree consists of a set of variables, as in Figure 5.13. A tree decomposition must satisfy these three requirements:

- Every variable in the original problem appears in at least one of the tree nodes.
- If two variables are connected by a constraint in the original problem, they must appear together (along with the constraint) in at least one of the tree nodes.
- If a variable appears in two nodes in the tree, it must appear in every node along the path connecting those nodes.

**Tree decomposition**

**Figure 5.13** A tree decomposition of the constraint graph in Figure 5.12(a).

The first two conditions ensure that all the variables and constraints are represented in the tree decomposition. The third condition seems rather technical, but allows us to say that any variable from the original problem must have the same value wherever it appears: the constraints in the tree say that a variable in one node of the tree must have the same value as the corresponding variable in the adjacent node in the tree. For example, SA appears in all four of the connected nodes in Figure 5.13, so each edge in the tree decomposition therefore includes the constraint that the value of SA in one node must be the same as the value of SA in the next. You can verify from Figure 5.12 that this decomposition makes sense.

Once we have a tree-structured graph, we can apply TREE-CSP-SOLVER to get a solution in  $O(nd^2)$  time, where  $n$  is the number of tree nodes and  $d$  is the size of the largest domain. But note that in the tree, a domain is a set of *tuples* of values, not just individual values.

For example, the top left node in Figure 5.13 represents, at the level of the original problem, a subproblem with variables  $\{WA, NT, SA\}$ , domain  $\{\text{red, green, blue}\}$ , and constraints  $WA \neq NT, SA \neq NT, WA \neq SA$ . At the level of the tree, the node represents a single variable, which we can call *SANTWA*, whose value must be a three-tuple of colors, such as  $(\text{red, green, blue})$ , but not  $(\text{red, red, blue})$ , because that would violate the constraint  $SA \neq NT$  from the original problem. We can then move from that node to the adjacent one, with the variable we can call *SANTQ*, and find that there is only one tuple,  $(\text{red, green, blue})$ , that is consistent with the choice for *SANTWA*. The exact same process is repeated for the next two nodes, and independently we can make any choice for *T*.

We can solve any tree decomposition problem in  $O(nd^2)$  time with TREE-CSP-SOLVER, which will be efficient as long as  $d$  remains small. Going back to our example with 100 Boolean variables, if each node has 10 variables, then  $d = 2^{10}$  and we should be able to solve the problem in seconds. But if there is a node with 30 variables, it would take centuries.

A given graph admits many tree decompositions; in choosing a decomposition, the aim is to make the subproblems as small as possible. (Putting all the variables into one node is technically a tree, but is not helpful.) The **tree width** of a tree decomposition of a graph is

one less than the size of the largest node; the tree width of the graph itself is defined to be the minimum width among all its tree decompositions. If a graph has tree width  $w$  then the problem can be solved in  $O(nd^{w+1})$  time given the corresponding tree decomposition. Hence, *CSPs with constraint graphs of bounded tree width are solvable in polynomial time.*

Unfortunately, finding the decomposition with minimal tree width is NP-hard, but there are heuristic methods that work well in practice. Which is better: the cutset decomposition with time  $O(d^c \cdot (n - c)d^2)$ , or the tree decomposition with time  $O(nd^{w+1})$ ? Whenever you have a cycle-cutset of size  $c$ , there is also a tree width of size  $w < c + 1$ , and it may be far smaller in some cases. So time consideration favors tree decomposition, but the advantage of the cycle-cutset approach is that it can be executed in linear memory, while tree decomposition requires memory exponential in  $w$ .

### 5.5.3 Value symmetry

So far, we have looked at the structure of the constraint graph. There can also be important structure in the *values* of variables, or in the structure of the constraint relations themselves. Consider the map-coloring problem with  $d$  colors. For every consistent solution, there is actually a set of  $d!$  solutions formed by permuting the color names. For example, on the Australia map we know that *WA*, *NT*, and *SA* must all have different colors, but there are  $3! = 6$  ways to assign three colors to three regions. This is called **value symmetry**. We would like to reduce the search space by a factor of  $d!$  by breaking the symmetry in assignments. We do this by introducing a **symmetry-breaking constraint**. For our example, we might impose an arbitrary ordering constraint,  $NT < SA < WA$ , that requires the three values to be in alphabetical order. This constraint ensures that only one of the  $d!$  solutions is possible:  $\{NT = \text{blue}, SA = \text{green}, WA = \text{red}\}$ .

For map coloring, it was easy to find a constraint that eliminates the symmetry. In general it is NP-hard to eliminate all symmetry, but breaking value symmetry has proved to be important and effective on a wide range of problems.

## Summary

- **Constraint satisfaction problems** (CSPs) represent a state with a set of variable/value pairs and represent the conditions for a solution by a set of constraints on the variables. Many important real-world problems can be described as CSPs.
- A number of **inference** techniques use the constraints to rule out certain variable assignments. These include node, arc, path, and  $k$ -consistency.
- **Backtracking search**, a form of depth-first search, is commonly used for solving CSPs. Inference can be interwoven with search.
- The **minimum-remaining-values** and **degree** heuristics are domain-independent methods for deciding which variable to choose next in a backtracking search. The **least-constraining-value** heuristic helps in deciding which value to try first for a given variable. Backtracking occurs when no legal assignment can be found for a variable. **Conflict-directed backjumping** backtracks directly to the source of the problem. **Constraint learning** records the conflicts as they are encountered during search in order to avoid the same conflict later in the search.

Value symmetry

Symmetry-breaking constraint

- Local search using the **min-conflicts** heuristic has also been applied to constraint satisfaction problems with great success.
- The complexity of solving a CSP is strongly related to the structure of its constraint graph. Tree-structured problems can be solved in linear time. **Cutset conditioning** can reduce a general CSP to a tree-structured one and is quite efficient (requiring only linear memory) if a small cutset can be found. **Tree decomposition** techniques transform the CSP into a tree of subproblems and are efficient if the **tree width** of the constraint graph is small; however they need memory exponential in the tree width of the constraint graph. Combining cutset conditioning with tree decomposition can allow a better tradeoff of memory versus time.

## Bibliographical and Historical Notes

---

**Diophantine equations**

The Greek mathematician Diophantus (c. 200–284) presented and solved problems involving algebraic constraints on equations, although he didn't develop a generalized methodology. We now call equations over integer domains **Diophantine equations**. The Indian mathematician Brahmagupta (c. 650) was the first to show a general solution over the domain of integers for the equation  $ax + by = c$ . Systematic methods for solving linear equations by variable elimination were studied by Gauss (1829); the solution of linear inequality constraints goes back to Fourier (1827).

Finite-domain constraint satisfaction problems also have a long history. For example, **graph coloring** (of which map coloring is a special case) is an old problem in mathematics. The four-color conjecture (that every planar graph can be colored with four or fewer colors) was first made by Francis Guthrie, a student of De Morgan, in 1852. It resisted solution—despite several published claims to the contrary—until a proof was devised by Appel and Haken (1977) (see the book *Four Colors Suffice* (Wilson, 2004)). Purists were disappointed that part of the proof relied on a computer, so Georges Gonthier (2008), using the COQ theorem prover, derived a formal proof that Appel and Haken's proof program was correct.

Specific classes of constraint satisfaction problems occur throughout the history of computer science. One of the most influential early examples was SKETCHPAD (Sutherland, 1963), which solved geometric constraints in diagrams and was the forerunner of modern drawing programs and CAD tools. The identification of CSPs as a *general* class is due to Ugo Montanari (1974). The reduction of higher-order CSPs to purely binary CSPs with auxiliary variables (see Exercise 5.NARY) is due originally to the 19th-century logician Charles Sanders Peirce. It was introduced into the CSP literature by Dechter (1990b) and was elaborated by Bacchus and van Beek (1998). CSPs with preferences among solutions are studied widely in the optimization literature; see Bistarelli *et al.* (1997) for a generalization of the CSP framework to allow for preferences.

Constraint propagation methods were popularized by Waltz's (1975) success on polyhedral line-labeling problems for computer vision. Waltz showed that in many problems, propagation completely eliminates the need for backtracking. Montanari (1974) introduced the notion of constraint graphs and propagation by path consistency. Alan Mackworth (1977) proposed the AC-3 algorithm for enforcing arc consistency as well as the general idea of combining backtracking with some degree of consistency enforcement. AC-4, a more efficient

arc-consistency algorithm developed by Mohr and Henderson (1986), runs in  $O(cd^2)$  worst-case time but can be slower than AC-3 on average cases. The PC-2 algorithm (Mackworth, 1977) achieves path consistency in much the same way that AC-3 achieves arc consistency.

Soon after Mackworth's paper appeared, researchers began experimenting with the trade-off between the cost of consistency enforcement and the benefits in terms of search reduction. Haralick and Elliott (1980) favored the minimal forward-checking algorithm described by McGregor (1979), whereas Gaschnig (1979) suggested full arc-consistency checking after each variable assignment—an algorithm later called MAC by Sabin and Freuder (1994). The latter paper provides somewhat convincing evidence that on harder CSPs, full arc-consistency checking pays off. Freuder (1978, 1982) investigated the notion of  $k$ -consistency and its relationship to the complexity of solving CSPs. Dechter and Dechter (1987) introduced directional arc consistency. Apt (1999) describes a generic algorithmic framework within which consistency propagation algorithms can be analyzed, and surveys are given by Bessière (2006) and Barták *et al.* (2010).

Special methods for handling higher-order or global constraints were developed first within the context of **constraint logic programming**. Marriott and Stuckey (1998) provide excellent coverage of research in this area. The *Alldiff* constraint was studied by Regin (1994), Stergiou and Walsh (1999), and van Hoeve (2001). There are more complex inference algorithms for *Alldiff* (see van Hoeve and Katriel, 2006) that propagate more constraints but are more computationally expensive to run. Bounds constraints were incorporated into constraint logic programming by Van Hentenryck *et al.* (1998). A survey of global constraints is provided by van Hoeve and Katriel (2006).

Constraint logic  
programming

Sudoku has become the most widely known CSP and was described as such by Simonis (2005). Agerbeck and Hansen (2008) describe some of the strategies and show that Sudoku on an  $n^2 \times n^2$  board is in the class of *NP*-hard problems.

In 1850, C. F. Gauss described a recursive backtracking algorithm for solving the 8-queens problem, which had been published in the German chess magazine *Schachzeitung* in 1848. Gauss called his method *Tattonniren*, derived from the French word *tâtonner*—to grope around, as if in the dark.

According to Donald Knuth (personal communication), R. J. Walker introduced the term *backtrack* in the 1950s. Walker (1960) described the basic backtracking algorithm and used it to find all solutions to the 13-queens problem. Golomb and Baumert (1965) formulated, with examples, the general class of combinatorial problems to which backtracking can be applied, and introduced what we call the MRV heuristic. Bitner and Reingold (1975) provided an influential survey of backtracking techniques. Brelaz (1979) used the degree heuristic as a tiebreaker after applying the MRV heuristic. The resulting algorithm, despite its simplicity, is still the best method for  $k$ -coloring arbitrary graphs. Haralick and Elliott (1980) proposed the least-constraining-value heuristic.

The basic backjumping method is due to John Gaschnig (1977, 1979). Kondrak and van Beek (1997) showed that this algorithm is essentially subsumed by forward checking. Conflict-directed backjumping was devised by Prosser (1993). Dechter (1990a) introduced graph-based backjumping, which bounds the complexity of backjumping-based algorithms as a function of the constraint graph (Dechter and Frost, 2002).

A very general form of intelligent backtracking was developed early on by Stallman and Sussman (1977). Their technique of **dependency-directed backtracking** combines back-

Dependency-directed  
backtracking

jumping with no-good learning (McAllester, 1990) and led to the development of **truth maintenance systems** (Doyle, 1979), which we discuss in Section 10.6.2. The connection between the two areas is analyzed by de Kleer (1989).

#### Constraint learning

The work of Stallman and Sussman also introduced the idea of **constraint learning**, in which partial results obtained by search can be saved and reused later in the search. The idea was formalized by Dechter (1990a). **Backmarking** (Gaschnig, 1979) is a particularly simple method in which consistent and inconsistent pairwise assignments are saved and used to avoid rechecking constraints. Backmarking can be combined with conflict-directed back-jumping; Kondrak and van Beek (1997) present a hybrid algorithm that provably subsumes either method taken separately.

The method of **dynamic backtracking** (Ginsberg, 1993) retains successful partial assignments from later subsets of variables when backtracking over an earlier choice that does not invalidate the later success. Moskewicz *et al.* (2001) show how these techniques and others are used to create an efficient SAT solver. Empirical studies of several randomized backtracking methods were done by Gomes *et al.* (2000) and Gomes and Selman (2001). Van Beek (2006) surveys backtracking.

Local search in constraint satisfaction problems was popularized by the work of Kirkpatrick *et al.* (1983) on simulated annealing (see Chapter 4), which is widely used for VLSI layout and scheduling problems. Beck *et al.* (2011) give an overview of recent work on job-shop scheduling. The min-conflicts heuristic was first proposed by Gu (1989) and was developed independently by Minton *et al.* (1992). Sosic and Gu (1994) showed how it could be applied to solve the 3,000,000 queens problem in less than a minute. The astounding success of local search using min-conflicts on the  $n$ -queens problem led to a reappraisal of the nature and prevalence of “easy” and “hard” problems. Peter Cheeseman *et al.* (1991) explored the difficulty of randomly generated CSPs and discovered that almost all such problems either are trivially easy or have no solutions. Only if the parameters of the problem generator are set in a certain narrow range, within which roughly half of the problems are solvable, do we find “hard” problem instances. We discuss this phenomenon further in Chapter 7.

Konolige (1994) showed that local search is inferior to backtracking search on problems with a certain degree of local structure; this led to work that combined local search and inference, such as that by Pinkas and Dechter (1995). Hoos and Tsang (2006) provide a survey of local search techniques, and textbooks are offered by Hoos and Stützle (2004) and Aarts and Lenstra (2003).

Work relating the structure and complexity of CSPs originates with Freuder (1985) and Mackworth and Freuder (1985), who showed that search on arc-consistent trees works without any backtracking. A similar result, with extensions to acyclic hypergraphs, was developed in the database community (Beeri *et al.*, 1983). Bayardo and Miranker (1994) present an algorithm for tree-structured CSPs that runs in linear time without any preprocessing. Dechter (1990a) describes the cycle-cutset approach.

Since those papers were published, there has been a great deal of progress in developing more general results relating the complexity of solving a CSP to the structure of its constraint graph. The notion of tree width was introduced by the graph theorists Robertson and Seymour (1986). Dechter and Pearl (1987, 1989), building on the work of Freuder, applied a related notion (which they called **induced width** but is identical to tree width) to constraint satisfaction problems and developed the tree decomposition approach sketched in Section 5.5.

Drawing on this work and on results from database theory, Gottlob *et al.* (1999a, 1999b) developed a notion, **hypertree width**, that is based on the characterization of the CSP as a hypergraph. In addition to showing that any CSP with hypertree width  $w$  can be solved in time  $O(n^{w+1} \log n)$ , they also showed that hypertree width subsumes all previously defined measures of “width” in the sense that there are cases where the hypertree width is bounded and the other measures are unbounded.

The RELSAT algorithm of Bayardo and Schrag (1997) combined constraint learning and backjumping and was shown to outperform many other algorithms of the time. This led to AND-OR search algorithms applicable to both CSPs and probabilistic reasoning (Dechter and Mateescu, 2007). Brown *et al.* (1988) introduce the idea of symmetry breaking in CSPs, and Gent *et al.* (2006) give a survey.

The field of **distributed constraint satisfaction** looks at solving CSPs when there is a collection of agents, each of which controls a subset of the constraint variables. There have been annual workshops on this problem since 2000, and good coverage elsewhere (Collin *et al.*, 1999; Pearce *et al.*, 2008).

Comparing CSP algorithms is mostly an empirical science: few theoretical results show that one algorithm dominates another on all problems; instead, we need to run experiments to see which algorithms perform better on typical instances of problems. As Hooker (1995) points out, we need to be careful to distinguish between competitive testing—as occurs in competitions among algorithms based on run time—and scientific testing, whose goal is to identify the properties of an algorithm that determine its efficacy on a class of problems.

The textbooks by Apt (2003), Dechter (2003), Tsang (1993), and Lecoutre (2009), and the collection by Rossi *et al.* (2006), are excellent resources on constraint processing. There are several good survey articles, including those by Dechter and Frost (2002), and Barták *et al.* (2010). Carbonnel and Cooper (2016) survey tractable classes of CSPs. Kondrak and van Beek (1997) give an analytical survey of backtracking search algorithms, and Bacchus and van Run (1995) give a more empirical survey. Constraint programming is covered in the books by Apt (2003) and Fruhwirth and Abdennadher (2003). Papers on constraint satisfaction appear regularly in *Artificial Intelligence* and in the specialist journal *Constraints*; the latest SAT solvers are described in the annual International SAT Competition. The primary conference venue is the International Conference on Principles and Practice of Constraint Programming, often called *CP*.

# CHAPTER 6

## ADVERSARIAL SEARCH AND GAMES

*In which we explore environments where other agents are plotting against us.*

Adversarial search

Economy

Pruning

Imperfect information

In this chapter we cover **competitive environments**, in which two or more agents have conflicting goals, giving rise to **adversarial search** problems. Rather than deal with the chaos of real-world skirmishes, we will concentrate on games, such as chess, Go, and poker. For AI researchers, the simplified nature of these games is a plus: the state of a game is easy to represent, and agents are usually restricted to a small number of actions whose effects are defined by precise rules. Physical games, such as croquet and ice hockey, have more complicated descriptions, a larger range of possible actions, and rather imprecise rules defining the legality of actions. With the exception of robot soccer, these physical games have not attracted much interest in the AI community.

### 6.1 Game Theory

There are at least three stances we can take towards multi-agent environments. The first stance, appropriate when there are a very large number of agents, is to consider them in the aggregate as an **economy**, allowing us to do things like predict that increasing demand will cause prices to rise, without having to predict the action of any individual agent.

Second, we could consider adversarial agents as just a part of the environment—a part that makes the environment nondeterministic. But if we model the adversaries in the same way that, say, rain sometimes falls and sometimes doesn’t, we miss the idea that our adversaries are actively trying to defeat us, whereas the rain supposedly has no such intention.

The third stance is to explicitly model the adversarial agents with the techniques of adversarial game-tree search. That is what this chapter covers. We begin with a restricted class of games and define the optimal move and an algorithm for finding it: minimax search, a generalization of AND–OR search (from Figure 4.11). We show that **pruning** makes the search more efficient by ignoring portions of the search tree that make no difference to the optimal move. For nontrivial games, we will usually not have enough time to be sure of finding the optimal move (even with pruning); we will have to cut off the search at some point.

For each state where we choose to stop searching, we ask who is winning. To answer this question we have a choice: we can apply a heuristic **evaluation function** to estimate who is winning based on features of the state (Section 6.3), or we can average the outcomes of many fast simulations of the game from that state all the way to the end (Section 6.4).

Section 6.5 discusses games that include an element of chance (through rolling dice or shuffling cards) and Section 6.6 covers games of **imperfect information** (such as poker and bridge, where not all cards are visible to all players).

### 6.1.1 Two-player zero-sum games

The games most commonly studied within AI (such as chess and Go) are what game theorists call deterministic, two-player, turn-taking, **perfect information**, **zero-sum games**. “Perfect information” is a synonym for “fully observable,”<sup>1</sup> and “zero-sum” means that what is good for one player is just as bad for the other: there is no “win-win” outcome. For games we often use the term **move** as a synonym for “action” and **position** as a synonym for “state.”

We will call our two players MAX and MIN, for reasons that will soon become obvious. MAX moves first, and then the players take turns moving until the game is over. At the end of the game, points are awarded to the winning player and penalties are given to the loser. A game can be formally defined with the following elements:

- $S_0$ : The **initial state**, which specifies how the game is set up at the start.
- $\text{TO-MOVE}(s)$ : The player whose turn it is to move in state  $s$ .
- $\text{ACTIONS}(s)$ : The set of legal moves in state  $s$ .
- $\text{RESULT}(s, a)$ : The **transition model**, which defines the state resulting from taking action  $a$  in state  $s$ .
- $\text{IS-TERMINAL}(s)$ : A **terminal test**, which is true when the game is over and false otherwise. States where the game has ended are called **terminal states**.
- $\text{UTILITY}(s, p)$ : A **utility function** (also called an objective function or payoff function), which defines the final numeric value to player  $p$  when the game ends in terminal state  $s$ . In chess, the outcome is a win, loss, or draw, with values 1, 0, or  $1/2$ .<sup>2</sup> Some games have a wider range of possible outcomes—for example, the payoffs in backgammon range from 0 to 192.

Much as in Chapter 3, the initial state, ACTIONS function, and RESULT function define the **state space graph**—a graph where the vertices are states, the edges are moves and a state might be reached by multiple paths. As in Chapter 3, we can superimpose a **search tree** over part of that graph to determine what move to make. We define the complete **game tree** as a search tree that follows every sequence of moves all the way to a terminal state. The game tree may be infinite if the state space itself is unbounded or if the rules of the game allow for infinitely repeating positions.

Figure 6.1 shows part of the game tree for tic-tac-toe (noughts and crosses). From the initial state, MAX has nine possible moves. Play alternates between MAX’s placing an X and MIN’s placing an O until we reach leaf nodes corresponding to terminal states such that one player has three squares in a row or all the squares are filled. The number on each leaf node indicates the utility value of the terminal state from the point of view of MAX; high values are good for MAX and bad for MIN (which is how the players get their names).

For tic-tac-toe the game tree is relatively small—fewer than  $9! = 362,880$  terminal nodes (with only 5,478 distinct states). But for chess there are over  $10^{40}$  nodes, so the game tree is best thought of as a theoretical construct that we cannot realize in the physical world.

<sup>1</sup> Some authors make a distinction, using “imperfect information game” for one like poker where the players get private information about their own hands that the other players do not have, and “partially observable game” to mean one like StarCraft II where each player can see the nearby environment, but not the environment far away.

<sup>2</sup> Chess is considered a “zero-sum” game, even though the sum of the outcomes for the two players is +1 for each game, not zero. “Constant-sum” would have been a more accurate term, but zero-sum is traditional and makes sense if you imagine each player is charged an entry fee of  $1/2$ .

**Figure 6.1** A (partial) game tree for the game of tic-tac-toe. The top node is the initial state, and MAX moves first, placing an X in an empty square. We show part of the tree, giving alternating moves by MIN (O) and MAX (X), until we eventually reach terminal states, which can be assigned utilities according to the rules of the game.

## 6.2 Optimal Decisions in Games

MAX wants to find a sequence of actions leading to a win, but MIN has something to say about it. This means that MAX's strategy must be a conditional plan—a contingent strategy specifying a response to each of MIN's possible moves. In games that have a binary outcome (win or lose), we could use AND-OR search (page 143) to generate the conditional plan. In fact, for such games, the definition of a winning strategy for the game is identical to the definition of a solution for a nondeterministic planning problem: in both cases the desirable outcome must be guaranteed no matter what the “other side” does. For games with multiple outcome scores, we need a slightly more general algorithm called **minimax search**.

Minimax search

Ply

Minimax value

Consider the trivial game in Figure 6.2. The possible moves for MAX at the root node are labeled  $a_1$ ,  $a_2$ , and  $a_3$ . The possible replies to  $a_1$  for MIN are  $b_1$ ,  $b_2$ ,  $b_3$ , and so on. This particular game ends after one move each by MAX and MIN. (Note: In some games, the word “move” means that both players have taken an action; therefore the word **ply** is used to unambiguously mean one move by one player, bringing us one level deeper in the game tree.) The utilities of the terminal states in this game range from 2 to 14.

Given a game tree, the optimal strategy can be determined by working out the **minimax value** of each state in the tree, which we write as  $\text{MINIMAX}(s)$ . The minimax value is the utility (for MAX) of being in that state, *assuming that both players play optimally* from there to the end of the game. The minimax value of a terminal state is just its utility. In a non-terminal state, MAX prefers to move to a state of maximum value when it is MAX's turn to

**Figure 6.2** A two-ply game tree. The  $\triangle$  nodes are “MAX nodes,” in which it is MAX’s turn to move, and the  $\diamond$  nodes are “MIN nodes.” The terminal nodes show the utility values for MAX; the other nodes are labeled with their minimax values. MAX’s best move at the root is  $a_1$ , because it leads to the state with the highest minimax value, and MIN’s best reply is  $b_1$ , because it leads to the state with the lowest minimax value.

move, and MIN prefers a state of minimum value (that is, minimum value for MAX and thus maximum value for MIN). So we have:

$$\text{MINIMAX}(s) = \begin{cases} \text{UTILITY}(s, \text{MAX}) & \text{if Is-TERMINAL}(s) \\ \max_{a \in \text{Actions}(s)} \text{MINIMAX}(\text{RESULT}(s, a)) & \text{if To-MOVE}(s) = \text{MAX} \\ \min_{a \in \text{Actions}(s)} \text{MINIMAX}(\text{RESULT}(s, a)) & \text{if To-MOVE}(s) = \text{MIN} \end{cases}$$

Let us apply these definitions to the game tree in Figure 6.2. The terminal nodes on the bottom level get their utility values from the game’s `UTILITY` function. The first MIN node, labeled  $B$ , has three successor states with values 3, 12, and 8, so its minimax value is 3. Similarly, the other two MIN nodes have minimax value 2. The root node is a MAX node; its successor states have minimax values 3, 2, and 2; so it has a minimax value of 3. We can also identify the **minimax decision** at the root: action  $a_1$  is the optimal choice for MAX because it leads to the state with the highest minimax value.

Minimax decision

This definition of optimal play for MAX assumes that MIN also plays optimally. What if MIN does not play optimally? Then MAX will do at least as well as against an optimal player, possibly better. However, that does not mean that it is always best to play the minimax optimal move when facing a suboptimal opponent. Consider a situation where optimal play by both sides will lead to a draw, but there is one risky move for MAX that leads to a state in which there are 10 possible response moves by MIN that all seem reasonable, but 9 of them are a loss for MIN and one is a loss for MAX. If MAX believes that MIN does not have sufficient computational power to discover the optimal move, MAX might want to try the risky move, on the grounds that a 9/10 chance of a win is better than a certain draw.

### 6.2.1 The minimax search algorithm

Now that we can compute  $\text{MINIMAX}(s)$ , we can turn that into a search algorithm that finds the best move for MAX by trying all actions and choosing the one whose resulting state has the highest  $\text{MINIMAX}$  value. Figure 6.3 shows the algorithm. It is a recursive algorithm that proceeds all the way down to the leaves of the tree and then **backs up** the minimax values through the tree as the recursion unwinds. For example, in Figure 6.2, the algorithm

```

function MINIMAX-SEARCH(game, state) returns an action
    player  $\leftarrow$  game.TO-MOVE(state)
    value, move  $\leftarrow$  MAX-VALUE(game, state)
    return move

function MAX-VALUE(game, state) returns a (utility, move) pair
    if game.IS-TERMINAL(state) then return game.UTILITY(state, player), null
    v, move  $\leftarrow$   $-\infty$ 
    for each a in game.ACTIONS(state) do
        v2, a2  $\leftarrow$  MIN-VALUE(game, game.RESULT(state, a))
        if v2  $>$  v then
            v, move  $\leftarrow$  v2, a
    return v, move

function MIN-VALUE(game, state) returns a (utility, move) pair
    if game.IS-TERMINAL(state) then return game.UTILITY(state, player), null
    v, move  $\leftarrow$   $+\infty$ 
    for each a in game.ACTIONS(state) do
        v2, a2  $\leftarrow$  MAX-VALUE(game, game.RESULT(state, a))
        if v2  $<$  v then
            v, move  $\leftarrow$  v2, a
    return v, move

```

**Figure 6.3** An algorithm for calculating the optimal move using minimax—the move that leads to a terminal state with maximum utility, under the assumption that the opponent plays to minimize utility. The functions MAX-VALUE and MIN-VALUE go through the whole game tree, all the way to the leaves, to determine the backed-up value of a state and the move to get there.

---

first recurses down to the three bottom-left nodes and uses the UTILITY function on them to discover that their values are 3, 12, and 8, respectively. Then it takes the minimum of these values, 3, and returns it as the backed-up value of node *B*. A similar process gives the backed-up values of 2 for *C* and 2 for *D*. Finally, we take the maximum of 3, 2, and 2 to get the backed-up value of 3 for the root node.

The minimax algorithm performs a complete depth-first exploration of the game tree. If the maximum depth of the tree is *m* and there are *b* legal moves at each point, then the time complexity of the minimax algorithm is  $O(b^m)$ . The space complexity is  $O(bm)$  for an algorithm that generates all actions at once, or  $O(m)$  for an algorithm that generates actions one at a time (see page 98). The exponential complexity makes MINIMAX impractical for complex games; for example, chess has a branching factor of about 35 and the average game has depth of about 80 ply, and it is not feasible to search  $35^{80} \approx 10^{123}$  states. MINIMAX does, however, serve as a basis for the mathematical analysis of games. By approximating the minimax analysis in various ways, we can derive more practical algorithms.

**Figure 6.4** The first three ply of a game tree with three players ( $A, B, C$ ). Each node is labeled with values from the viewpoint of each player. The best move is marked at the root.

## 6.2.2 Optimal decisions in multiplayer games

Many popular games allow more than two players. Let us examine how to extend the minimax idea to multiplayer games. This is straightforward from the technical viewpoint, but raises some interesting new conceptual issues.

First, we need to replace the single value for each node with a *vector* of values. For example, in a three-player game with players  $A$ ,  $B$ , and  $C$ , a vector  $\langle v_A, v_B, v_C \rangle$  is associated with each node. For terminal states, this vector gives the utility of the state from each player's viewpoint. (In two-player, zero-sum games, the two-element vector can be reduced to a single value because the values are always opposite.) The simplest way to implement this is to have the `UTILITY` function return a vector of utilities.

Now we have to consider nonterminal states. Consider the node marked  $X$  in the game tree shown in Figure 6.4. In that state, player  $C$  chooses what to do. The two choices lead to terminal states with utility vectors  $\langle v_A = 1, v_B = 2, v_C = 6 \rangle$  and  $\langle v_A = 4, v_B = 2, v_C = 3 \rangle$ . Since 6 is bigger than 3,  $C$  should choose the first move. This means that if state  $X$  is reached, subsequent play will lead to a terminal state with utilities  $\langle v_A = 1, v_B = 2, v_C = 6 \rangle$ . Hence, the backed-up value of  $X$  is this vector. In general, the backed-up value of a node  $n$  is the utility vector of the successor state with the highest value for the player choosing at  $n$ .

Anyone who plays multiplayer games, such as Diplomacy or Settlers of Catan, quickly becomes aware that much more is going on than in two-player games. Multiplayer games usually involve **alliances**, whether formal or informal, among the players. Alliances are made and broken as the game proceeds. How are we to understand such behavior? Are alliances a natural consequence of optimal strategies for each player in a multiplayer game? It turns out that they can be.

For example, suppose  $A$  and  $B$  are in weak positions and  $C$  is in a stronger position. Then it is often optimal for both  $A$  and  $B$  to attack  $C$  rather than each other, lest  $C$  destroy each of them individually. In this way, collaboration emerges from purely selfish behavior. Of course, as soon as  $C$  weakens under the joint onslaught, the alliance loses its value, and either  $A$  or  $B$  could violate the agreement.

In some cases, explicit alliances merely make concrete what would have happened anyway. In other cases, a social stigma attaches to breaking an alliance, so players must balance

Alliance

the immediate advantage of breaking an alliance against the long-term disadvantage of being perceived as untrustworthy. See Section 17.2 for more on these complications.

If the game is not zero-sum, then collaboration can also occur with just two players. Suppose, for example, that there is a terminal state with utilities  $\langle v_A = 1000, v_B = 1000 \rangle$  and that 1000 is the highest possible utility for each player. Then the optimal strategy is for both players to do everything possible to reach this state—that is, the players will automatically cooperate to achieve a mutually desirable goal.

### 6.2.3 Alpha–Beta Pruning

The number of game states is exponential in the depth of the tree. No algorithm can completely eliminate the exponent, but we can sometimes cut it in half, computing the correct minimax decision without examining every state by **pruning** (see page 108) large parts of the tree that make no difference to the outcome. The particular technique we examine is called **alpha–beta pruning**.

Alpha–beta pruning

Consider again the two-ply game tree from Figure 6.2. Let's go through the calculation of the optimal decision once more, this time paying careful attention to what we know at each point in the process. The steps are explained in Figure 6.5. The outcome is that we can identify the minimax decision without ever evaluating two of the leaf nodes.

Another way to look at this is as a simplification of the formula for MINIMAX. Let the two unevaluated successors of node  $C$  in Figure 6.5 have values  $x$  and  $y$ . Then the value of the root node is given by

$$\begin{aligned} \text{MINIMAX}(root) &= \max(\min(3, 12, 8), \min(2, x, y), \min(14, 5, 2)) \\ &= \max(3, \min(2, x, y), 2) \\ &= \max(3, z, 2) \quad \text{where } z = \min(2, x, y) \leq 2 \\ &= 3. \end{aligned}$$

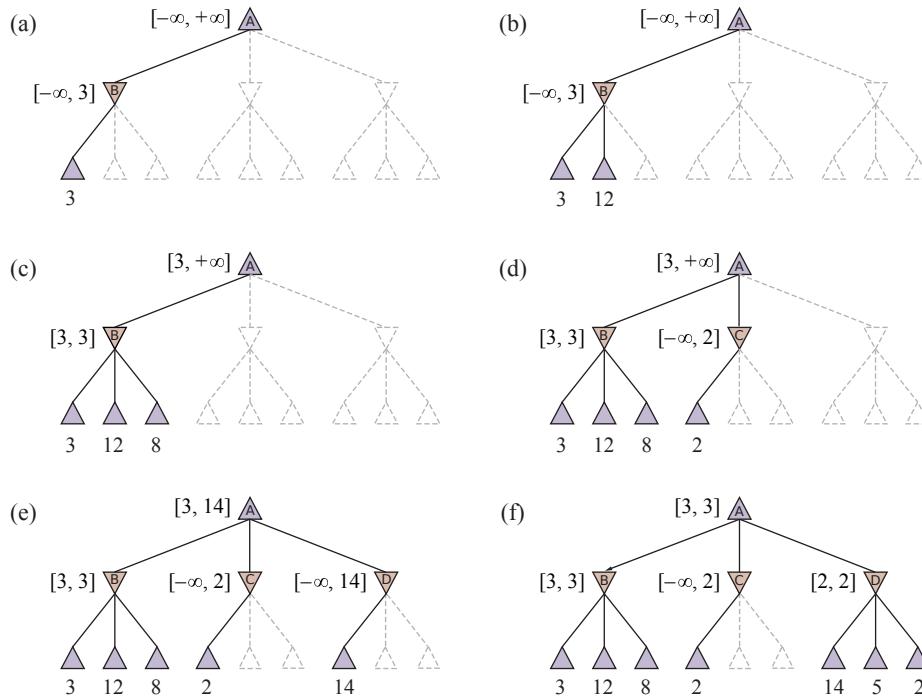

In other words, the value of the root and hence the minimax decision are *independent* of the values of the leaves  $x$  and  $y$ , and therefore they can be pruned.

Alpha–beta pruning can be applied to trees of any depth, and it is often possible to prune entire subtrees rather than just leaves. The general principle is this: consider a node  $n$  somewhere in the tree (see Figure 6.6), such that Player has a choice of moving to  $n$ . If Player has a better choice either at the same level (e.g.  $m'$  in Figure 6.6) or at any point higher up in the tree (e.g.  $m$  in Figure 6.6), then Player will never move to  $n$ . So once we have found out enough about  $n$  (by examining some of its descendants) to reach this conclusion, we can prune it.

Remember that minimax search is depth-first, so at any one time we just have to consider the nodes along a single path in the tree. Alpha–beta pruning gets its name from the two extra parameters in  $\text{MAX-VALUE}(state, \alpha, \beta)$  (see Figure 6.7) that describe bounds on the backed-up values that appear anywhere along the path:

$\alpha$  = the value of the best (i.e., highest-value) choice we have found so far at any choice point along the path for MAX. Think:  $\alpha$  = “at least.”

$\beta$  = the value of the best (i.e., lowest-value) choice we have found so far at any choice point along the path for MIN. Think:  $\beta$  = “at most.”

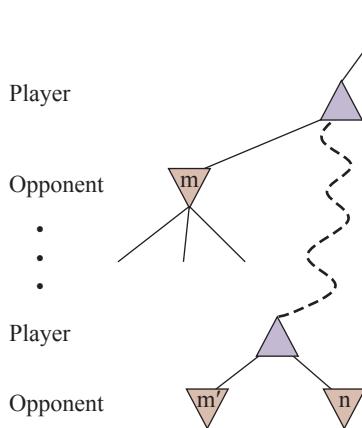

**Figure 6.5** Stages in the calculation of the optimal decision for the game tree in Figure 6.2.

At each point, we show the range of possible values for each node. (a) The first leaf below  $B$  has the value 3. Hence,  $B$ , which is a MIN node, has a value of *at most* 3. (b) The second leaf below  $B$  has a value of 12; MIN would avoid this move, so the value of  $B$  is still at most 3. (c) The third leaf below  $B$  has a value of 8; we have seen all  $B$ 's successor states, so the value of  $B$  is exactly 3. Now we can infer that the value of the root is *at least* 3, because MAX has a choice worth 3 at the root. (d) The first leaf below  $C$  has the value 2. Hence,  $C$ , which is a MIN node, has a value of *at most* 2. But we know that  $B$  is worth 3, so MAX would never choose  $C$ . Therefore, there is no point in looking at the other successor states of  $C$ . This is an example of alpha–beta pruning. (e) The first leaf below  $D$  has the value 14, so  $D$  is worth *at most* 14. This is still higher than MAX's best alternative (i.e., 3), so we need to keep exploring  $D$ 's successor states. Notice also that we now have bounds on all of the successors of the root, so the root's value is also at most 14. (f) The second successor of  $D$  is worth 5, so again we need to keep exploring. The third successor is worth 2, so now  $D$  is worth exactly 2. MAX's decision at the root is to move to  $B$ , giving a value of 3.

Alpha–beta search updates the values of  $\alpha$  and  $\beta$  as it goes along and prunes the remaining branches at a node (i.e., terminates the recursive call) as soon as the value of the current node is known to be worse than the current  $\alpha$  or  $\beta$  value for MAX or MIN, respectively. The complete algorithm is given in Figure 6.7. Figure 6.5 traces the progress of the algorithm on a game tree.

#### 6.2.4 Move ordering

The effectiveness of alpha–beta pruning is highly dependent on the order in which the states are examined. For example, in Figure 6.5(e) and (f), we could not prune any successors of  $D$  at all because the worst successors (from the point of view of MIN) were generated first. If the

**Figure 6.6** The general case for alpha–beta pruning. If  $m$  or  $m'$  is better than  $n$  for Player, we will never get to  $n$  in play.

```

function ALPHA-BETA-SEARCH(game, state) returns an action
    player  $\leftarrow$  game.TO-MOVE(state)
    value, move  $\leftarrow$  MAX-VALUE(game, state,  $-\infty$ ,  $+\infty$ )
    return move

function MAX-VALUE(game, state,  $\alpha$ ,  $\beta$ ) returns a (utility, move) pair
    if game.IS-TERMINAL(state) then return game.UTILITY(state, player), null
    v  $\leftarrow$   $-\infty$ 
    for each a in game.ACTIONS(state) do
        v2, a2  $\leftarrow$  MIN-VALUE(game, game.RESULT(state, a),  $\alpha$ ,  $\beta$ )
        if v2  $>$  v then
            v, move  $\leftarrow$  v2, a
             $\alpha \leftarrow \text{MAX}(\alpha, v)$ 
        if v  $\geq \beta$  then return v, move
    return v, move

function MIN-VALUE(game, state,  $\alpha$ ,  $\beta$ ) returns a (utility, move) pair
    if game.IS-TERMINAL(state) then return game.UTILITY(state, player), null
    v  $\leftarrow$   $+\infty$ 
    for each a in game.ACTIONS(state) do
        v2, a2  $\leftarrow$  MAX-VALUE(game, game.RESULT(state, a),  $\alpha$ ,  $\beta$ )
        if v2  $< v$  then
            v, move  $\leftarrow$  v2, a
             $\beta \leftarrow \text{MIN}(\beta, v)$ 
        if v  $\leq \alpha$  then return v, move
    return v, move
```

**Figure 6.7** The alpha–beta search algorithm. Notice that these functions are the same as the MINIMAX-SEARCH functions in Figure 6.3, except that we maintain bounds in the variables  $\alpha$  and  $\beta$ , and use them to cut off search when a value is outside the bounds.

third successor of  $D$  had been generated first, with value 2, we would have been able to prune the other two successors. This suggests that it might be worthwhile to try to first examine the successors that are likely to be best.

If this could be done perfectly, alpha–beta would need to examine only  $O(b^{m/2})$  nodes to pick the best move, instead of  $O(b^m)$  for minimax. This means that the effective branching factor becomes  $\sqrt{b}$  instead of  $b$ —for chess, about 6 instead of 35. Put another way, alpha–beta with perfect move ordering can solve a tree roughly twice as deep as minimax in the same amount of time. With random move ordering, the total number of nodes examined will be roughly  $O(b^{3m/4})$  for moderate  $b$ . Now, obviously we cannot achieve *perfect* move ordering—in that case the ordering function could be used to play a perfect game! But we can often get fairly close. For chess, a fairly simple ordering function (such as trying captures first, then threats, then forward moves, and then backward moves) gets you to within about a factor of 2 of the best-case  $O(b^{m/2})$  result.

Adding dynamic move-ordering schemes, such as trying first the moves that were found to be best in the past, brings us quite close to the theoretical limit. The past could be the previous move—often the same threats remain—or it could come from previous exploration of the current move through a process of **iterative deepening** (see page 98). First, search one ply deep and record the ranking of moves based on their evaluations. Then search one ply deeper, using the previous ranking to inform move ordering; and so on. The increased search time from iterative deepening can be more than made up from better move ordering. The best moves are known as **killer moves**, and to try them first is called the killer move heuristic.

In Section 3.3.3, we noted that redundant paths to repeated states can cause an exponential increase in search cost, and that keeping a table of previously reached states can address this problem. In game tree search, repeated states can occur because of **transpositions**—different permutations of the move sequence that end up in the same position, and the problem can be addressed with a **transposition table** that caches the heuristic value of states.

For example, suppose White has a move  $w_1$  that can be answered by Black with  $b_1$  and an unrelated move  $w_2$  on the other side of the board that can be answered by  $b_2$ , and that we search the sequence of moves  $[w_1, b_1, w_2, b_2]$ ; let’s call the resulting state  $s$ . After exploring a large subtree below  $s$ , we find its backed-up value, which we store in the transposition table. When we later search the sequence of moves  $[w_2, b_2, w_1, b_1]$ , we end up in  $s$  again, and we can look up the value instead of repeating the search. In chess, use of transposition tables is very effective, allowing us to double the reachable search depth in the same amount of time.

Even with alpha–beta pruning and clever move ordering, minimax won’t work for games like chess and Go, because there are still too many states to explore in the time available. In the very first paper on computer game-playing, *Programming a Computer for Playing Chess* (Shannon, 1950), Claude Shannon recognized this problem and proposed two strategies: a **Type A strategy** considers all possible moves to a certain depth in the search tree, and then uses a heuristic evaluation function to estimate the utility of states at that depth. It explores a *wide but shallow* portion of the tree. A **Type B strategy** ignores moves that look bad, and follows promising lines “as far as possible.” It explores a *deep but narrow* portion of the tree.

Historically, most chess programs have been Type A (which we cover in the next section), whereas Go programs are more often Type B (covered in Section 6.4), because the branching factor is much higher in Go. More recently, Type B programs have shown world-champion-level play across a variety of games, including chess (Silver *et al.*, 2018).

Cutoff test

## 6.3 Heuristic Alpha–Beta Tree Search

To make use of our limited computation time, we can cut off the search early and apply a heuristic **evaluation function** to states, effectively treating nonterminal nodes as if they were terminal. In other words, we replace the UTILITY function with EVAL, which estimates a state's utility. We also replace the terminal test by a **cutoff test**, which must return true for terminal states, but is otherwise free to decide when to cut off the search, based on the search depth and any property of the state that it chooses to consider. That gives us the formula H-MINIMAX( $s, d$ ) for the heuristic minimax value of state  $s$  at search depth  $d$ :

$$\text{H-MINIMAX}(s, d) = \begin{cases} \text{EVAL}(s, \text{MAX}) & \text{if IS-CUTOFF}(s, d) \\ \max_{a \in \text{Actions}(s)} \text{H-MINIMAX}(\text{RESULT}(s, a), d + 1) & \text{if TO-MOVE}(s) = \text{MAX} \\ \min_{a \in \text{Actions}(s)} \text{H-MINIMAX}(\text{RESULT}(s, a), d + 1) & \text{if TO-MOVE}(s) = \text{MIN}. \end{cases}$$

### 6.3.1 Evaluation functions

A heuristic evaluation function  $\text{EVAL}(s, p)$  returns an *estimate* of the expected utility of state  $s$  to player  $p$ , just as the heuristic functions of Chapter 3 return an estimate of the distance to the goal. For terminal states, it must be that  $\text{EVAL}(s, p) = \text{UTILITY}(s, p)$  and for nonterminal states, the evaluation must be somewhere between a loss and a win:  $\text{UTILITY}(\text{loss}, p) \leq \text{EVAL}(s, p) \leq \text{UTILITY}(\text{win}, p)$ .

Beyond those requirements, what makes for a good evaluation function? First, the computation must not take too long! (The whole point is to search faster.) Second, the evaluation function should be strongly correlated with the actual chances of winning. One might well wonder about the phrase “chances of winning.” After all, chess is not a game of chance: we know the current state with certainty, and no dice are involved; if neither player makes a mistake, the outcome is predetermined. But if the search must be cut off at nonterminal states, then the algorithm will necessarily be *uncertain* about the final outcomes of those states (even though that uncertainty could be resolved with infinite computing resources).

Features

Let us make this idea more concrete. Most evaluation functions work by calculating various **features** of the state—for example, in chess, we would have features for the number of white pawns, black pawns, white queens, black queens, and so on. The features, taken together, define various *categories* or *equivalence classes* of states: the states in each category have the same values for all the features. For example, one category might contain all two-pawn versus one-pawn endgames. Any given category will contain some states that lead (with perfect play) to wins, some that lead to draws, and some that lead to losses.

Expected value

The evaluation function does not know which states are which, but it can return a single value that estimates the *proportion* of states with each outcome. For example, suppose our experience suggests that 82% of the states encountered in the two-pawns versus one-pawn category lead to a win (utility +1); 2% to a loss (0), and 16% to a draw (1/2). Then a reasonable evaluation for states in the category is the **expected value**:  $(0.82 \times +1) + (0.02 \times 0) + (0.16 \times 1/2) = 0.90$ . In principle, the expected value can be determined for each category of states, resulting in an evaluation function that works for any state.

In practice, this kind of analysis requires too many categories and hence too much experience to estimate all the probabilities. Instead, most evaluation functions compute separate numerical contributions from each feature and then *combine* them to find the total value. For

**Figure 6.8** Two chess positions that differ only in the position of the rook at lower right. In (a), Black has an advantage of a knight and two pawns, which should be enough to win the game. In (b), White will capture the queen, giving it an advantage that should be strong enough to win.

centuries, chess players have developed ways of judging the value of a position using just this idea. For example, introductory chess books give an approximate **material value** for each piece: each pawn is worth 1, a knight or bishop is worth 3, a rook 5, and the queen 9. Other features such as “good pawn structure” and “king safety” might be worth half a pawn, say. These feature values are then simply added up to obtain the evaluation of the position.

Mathematically, this kind of evaluation function is called a **weighted linear function** because it can be expressed as

$$\text{EVAL}(s) = w_1 f_1(s) + w_2 f_2(s) + \cdots + w_n f_n(s) = \sum_{i=1}^n w_i f_i(s),$$

where each  $f_i$  is a feature of the position (such as “number of white bishops”) and each  $w_i$  is a weight (saying how important that feature is). The weights should be normalized so that the sum is always within the range of a loss (0) to a win (+1). A secure advantage equivalent to a pawn gives a substantial likelihood of winning, and a secure advantage equivalent to three pawns should give almost certain victory, as illustrated in Figure 6.8(a). We said that the evaluation function should be strongly correlated with the actual chances of winning, but it need not be linearly correlated: if state  $s$  is twice as likely to win as state  $s'$  we don’t require that  $\text{EVAL}(s)$  be twice  $\text{EVAL}(s')$ ; all we require is that  $\text{EVAL}(s) > \text{EVAL}(s')$ .

Adding up the values of features seems like a reasonable thing to do, but in fact it involves a strong assumption: that the contribution of each feature is *independent* of the values of the other features. For this reason, current programs for chess and other games also use *nonlinear* combinations of features. For example, a pair of bishops might be worth more than twice the value of a single bishop, and a bishop is worth more in the endgame than earlier—when the *move number* feature is high or the *number of remaining pieces* feature is low.

Where do the features and weights come from? They’re not part of the rules of chess, but they are part of the culture of human chess-playing experience. In games where this

Material value

Weighted linear function

kind of experience is not available, the weights of the evaluation function can be estimated by the machine learning techniques of Chapter 23. Applying these techniques to chess has confirmed that a bishop is indeed worth about three pawns, and it appears that centuries of human experience can be replicated in just a few hours of machine learning.

### 6.3.2 Cutting off search

The next step is to modify ALPHA-BETA-SEARCH so that it will call the heuristic EVAL function when it is appropriate to cut off the search. We replace the two lines in Figure 6.7 that mention IS-TERMINAL with the following line:

```
if game.IS-CUTOFF(state, depth) then return game.EVAL(state, player), null
```

We also must arrange for some bookkeeping so that the current *depth* is incremented on each recursive call. The most straightforward approach to controlling the amount of search is to set a fixed depth limit so that IS-CUTOFF(*state, depth*) returns *true* for all *depth* greater than some fixed depth *d* (as well as for all terminal states). The depth *d* is chosen so that a move is selected within the allocated time. A more robust approach is to apply iterative deepening. (See Chapter 3.) When time runs out, the program returns the move selected by the deepest completed search. As a bonus, if in each round of iterative deepening we keep entries in the transposition table, subsequent rounds will be faster, and we can use the evaluations to improve move ordering.

These simple approaches can lead to errors due to the approximate nature of the evaluation function. Consider again the simple evaluation function for chess based on material advantage. Suppose the program searches to the depth limit, reaching the position in Figure 6.8(b), where Black is ahead by a knight and two pawns. It would report this as the heuristic value of the state, thereby declaring that the state is a probable win by Black. But White's next move captures Black's queen with no compensation. Hence, the position is actually favorable for White, but this can be seen only by looking ahead.

Quiescence

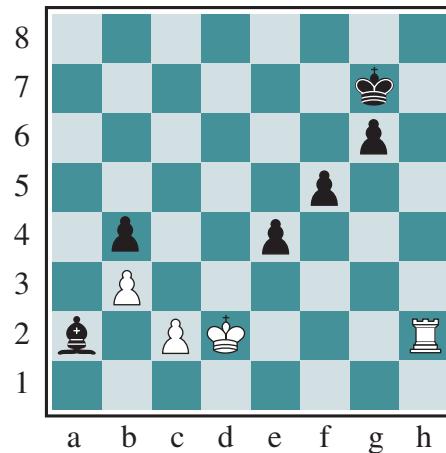

The evaluation function should be applied only to positions that are **quiescent**—that is, positions in which there is no pending move (such as a capturing the queen) that would wildly swing the evaluation. For nonquiescent positions the IS-CUTOFF returns false, and the search continues until quiescent positions are reached. This extra **quiescence search** is sometimes restricted to consider only certain types of moves, such as capture moves, that will quickly resolve the uncertainties in the position.

Quiescence search

Horizon effect

The **horizon effect** is more difficult to eliminate. It arises when the program is facing an opponent's move that causes serious damage and is ultimately unavoidable, but can be temporarily avoided by the use of delaying tactics. Consider the chess position in Figure 6.9. It is clear that there is no way for the black bishop to escape. For example, the white rook can capture it by moving to h1, then a1, then a2; a capture at depth 6 ply.

But Black does have a sequence of moves that pushes the capture of the bishop "over the horizon." Suppose Black searches to depth 8 ply. Most moves by Black will lead to the eventual capture of the bishop, and thus will be marked as "bad" moves. But Black will also consider the sequence of moves that starts by checking the king with a pawn, and enticing the king to capture the pawn. Black can then do the same thing with a second pawn. That takes up enough moves that the capture of the bishop would not be discovered during the remainder of Black's search. Black thinks that the line of play has saved the bishop at the price of two

**Figure 6.9** The horizon effect. With Black to move, the black bishop is surely doomed. But Black can forestall that event by checking the white king with its pawns, encouraging the king to capture the pawns. This pushes the inevitable loss of the bishop over the horizon, and thus the pawn sacrifices are seen by the search algorithm as good moves rather than bad ones.

pawns, when actually all it has done is waste pawns and push the inevitable capture of the bishop beyond the horizon that Black can see.

One strategy to mitigate the horizon effect is to allow **singular extensions**, moves that are “clearly better” than all other moves in a given position, even when the search would normally be cut off at that point. In our example, a search will have revealed that three moves of the white rook— $h2$  to  $h1$ , then  $h1$  to  $a1$ , and then  $a1$  capturing the bishop on  $a2$ —are each in turn clearly better moves, so even if a sequence of pawn moves pushes us to the horizon, these clearly better moves will be given a chance to extend the search. This makes the tree deeper, but because there are usually few singular extensions, the strategy does not add many total nodes to the tree, and has proven to be effective in practice.

Singular extension

### 6.3.3 Forward pruning

Alpha–beta pruning prunes branches of the tree that can have no effect on the final evaluation, but **forward pruning** prunes moves that appear to be poor moves, but might possibly be good ones. Thus, the strategy saves computation time at the risk of making an error. In Shannon’s terms, this is a Type B strategy. Clearly, most human chess players do this, considering only a few moves from each position (at least consciously).

Forward pruning

One approach to forward pruning is **beam search** (see page 133): on each ply, consider only a “beam” of the  $n$  best moves (according to the evaluation function) rather than considering all possible moves. Unfortunately, this approach is rather dangerous because there is no guarantee that the best move will not be pruned away.

The PROBCUT, or probabilistic cut, algorithm (Buro, 1995) is a forward-pruning version of alpha–beta search that uses statistics gained from prior experience to lessen the chance that the best move will be pruned. Alpha–beta search prunes any node that is *provably* outside the current  $(\alpha, \beta)$  window. PROBCUT also prunes nodes that are *probably* outside the window. It computes this probability by doing a shallow search to compute the backed-up value

$v$  of a node and then using past experience to estimate how likely it is that a score of  $v$  at depth  $d$  in the tree would be outside  $(\alpha, \beta)$ . Buro applied this technique to his Othello program, LOGISTELLO, and found that a version of his program with PROBCUT beat the regular version 64% of the time, even when the regular version was given twice as much time.

#### Late move reduction

Another technique, **late move reduction**, works under the assumption that move ordering has been done well, and therefore moves that appear later in the list of possible moves are less likely to be good moves. But rather than pruning them away completely, we just reduce the depth to which we search these moves, thereby saving time. If the reduced search comes back with a value above the current  $\alpha$  value, we can re-run the search with the full depth.

Combining all the techniques described here results in a program that can play creditable chess (or other games). Let us assume we have implemented an evaluation function for chess, a reasonable cutoff test with a quiescence search. Let us also assume that, after months of tedious bit-bashing, we can generate and evaluate around a million nodes per second on the latest PC. The branching factor for chess is about 35, on average, and  $35^5$  is about 50 million, so if we used minimax search, we could look ahead only five ply in about a minute of computation; the rules of competition would not give us enough time to search six ply. Though not incompetent, such a program can be defeated by an average human chess player, who can occasionally plan six or eight ply ahead.

With alpha-beta search and a large transposition table we get to about 14 ply, which results in an expert level of play. We could trade in our PC for a workstation with 8 GPUs, getting us over a billion nodes per second, but to obtain grandmaster status we would still need an extensively tuned evaluation function and a large database of endgame moves. Top chess programs like STOCKFISH have all of these, often reaching depth 30 or more in the search tree and far exceeding the ability of any human player.

### 6.3.4 Search versus lookup

Somehow it seems like overkill for a chess program to start a game by considering a tree of a billion game states, only to conclude that it will play pawn to e4 (the most popular first move). Books describing good play in the opening and endgame in chess have been available for more than a century (Tattersall, 1911). It is not surprising, therefore, that many game-playing programs use *table lookup* rather than search for the opening and ending of games.

For the openings, the computer is mostly relying on the expertise of humans. The best advice of human experts on how to play each opening can be copied from books and entered into tables for the computer's use. In addition, computers can gather statistics from a database of previously played games to see which opening sequences most often lead to a win. For the first few moves there are few possibilities, and most positions will be in the table. Usually after about 10 or 15 moves we end up in a rarely seen position, and the program must switch from table lookup to search.

Near the end of the game there are again fewer possible positions, and thus it is easier to do lookup. But here it is the computer that has the expertise: computer analysis of endgames goes far beyond human abilities. Novice humans can win a king-and-rook-versus-king (KRK) endgame by following a few simple rules. Other endings, such as king, bishop, and knight versus king (KBNK), are difficult to master and have no succinct strategy description.

A computer, on the other hand, can completely *solve* the endgame by producing a **policy**, which is a mapping from every possible state to the best move in that state. Then the computer

can play perfectly by looking up the right move in this table. The table is constructed by **retrograde** minimax search: start by considering all ways to place the KBNK pieces on the board. Some of the positions are wins for white; mark them as such. Then reverse the rules of chess to do reverse moves rather than moves. Any move by White that, no matter what move Black responds with, ends up in a position marked as a win, must also be a win. Continue this search until all possible positions are resolved as win, loss, or draw, and you have an infallible lookup table for all endgames with those pieces. This has been done not only for KBNK endings, but for all endings with seven or fewer pieces. The tables contain 400 trillion positions. An eight-piece table would require 40 quadrillion positions.

Retrograde

## 6.4 Monte Carlo Tree Search

The game of Go illustrates two major weaknesses of heuristic alpha–beta tree search: First, Go has a branching factor that starts at 361, which means alpha–beta search would be limited to only 4 or 5 ply. Second, it is difficult to define a good evaluation function for Go because material value is not a strong indicator and most positions are in flux until the endgame. In response to these two challenges, modern Go programs have abandoned alpha–beta search and instead use a strategy called **Monte Carlo tree search (MCTS)**.<sup>3</sup>

The basic MCTS strategy does not use a heuristic evaluation function. Instead, the value of a state is estimated as the average utility over a number of **simulations** of complete games starting from the state. A simulation (also called a **playout** or **rollout**) chooses moves first for one player, then for the other, repeating until a terminal position is reached. At that point the rules of the game (not fallible heuristics) determine who has won or lost, and by what score. For games in which the only outcomes are a win or a loss, “average utility” is the same as “win percentage.”

How do we choose what moves to make during the playout? If we just choose randomly, then after multiple simulations we get an answer to the question “what is the best move if both players play randomly?” For some simple games, that happens to be the same answer as “what is the best move if both players play well?,” but for most games it is not. To get useful information from the playout we need a **playout policy** that biases the moves towards good ones. For Go and other games, playout policies have been successfully learned from self-play by using neural networks. Sometimes game-specific heuristics are used, such as “consider capture moves” in chess or “take the corner square” in Othello.

Given a playout policy, we next need to decide two things: from what positions do we start the playouts, and how many playouts do we allocate to each position? The simplest answer, called **pure Monte Carlo search**, is to do  $N$  simulations starting from the current state of the game, and track which of the possible moves from the current position has the highest win percentage.

For some stochastic games this converges to optimal play as  $N$  increases, but for most games it is not sufficient—we need a **selection policy** that selectively focuses the computational resources on the important parts of the game tree. It balances two factors: **exploration** of states that have had few playouts, and **exploitation** of states that have done well in past playouts, to get a more accurate estimate of their value. (See Section 16.3 for more on the

Exploitation

<sup>3</sup> “Monte Carlo” algorithms are randomized algorithms named after the Casino de Monte-Carlo in Monaco.

exploration/exploitation tradeoff.) Monte Carlo tree search does that by maintaining a search tree and growing it on each iteration of the following four steps, as shown in Figure 6.10:

- **Selection:** Starting at the root of the search tree, we choose a move (guided by the selection policy), leading to a successor node, and repeat that process, moving down the tree to a leaf. Figure 6.10(a) shows a search tree with the root representing a state where white has just moved, and white has won 37 out of the 100 playouts done so far. The thick arrow shows the selection of a move by black that leads to a node where black has won 60/79 playouts. This is the best win percentage among the three moves, so selecting it is an example of exploitation. But it would also have been reasonable to select the 2/11 node for the sake of exploration—with only 11 playouts, the node still has high uncertainty in its valuation, and might end up being best if we gain more information about it. Selection continues on to the leaf node marked 27/35.
- **Expansion:** We grow the search tree by generating a new child of the selected node; Figure 6.10(b) shows the new node marked with 0/0. (Some versions generate more than one child in this step.)
- **Simulation:** We perform a playout from the newly generated child node, choosing moves for both players according to the playout policy. These moves are *not* recorded in the search tree. In the figure, the simulation results in a win for black.
- **Back-propagation:** We now use the result of the simulation to update all the search tree nodes going up to the root. Since black won the playout, black nodes are incremented in both the number of wins and the number of playouts, so 27/35 becomes 28/36 and 60/79 becomes 61/80. Since white lost, the white nodes are incremented in the number of playouts only, so 16/53 becomes 16/54 and the root 37/100 becomes 37/101.

**Figure 6.10** One iteration of the process of choosing a move with Monte Carlo tree search (MCTS) using the upper confidence bounds applied to trees (UCT) selection metric, shown after 100 iterations have already been done. In (a) we select moves, all the way down the tree, ending at the leaf node marked 27/35 (for 27 wins for black out of 35 playouts). In (b) we expand the selected node and do a simulation (playout), which ends in a win for black. In (c), the results of the simulation are back-propagated up the tree.

---

```

function MONTE-CARLO-TREE-SEARCH(state) returns an action
  tree  $\leftarrow$  NODE(state)
  while Is-Time-Remaining() do
    leaf  $\leftarrow$  SELECT(tree)
    child  $\leftarrow$  EXPAND(leaf)
    result  $\leftarrow$  SIMULATE(child)
    BACK-PROPAGATE(result, child)
  return the move in ACTIONS(state) whose node has highest number of playouts

```

**Figure 6.11** The Monte Carlo tree search algorithm. A game tree, *tree*, is initialized, and then we repeat a cycle of SELECT / EXPAND / SIMULATE / BACK-PROPAGATE until we run out of time, and return the move that led to the node with the highest number of playouts.

---

We repeat these four steps either for a set number of iterations, or until the allotted time has expired, and then return the move with the highest number of playouts.

One very effective selection policy is called “upper confidence bounds applied to trees” or **UCT**. The policy ranks each possible move based on an upper confidence bound formula called **UCB1**. (See Section 16.3.3 for more details.) For a node *n*, the formula is: **UCT** **UCB1**

$$UCB1(n) = \frac{U(n)}{N(n)} + C \times \sqrt{\frac{\log N(PARENT(n))}{N(n)}}$$

where  $U(n)$  is the total utility of all playouts that went through node *n*,  $N(n)$  is the number of playouts through node *n*, and  $PARENT(n)$  is the parent node of *n* in the tree. Thus  $\frac{U(n)}{N(n)}$  is the exploitation term: the average utility of *n*. The term with the square root is the exploration term: it has the count  $N(n)$  in the denominator, which means the term will be high for nodes that have only been explored a few times. In the numerator it has the log of the number of times we have explored the parent of *n*. This means that if we are selecting *n* some non-zero percentage of the time, the exploration term goes to zero as the counts increase, and eventually the playouts are given to the node with highest average utility.

$C$  is a constant that balances exploitation and exploration. There is a theoretical argument that  $C$  should be  $\sqrt{2}$ , but in practice, game programmers try multiple values for  $C$  and choose the one that performs best. (Some programs use slightly different formulas; for example, ALPHAZERO adds in a term for move probability, which is calculated by a neural network trained from past self-play.) With  $C=1.4$ , the 60/79 node in Figure 6.10 has the highest UCB1 score, but with  $C=1.5$ , it would be the 2/11 node.

Figure 6.11 shows the complete UCT MCTS algorithm. When the iterations terminate, the move with the highest number of playouts is returned. You might think that it would be better to return the node with the highest average utility, but the idea is that a node with 65/100 wins is better than one with 2/3 wins, because the latter has a lot of uncertainty. In any event, the UCB1 formula ensures that the node with the most playouts is almost always the node with the highest win percentage, because the selection process favors win percentage more and more as the number of playouts goes up.

The time to compute a playout is linear, not exponential, in the depth of the game tree, because only one move is taken at each choice point. That gives us plenty of time for multiple

playouts. For example: consider a game with a branching factor of 32, where the average game lasts 100 ply. If we have enough computing power to consider a billion game states before we have to make a move, then minimax can search 6 ply deep, alpha–beta with perfect move ordering can search 12 ply, and Monte Carlo search can do 10 million playouts. Which approach will be better? That depends on the accuracy of the heuristic function versus the selection and playout policies.

The conventional wisdom has been that Monte Carlo search has an advantage over alpha–beta for games like Go where the branching factor is very high (and thus alpha–beta can't search deep enough), or when it is difficult to define a good evaluation function. What alpha–beta does is choose the path to a node that has the highest achievable evaluation function score, given that the opponent will be trying to minimize the score. Thus, if the evaluation function is inaccurate, alpha–beta will be inaccurate. A miscalculation on a single node can lead alpha–beta to erroneously choose (or avoid) a path to that node. But Monte Carlo search relies on the aggregate of many playouts, and thus is not as vulnerable to a single error. It is possible to combine MCTS and evaluation functions by doing a playout for a certain number of moves, but then truncating the playout and applying an evaluation function.

**Early playout termination**

It is also possible to combine aspects of alpha–beta and Monte Carlo search. For example, in games that can last many moves, we may want to use **early playout termination**, in which we stop a playout that is taking too many moves, and either evaluate it with a heuristic evaluation function or just declare it a draw.

Monte Carlo search can be applied to brand-new games, in which there is no body of experience to draw upon to define an evaluation function. As long as we know the rules of the game, Monte Carlo search does not need any additional information. The selection and playout policies can make good use of hand-crafted expert knowledge when it is available, but good policies can be learned using neural networks trained by self-play alone.

Monte Carlo search has a disadvantage when it is likely that a single move can change the course of the game, because the stochastic nature of Monte Carlo search means it might fail to consider that move. In other words, Type B pruning in Monte Carlo search means that a vital line of play might not be explored at all. Monte Carlo search also has a disadvantage when there are game states that are “obviously” a win for one side or the other (according to human knowledge and to an evaluation function), but where it will still take many moves in a playout to verify the winner. It was long held that alpha–beta search was better suited for games like chess with low branching factor and good evaluation functions, but recently Monte Carlo approaches have demonstrated success in chess and other games.

The general idea of simulating moves into the future, observing the outcome, and using the outcome to determine which moves are good ones is one kind of **reinforcement learning**, which is covered in Chapter 23.

## 6.5 Stochastic Games

**Stochastic game**

**Stochastic games** bring us a little closer to the unpredictability of real life by including a random element, such as the throwing of dice. Backgammon is a typical stochastic game that combines luck and skill. In the backgammon position of Figure 6.12, Black has rolled a 6–5 and has four possible moves (each of which moves one piece forward (clockwise) 5 positions, and one piece forward 6 positions).

**Figure 6.12** A typical backgammon position. The goal of the game is to move all one's pieces off the board. Black moves clockwise toward 25, and White moves counterclockwise toward 0. A piece can move to any position unless multiple opponent pieces are there; if there is one opponent, it is captured and must start over. In the position shown, Black has rolled 6–5 and must choose among four legal moves: (5–11,5–10), (5–11,19–24), (5–10,10–16), and (5–11,11–16), where the notation (5–11,11–16) means move one piece from position 5 to 11, and then move a piece from 11 to 16.

At this point Black knows what moves can be made, but does not know what White is going to roll and thus does not know what White's legal moves will be. That means Black cannot construct a standard game tree of the sort we saw in chess and tic-tac-toe. A game tree in backgammon must include **chance nodes** in addition to MAX and MIN nodes. Chance nodes are shown as circles in Figure 6.13. The branches leading from each chance node denote the possible dice rolls; each branch is labeled with the roll and its probability. There are 36 ways to roll two dice, each equally likely; but because a 6–5 is the same as a 5–6, there are only 21 distinct rolls. The six doubles (1–1 through 6–6) each have a probability of  $1/36$ , so we say  $P(1–1) = 1/36$ . The other 15 distinct rolls each have a  $1/18$  probability.

The next step is to understand how to make correct decisions. Obviously, we still want to pick the move that leads to the best position. However, positions do not have definite minimax values. Instead, we can only calculate the **expected value** of a position: the average over all possible outcomes of the chance nodes.

This leads us to the **expectiminimax value** for games with chance nodes, a generalization of the minimax value for deterministic games. Terminal nodes and MAX and MIN nodes work exactly the same way as before (with the caveat that the legal moves for MAX and MIN will depend on the outcome of the dice roll in the previous chance node). For chance nodes we

Chance nodes

Expected value

Expectiminimax value

**Figure 6.13** Schematic game tree for a backgammon position.

compute the expected value, which is the sum of the value over all outcomes, weighted by the probability of each chance action:

$$\text{EXPECTIMINIMAX}(s) = \begin{cases} \text{UTILITY}(s, \text{MAX}) & \text{if IS-TERMINAL}(s) \\ \max_a \text{EXPECTIMINIMAX}(\text{RESULT}(s, a)) & \text{if To-MOVE}(s) = \text{MAX} \\ \min_a \text{EXPECTIMINIMAX}(\text{RESULT}(s, a)) & \text{if To-MOVE}(s) = \text{MIN} \\ \sum_r P(r) \text{EXPECTIMINIMAX}(\text{RESULT}(s, r)) & \text{if To-MOVE}(s) = \text{CHANCE} \end{cases}$$

where  $r$  represents a possible dice roll (or other chance event) and  $\text{RESULT}(s, r)$  is the same state as  $s$ , with the additional fact that the result of the dice roll is  $r$ .

### 6.5.1 Evaluation functions for games of chance

As with minimax, the obvious approximation to make with expectiminimax is to cut the search off at some point and apply an evaluation function to each leaf. One might think that evaluation functions for games such as backgammon should be just like evaluation functions for chess—they just need to give higher values to better positions. But in fact, the presence of chance nodes means that one has to be more careful about what the values mean.

Figure 6.14 shows what happens: with an evaluation function that assigns the values [1, 2, 3, 4] to the leaves, move  $a_1$  is best; with values [1, 20, 30, 400], move  $a_2$  is best. Hence, the program behaves totally differently if we make a change to some of the evaluation values, even if the preference order remains the same.

It turns out that to avoid this problem, the evaluation function must return values that are a positive linear transformation of the **probability** of winning (or of the expected utility, for games that have outcomes other than win/lose). This relation to probability is an important

**Figure 6.14** An order-preserving transformation on leaf values changes the best move.

and general property of situations in which uncertainty is involved, and we discuss it further in Chapter 15.

If the program knew in advance all the dice rolls that would occur for the rest of the game, solving a game with dice would be just like solving a game without dice, which minimax does in  $O(b^m)$  time, where  $b$  is the branching factor and  $m$  is the maximum depth of the game tree. Because expectiminimax is also considering all the possible dice-roll sequences, it will take  $O(b^m n^m)$ , where  $n$  is the number of distinct rolls.

Even if the search is limited to some small depth  $d$ , the extra cost compared with that of minimax makes it unrealistic to consider looking ahead very far in most games of chance. In backgammon  $n$  is 21 and  $b$  is usually around 20, but in some situations can be as high as 4000 for dice rolls that are doubles. We could probably only manage three ply of search.

Another way to think about the problem is this: the advantage of alpha–beta is that it ignores future developments that just are not going to happen, given best play. Thus, it concentrates on likely occurrences. But in a game where a throw of two dice precedes each move, there are *no* likely sequences of moves; even the most likely move occurs only 2/36 of the time, because for the move to take place, the dice would first have to come out the right way to make it legal. This is a general problem whenever uncertainty enters the picture: the possibilities are multiplied enormously, and forming detailed plans of action becomes pointless because the world probably will not play along.

It may have occurred to you that something like alpha–beta pruning could be applied to game trees with chance nodes. It turns out that it can. The analysis for MIN and MAX nodes is unchanged, but we can also prune chance nodes, using a bit of ingenuity. Consider the chance node  $C$  in Figure 6.13 and what happens to its value as we evaluate its children. Is it possible to find an upper bound on the value of  $C$  before we have looked at all its children? (Recall that this is what alpha–beta needs in order to prune a node and its subtree.)

At first sight, it might seem impossible because the value of  $C$  is the *average* of its children’s values, and in order to compute the average of a set of numbers, we must look at all the numbers. But if we put bounds on the possible values of the utility function, then we can

arrive at bounds for the average without looking at every number. For example, say that all utility values are between  $-2$  and  $+2$ ; then the value of leaf nodes is bounded, and in turn we can place an upper bound on the value of a chance node without looking at all its children.

In games where the branching factor for chance nodes is high—consider a game like Yahtzee where you roll 5 dice on every turn—you may want to consider forward pruning that samples a smaller number of the possible chance branches. Or you may want to avoid using an evaluation function altogether, and opt for Monte Carlo tree search instead, where each playout includes random dice rolls.

## 6.6 Partially Observable Games

---

Bobby Fischer declared that “chess is war,” but chess lacks at least one major characteristic of real wars, namely, **partial observability**. In the “fog of war,” the whereabouts of enemy units is often unknown until revealed by direct contact. As a result, warfare includes the use of scouts and spies to gather information and the use of concealment and bluff to confuse the enemy.

Partially observable games share these characteristics and are thus qualitatively different from the games in the preceding sections. Video games such as StarCraft are particularly challenging, being partially observable, multi-agent, nondeterministic, dynamic, and unknown.

In *deterministic* partially observable games, uncertainty about the state of the board arises entirely from lack of access to the choices made by the opponent. This class includes children’s games such as Battleship (where each player’s ships are placed in locations hidden from the opponent) and Stratego (where piece locations are known but piece types are hidden). We will examine the game of **Kriegspiel**, a partially observable variant of chess in which pieces are completely invisible to the opponent. Other games also have partially observable versions: Phantom Go, Phantom tic-tac-toe, and Screen Shogi.

Kriegspiel

### 6.6.1 Kriegspiel: Partially observable chess

The rules of Kriegspiel are as follows: White and Black each see a board containing only their own pieces. A referee, who can see all the pieces, adjudicates the game and periodically makes announcements that are heard by both players. First, White proposes to the referee a move that would be legal if there were no black pieces. If the black pieces prevent the move, the referee announces “illegal,” and White keeps proposing moves until a legal one is found—learning more about the location of Black’s pieces in the process.

Once a legal move is proposed, the referee announces one or more of the following: “Capture on square  $X$ ” if there is a capture, and “Check by  $D$ ” if the black king is in check, where  $D$  is the direction of the check, and can be one of “Knight,” “Rank,” “File,” “Long diagonal,” or “Short diagonal.” If Black is checkmated or stalemated, the referee says so; otherwise, it is Black’s turn to move.

Kriegspiel may seem terrifyingly impossible, but humans manage it quite well and computer programs are beginning to catch up. It helps to recall the notion of a **belief state** as defined in Section 4.4 and illustrated in Figure 4.14—the set of all *logically possible* board states given the complete history of percepts to date. Initially, White’s belief state is a singleton because Black’s pieces haven’t moved yet. After White makes a move and Black responds, White’s belief state contains 20 positions, because Black has 20 replies to any

opening move. Keeping track of the belief state as the game progresses is exactly the problem of **state estimation**, for which the update step is given in Equation (4.6) on page 150. We can map Kriegspiel state estimation directly onto the partially observable, nondeterministic framework of Section 4.4 if we consider the opponent as the source of nondeterminism; that is, the **RESULTS** of White’s move are composed from the (predictable) outcome of White’s own move and the unpredictable outcome given by Black’s reply.<sup>4</sup>

Given a current belief state, White may ask, “Can I win the game?” For a partially observable game, the notion of a **strategy** is altered; instead of specifying a move to make for each possible *move* the opponent might make, we need a move for every possible *percept sequence* that might be received.

For Kriegspiel, a winning strategy, or **guaranteed checkmate**, is one that, for each possible percept sequence, leads to an actual checkmate for every possible board state in the current belief state, regardless of how the opponent moves. With this definition, the opponent’s belief state is irrelevant—the strategy has to work even if the opponent can see all the pieces. This greatly simplifies the computation. Figure 6.15 shows part of a guaranteed checkmate for the KRK (king and rook versus king) endgame. In this case, Black has just one piece (the king), so a belief state for White can be shown in a single board by marking each possible position of the Black king.

The general AND-OR search algorithm can be applied to the belief-state space to find guaranteed checkmates, just as in Section 4.4. The incremental belief-state algorithm mentioned in Section 4.4.2 often finds midgame checkmates up to depth 9—well beyond the abilities of most human players.

In addition to guaranteed checkmates, Kriegspiel admits an entirely new concept that makes no sense in fully observable games: **probabilistic checkmate**. Such checkmates are still required to work in every board state in the belief state; they are probabilistic with respect to randomization of the winning player’s moves. To get the basic idea, consider the problem of finding a lone black king using just the white king. Simply by moving randomly, the white king will *eventually* bump into the black king even if the latter tries to avoid this fate, since Black cannot keep guessing the right evasive moves indefinitely. In the terminology of probability theory, detection occurs *with probability 1*.

The KBNK endgame—king, bishop and knight versus king—is won in this sense; White presents Black with an infinite random sequence of choices, for one of which Black will guess incorrectly and reveal his position, leading to checkmate. On the other hand, the KBBK endgame is won with probability  $1 - \epsilon$ . White can force a win only by leaving one of his bishops unprotected for one move. If Black happens to be in the right place and captures the bishop (a move that would be illegal if the bishops are protected), the game is drawn. White can choose to make the risky move at some randomly chosen point in the middle of a very long sequence, thus reducing  $\epsilon$  to an arbitrarily small constant, but cannot reduce  $\epsilon$  to zero.

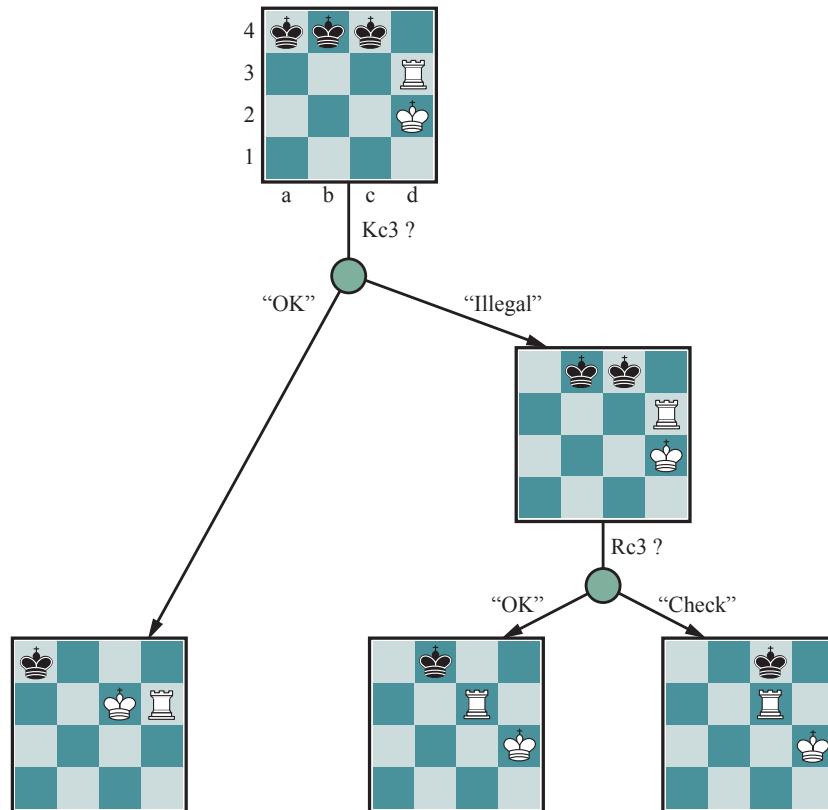

Sometimes a checkmate strategy works for *some* of the board states in the current belief state but not others. Trying such a strategy may succeed, leading to an **accidental checkmate**—accidental in the sense that White could not *know* that it would be checkmate—if Black’s pieces happen to be in the right places. (Most checkmates in games between humans

Guaranteed checkmate

Probabilistic checkmate

Accidental checkmate

<sup>4</sup> Sometimes, the belief state will become too large to represent just as a list of board states, but we will ignore this issue for now; Chapters 7 and 8 suggest methods for compactly representing very large belief states.

**Figure 6.15** Part of a guaranteed checkmate in the KRK endgame, shown on a reduced board. In the initial belief state, Black's king is in one of three possible locations. By a combination of probing moves, the strategy narrows this down to one. Completion of the checkmate is left as an exercise.

are of this accidental nature.) This idea leads naturally to the question of *how likely* it is that a given strategy will win, which leads in turn to the question of *how likely* it is that each board state in the current belief state is the true board state.

One's first inclination might be to propose that all board states in the current belief state are equally likely—but this can't be right. Consider, for example, White's belief state after Black's first move of the game. By definition (assuming that Black plays optimally), Black must have played an optimal move, so all board states resulting from suboptimal moves ought to be assigned zero probability.

 This argument is not quite right either, because *each player's goal is not just to move pieces to the right squares but also to minimize the information that the opponent has about their location*. Playing any *predictable* “optimal” strategy provides the opponent with information. Hence, optimal play in partially observable games requires a willingness to play somewhat *randomly*. (This is why restaurant hygiene inspectors do *random* inspection visits.) This means occasionally selecting moves that may seem “intrinsically” weak—but they gain strength from their very unpredictability, because the opponent is unlikely to have prepared any defense against them.

From these considerations, it seems that the probabilities associated with the board states in the current belief state can only be calculated given an optimal randomized strategy; in turn, computing that strategy seems to require knowing the probabilities of the various states the board might be in. This conundrum can be resolved by adopting the game-theoretic notion of an **equilibrium** solution, which we pursue further in Chapter 16. An equilibrium specifies an optimal randomized strategy for each player. Computing equilibria is too expensive for Kriegspiel. At present, the design of effective algorithms for general Kriegspiel play is an open research topic. Most systems perform bounded-depth look-ahead in their own belief-state space, ignoring the opponent’s belief state. Evaluation functions resemble those for the observable game but include a component for the size of the belief state—smaller is better! We will return to partially observable games under the topic of Game Theory in Section 17.2.

### 6.6.2 Card games

Card games such as bridge, whist, hearts, and poker feature *stochastic* partial observability, where the missing information is generated by the random dealing of cards.

At first sight, it might seem that these card games are just like dice games: the cards are dealt randomly and determine the moves available to each player, but all the “dice” are rolled at the beginning! Even though this analogy turns out to be incorrect, it suggests an algorithm: treat the start of the game as a chance node with every possible deal as an outcome, and then use the EXPECTIMINIMAX formula to pick the best move. Note that in this approach the only chance node is the root node; after that the game becomes fully observable. This approach is sometimes called *averaging over clairvoyance* because it assumes that once the actual deal has occurred, the game becomes fully observable to both players. Despite its intuitive appeal, the strategy can lead one astray. Consider the following story:

Day 1: Road A leads to a pot of gold; Road B leads to a fork. You can see that the left fork leads to two pots of gold, and the right fork leads to you being run over by a bus.

Day 2: Road A leads to a pot of gold; Road B leads to a fork. You can see that the right fork leads to two pots of gold, and the left fork leads to you being run over by a bus.

Day 3: Road A leads to a pot of gold; Road B leads to a fork. You are told that one fork leads to two pots of gold, and one fork leads to you being run over by a bus. Unfortunately you don’t know which fork is which.

Averaging over clairvoyance leads to the following reasoning: on Day 1, *B* is the right choice; on Day 2, *B* is the right choice; on Day 3, the situation is the same as either Day 1 or Day 2, so *B* must still be the right choice.

Now we can see how averaging over clairvoyance fails: it does not consider the *belief state* that the agent will be in after acting. A belief state of total ignorance is not desirable, especially when one possibility is certain death. Because it assumes that every future state will automatically be one of perfect knowledge, the clairvoyance approach never selects actions that *gather information* (like the first move in Figure 6.15); nor will it choose actions that hide information from the opponent or provide information to a partner, because it assumes that they already know the information; and it will never **bluff** in poker,<sup>5</sup> because it assumes the opponent can see its cards. In Chapter 16, we show how to construct algorithms that do

Bluff

<sup>5</sup> Bluffing—betting as if one’s hand is good, even when it’s not—is a core part of poker strategy.

all these things by virtue of solving the true partially observable decision problem, resulting in an optimal equilibrium strategy (see Section 17.2).

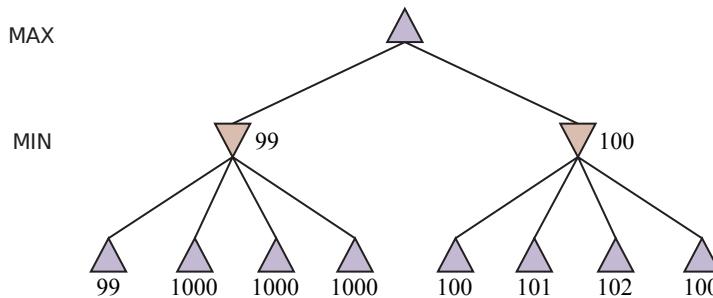

Despite the drawbacks, averaging over clairvoyance can be an effective strategy, with some tricks to make it work better. In most card games, the number of possible deals is rather large. For example, in bridge play, each player sees just two of the four hands; there are two unseen hands of 13 cards each, so the number of deals is  $\binom{26}{13} = 10,400,600$ . Solving even one deal is quite difficult, so solving ten million is out of the question. One way to deal with this huge number is with **abstraction**: i.e. by treating similar hands as identical. For example, it is very important which aces and kings are in a hand, but whether the hand has a 4 or 5 is not as important, and can be abstracted away.

Another way to deal with the large number is forward pruning: consider only a small random sample of  $N$  deals, and again calculate the EXPECTIMINIMAX score. Even for fairly small  $N$ —say, 100 to 1,000—this method gives a good approximation. It can also be applied to deterministic games such as Kriegspiel, where we sample over possible states of the game rather than over possible deals, as long as we have some way to estimate how likely each state is. It can also be helpful to do heuristic search with a depth cutoff rather than to search the entire game tree.

So far we have assumed that each deal is equally likely. That makes sense for games like whist and hearts. But for bridge, play is preceded by a bidding phase in which each team indicates how many tricks it expects to win. Since players bid based on the cards they hold, the other players learn something about the probability  $P(s)$  of each deal. Taking this into account in deciding how to play the hand is tricky, for the reasons mentioned in our description of Kriegspiel: players may bid in such a way as to minimize the information conveyed to their opponents.

Computers have reached a superhuman level of performance in poker. The poker program Libratus took on four of the top poker players in the world in a 20-day match of no-limit Texas hold 'em and decisively beat them all. Since there are so many possible states in poker, Libratus uses abstraction to reduce the state space: it might consider the two hands AAA72 and AAA64 to be equivalent (they're both “three aces and some low cards”), and it might consider a bet of 200 dollars to be the same as 201 dollars. But Libratus also monitors the other players, and if it detects they are exploiting an abstraction, it will do some additional computation overnight to plug that hole. Overall it used 25 million CPU hours on a supercomputer to pull off the win.

The computational costs incurred by Libratus (and similar costs by ALPHAZERO and other systems) suggests that world champion game play may not be achievable for researchers with limited budgets. To some extent that is true: just as you should not expect to be able to assemble a champion Formula One race car out of spare parts in your garage, there is an advantage to having access to supercomputers or specialty hardware such as Tensor Processing Units. That is particularly true when training a system, but training could also be done via crowdsourcing. For example the open-source LEELAZERO system is a reimplementation of ALPHAZERO that trains through self-play on the computers of volunteer participants. Once trained, the computational requirements for actual tournament play are modest. ALPHASTAR won StarCraft II games running on a commodity desktop with a single GPU, and ALPHAZERO could have been run in that mode.

**Figure 6.16** A two-ply game tree for which heuristic minimax may make an error.

## 6.7 Limitations of Game Search Algorithms

Because calculating optimal decisions in complex games is intractable, all algorithms must make some assumptions and approximations. Alpha–beta search uses the heuristic evaluation function as an approximation, and Monte Carlo search computes an approximate average over a random selection of playouts. The choice of which algorithm to use depends in part on the features of each game: when the branching factor is high or it is difficult to define an evaluation function, Monte Carlo search is preferred. But both algorithms suffer from fundamental limitations.

One limitation of alpha–beta search is its vulnerability to errors in the heuristic function. Figure 6.16 shows a two-ply game tree for which minimax suggests taking the right-hand branch because  $100 > 99$ . That is the correct move if the evaluations are all exactly accurate. But suppose that the evaluation of each node has an error that is independent of other nodes and is randomly distributed with a standard deviation of  $\sigma$ . Then the left-hand branch is actually better 71% of the time when  $\sigma = 5$ , and 58% of the time when  $\sigma = 2$  (because one of the four right-hand leaves is likely to slip below 99 in these cases). If errors in the evaluation function are *not* independent, then the chance of a mistake rises. It is difficult to compensate for this because we don't have a good model of the dependencies between the values of sibling nodes.

A second limitation of both alpha–beta and Monte Carlo is that they are designed to calculate (bounds on) the values of legal moves. But sometimes there is one move that is obviously best (for example when there is only one legal move), and in that case, there is no point wasting computation time to figure out the value of the move—it is better to just make the move. A better search algorithm would use the idea of the *utility of a node expansion*, selecting node expansions of high utility—that is, ones that are likely to lead to the discovery of a significantly better move. If there are no node expansions whose utility is higher than their cost (in terms of time), then the algorithm should stop searching and make a move. This works not only for clear-favorite situations but also for the case of *symmetrical* moves, for which no amount of search will show that one move is better than another.

This kind of reasoning about what computations to do is called **metareasoning** (reasoning about reasoning). It applies not just to game playing but to any kind of reasoning at all. All computations are done in the service of trying to reach better decisions, all have costs, and all have some likelihood of resulting in a certain improvement in decision quality. Monte

Carlo search does attempt to do metareasoning to allocate resources to the most important parts of the tree, but does not do so in an optimal way.

A third limitation is that both alpha-beta and Monte Carlo do all their reasoning at the level of individual moves. Clearly, humans play games differently: they can reason at a more abstract level, considering a higher-level goal—for example, trapping the opponent’s queen—and using the goal to *selectively* generate plausible plans. In Chapter 11 we will study this type of **planning**, and in Section 11.4 we will show how to plan with a hierarchy of abstract to concrete representations.

A fourth issue is the ability to incorporate **machine learning** into the game search process. Early game programs relied on human expertise to hand-craft evaluation functions, opening books, search strategies, and efficiency tricks. We are just beginning to see programs like ALPHAZERO (Silver *et al.*, 2018), which relied on machine learning from self-play rather than game-specific human-generated expertise. We cover machine learning in depth starting with Chapter 19.

## Summary

---

We have looked at a variety of games to understand what optimal play means, to understand how to play well in practice, and to get a feel for how an agent should act in any type of adversarial environment. The most important ideas are as follows:

- A game can be defined by the **initial state** (how the board is set up), the legal **actions** in each state, the **result** of each action, a **terminal test** (which says when the game is over), and a **utility function** that applies to terminal states to say who won and what the final score is.
- In two-player, discrete, deterministic, turn-taking zero-sum games with **perfect information**, the **minimax** algorithm can select optimal moves by a depth-first enumeration of the game tree.
- The **alpha–beta** search algorithm computes the same optimal move as minimax, but achieves much greater efficiency by eliminating subtrees that are provably irrelevant.
- Usually, it is not feasible to consider the whole game tree (even with alpha–beta), so we need to cut the search off at some point and apply a heuristic **evaluation function** that estimates the utility of a state.
- An alternative called **Monte Carlo tree search** (MCTS) evaluates states not by applying a heuristic function, but by playing out the game all the way to the end and using the rules of the game to see who won. Since the moves chosen during the **playout** may not have been optimal moves, the process is repeated multiple times and the evaluation is an average of the results.
- Many game programs precompute tables of best moves in the opening and endgame so that they can look up a move rather than search.
- Games of chance can be handled by **expectiminimax**, an extension to the minimax algorithm that evaluates a **chance node** by taking the average utility of all its children, weighted by the probability of each child.
- In games of **imperfect information**, such as Kriegspiel and poker, optimal play requires reasoning about the current and future **belief states** of each player. A simple

approximation can be obtained by averaging the value of an action over each possible configuration of missing information.

- Programs have soundly defeated champion human players at chess, checkers, Othello, Go, poker, and many other games. Humans retain the edge in a few games of imperfect information, such as bridge and Kriegspiel. In video games such as StarCraft and Dota 2, programs are competitive with human experts, but part of their success may be due to their ability to perform many actions very quickly.

## Bibliographical and Historical Notes

---

In 1846, Charles Babbage discussed the feasibility of computer chess and checkers (Morrison and Morrison, 1961). He did not understand the exponential complexity of search trees, claiming “the combinations involved in the Analytical Engine enormously surpassed any required, even by the game of chess.” Babbage also designed, but did not build, a special-purpose machine for playing tic-tac-toe. The first game-playing machine was built around 1890 by the Spanish engineer Leonardo Torres y Quevedo. It specialized in the “KRK” (king and rook versus king) chess endgame, guaranteeing a win when the side with the rook has the move. The **minimax** algorithm is traced to a 1912 paper by Ernst Zermelo, the developer of modern set theory.

Game playing was one of the first tasks undertaken in AI, with early efforts by such pioneers as Konrad Zuse (1945), Norbert Wiener in his book *Cybernetics* (1948), and Alan Turing (1953). But it was Claude Shannon’s article *Programming a Computer for Playing Chess* (1950) that laid out all the major ideas: a representation for board positions, an evaluation function, quiescence search, and some ideas for selective game-tree search. Slater (1950) had the idea of an evaluation function as a linear combination of features, and stressed the mobility feature in chess.

John McCarthy conceived the idea of **alpha-beta** search in 1956, although the idea did not appear in print until later (Hart and Edwards, 1961). Knuth and Moore (1975) proved the correctness of alpha-beta and analysed its time complexity, while Pearl (1982b) showed alpha-beta to be asymptotically optimal among all fixed-depth game-tree search algorithms.

Berliner (1979) introduced B\*, a heuristic search algorithm that maintains interval bounds on the possible value of a node in the game tree rather than giving it a single point-valued estimate. David McAllester’s (1988) conspiracy number search expands leaf nodes that, by changing their values, could cause the program to prefer a new move at the root of the tree. MGSS\* (Russell and Wefald, 1989) uses the decision-theoretic techniques of Chapter 15 to estimate the value of expanding each leaf in terms of the expected improvement in decision quality at the root.

The SSS\* algorithm (Stockman, 1979) can be viewed as a two-player A\* that never expands more nodes than alpha-beta. The memory requirements make it impractical, but a linear-space version has been developed from the RBFS algorithm (Korf and Chickering, 1996). Baum and Smith (1997) propose a probability-based replacement for minimax, showing that it results in better choices in certain games. The **expectiminimax** algorithm was proposed by Donald Michie (1966). Bruce Ballard (1983) extended alpha-beta pruning to cover trees with chance nodes.

Pearl’s book *Heuristics* (1984) thoroughly analyzes many game-playing algorithms.

Monte Carlo simulation was pioneered by Metropolis and Ulam (1949) for calculations related to the development of the atomic bomb. Monte Carlo tree search (MCTS) was introduced by Abramson (1987). Tesauro and Galperin (1997) showed how a Monte Carlo search could be combined with an evaluation function for the game of backgammon. Early payout termination is studied by Lorentz (2015). ALPHAGO terminated playouts and applied an evaluation function (Silver *et al.*, 2016). Kocsis and Szepesvari (2006) refined the approach with the “Upper Confidence Bounds applied to Trees” selection mechanism. Chaslot *et al.* (2008) show how MCTS can be applied to a variety of games and Browne *et al.* (2012) give a survey.

Koller and Pfeffer (1997) describe a system for completely solving **partially observable** games. It handles larger games than previous systems, but not the full version of complex games like poker and bridge. Frank *et al.* (1998) describe several variants of Monte Carlo search for partially observable games, including one where MIN has complete information but MAX does not. Schofield and Thielscher (2015) adapt a general game-playing system for partially observable games.

Ferguson hand-derived randomized strategies for winning Kriegspiel with a bishop and knight (1992) or two bishops (1995) against a king. The first Kriegspiel programs concentrated on finding endgame checkmates and performed AND–OR search in belief-state space (Sakuta and Iida, 2002; Bolognesi and Ciancarini, 2003). Incremental belief-state algorithms enabled much more complex midgame checkmates to be found (Russell and Wolfe, 2005; Wolfe and Russell, 2007), but efficient state estimation remains the primary obstacle to effective general play (Parker *et al.*, 2005). Ciancarini and Favini (2010) apply MCTS to Kriegspiel, and Wang *et al.* (2018b) describe a belief-state version of MCTS for Phantom Go.

**Chess** milestones have been marked by successive winners of the Fredkin Prize: BELLE (Condon and Thompson, 1982), the first program to achieve master status; DEEP THOUGHT (Hsu *et al.*, 1990), the first to reach international master status; and Deep Blue (Campbell *et al.*, 2002; Hsu, 2004), which defeated world champion Garry Kasparov in a 1997 exhibition match. Deep Blue ran alpha–beta search at over 100 million positions per second, and could generate singular extensions to occasionally reach a depth of 40 ply.

The top chess programs today (e.g., STOCKFISH, KOMODO, HOUDINI) far exceed any human player. These programs have reduced the effective branching factor to less than 3 (compared with the actual branching factor of about 35), searching to about 20 ply at a speed of about a million nodes per second on a standard 1-core computer. They use pruning techniques such as the **null move** heuristic, which generates a good lower bound on the value of a position, using a shallow search in which the opponent gets to move twice at the beginning. Also important is **futility pruning**, which helps decide in advance which moves will cause a beta cutoff in the successor nodes. SUNFISH is a simplified chess program for teaching purposes; the core is less than 200 lines of Python.

The idea of retrograde analysis for computing endgame tables is due to Bellman (1965). Using this idea, Ken Thompson (1986, 1996) and Lewis Stiller (1992, 1996) solved all chess endgames with up to five pieces. Stiller discovered one case where a forced mate existed but required 262 moves; this caused some consternation because the rules of chess require a capture or pawn move to occur within 50 moves, or else a draw is declared. In 2012 Vladimir Makhnychev and Victor Zakharov compiled the Lomonosov Endgame Tablebase,

Null move

Futility pruning

which solved all endgame positions with up to seven pieces—some require over 500 moves without a capture. The 7-piece table consumes 140 terabytes; an 8-piece table would be 100 times larger.

In 2017, ALPHAZERO (Silver *et al.*, 2018) defeated STOCKFISH (the 2017 TCEC computer chess champion) in a 1000-game trial, with 155 wins and 6 losses. Additional matches also resulted in decisive wins for ALPHAZERO, even when it was given only 1/10th the time allotted to STOCKFISH.

Grandmaster Larry Kaufman was surprised at the success of this Monte Carlo program and noted, “It may well be that the current dominance of minimax chess engines may be at an end, but it’s too soon to say so.” Garry Kasparov commented “It’s a remarkable achievement, even if we should have expected it after ALPHAGO. It approaches the Type B human-like approach to machine chess dreamt of by Claude Shannon and Alan Turing instead of brute force.” He went on to predict “Chess has been shaken to its roots by ALPHAZERO, but this is only a tiny example of what is to come. Hidebound disciplines like education and medicine will also be shaken” (Sadler and Regan, 2019).

**Checkers** was the first of the classic games played by a computer (Strachey, 1952). Arthur Samuel (1959, 1967) developed a checkers program that learned its own evaluation function through self-play using a form of reinforcement learning. It is quite an achievement that Samuel was able to create a program that played better than he did, on an IBM 704 computer with only 10,000 words of memory and a 0.000001 GHz processor. MENACE—the Machine Educable Noughts And Crosses Engine (Michie, 1963)—also used reinforcement learning to become competent at tic-tac-toe. Its processor was even slower: a collection of 304 matchboxes holding colored beads to represent the best learned move in each position.

In 1992, Jonathan Schaeffer’s CHINOOK checkers program challenged the legendary Marion Tinsley, who had been world champion for over 20 years. Tinsley won the match, but lost two games—the fourth and fifth losses in his entire career. After Tinsley retired for health reasons, CHINOOK took the crown. The saga was chronicled by Schaeffer (2008).

In 2007 Schaeffer and his team “solved” checkers (Schaeffer *et al.*, 2007): the game is a draw with perfect play. Richard Bellman (1965) had predicted this: “In checkers, the number of possible moves in any given situation is so small that we can confidently expect a complete digital computer solution to the problem of optimal play in this game.” Bellman did not anticipate the scale of the effort: the endgame table for 10 pieces has 39 trillion entries. Given this table, it took 18 CPU-years of alpha–beta search to solve the game.

I. J. Good, who was taught the Game of **Go** by Alan Turing, wrote (1965a) “I think it will be even more difficult to programme a computer to play a reasonable game of Go than of chess.” He was right: through 2015, Go programs played only at an amateur level. The early literature is summarized by Bouzy and Cazenave (2001) and Müller (2002).

Visual pattern recognition was proposed as a promising technique for Go by Zobrist (1970), while Schraudolph *et al.* (1994) analyzed the use of reinforcement learning, Lubberts and Miikkulainen (2001) recommended neural networks, and Brügmann (1993) introduced Monte Carlo tree search to Go. ALPHAGO (Silver *et al.*, 2016) put those four ideas together to defeat top-ranked professionals Lee Sedol (by a score of 4–1 in 2015) and Ke Jie (by 3–0 in 2016).

Ke Jie remarked “After humanity spent thousands of years improving our tactics, computers tell us that humans are completely wrong. I would go as far as to say not a single human

has touched the edge of the truth of Go.” Lee Sedol retired from Go, lamenting, “Even if I became the number one, there is an entity that cannot be defeated.”

In 2018, ALPHAZERO surpassed ALPHAGO at Go, and also defeated top programs in chess and shogi, learning through self-play without any expert human knowledge and without access to any past games. (It does, of course, rely on humans to define the basic architecture as Monte Carlo tree search with deep neural networks and reinforcement learning, and to encode the rules of the game.) The success of ALPHAZERO has led to increased interest in reinforcement learning as a key component of general AI (see Chapter 23). Going one step further, the MUZERO system operates without even being told the rules of the game it is playing—it has to figure out the rules by making plays. MUZERO achieved state-of-the-art results in Pacman, chess, Go, and 75 Atari games (Schrittwieser *et al.*, 2019). It learns to generalize; for example, it learns that in Pacman the “up” action moves the player up a square (unless there is a wall there), even though it has only observed the result of the “up” action in a small percentage of the locations on the board.

**Othello**, also called Reversi, has a smaller search space than chess, but defining an evaluation function is difficult, because material advantage is not as important as mobility. Programs have been at superhuman level since 1997 (Buro, 2002).

**Backgammon**, a game of chance, was analyzed mathematically by Gerolamo Cardano (1663), and taken up for computer play with the BKG program (Berliner, 1980b), which used a manually constructed evaluation function and searched only to depth 1. It was the first program to defeat a human world champion at a major game (Berliner, 1980a), although Berliner readily acknowledged that BKG was very lucky with the dice. Gerry Tesauro’s (1995) TD-GAMMON learned its evaluation function using neural networks trained by self-play. It consistently played at world champion level and caused human analysts to change their opinion on the best opening move for several dice rolls.

**Poker**, like Go, has seen surprising advances in recent years. Bowling *et al.* (2015) used game theory (see Section 17.2) to determine the exact optimal strategy for a version of poker with just two players and a fixed number of raises with fixed bet sizes. In 2017, for the first time, champion poker players were beaten at heads-up (two player) no-limit Texas hold ’em in two separate matches against the programs Libratus (Brown and Sandholm, 2017) and DeepStack (Moravčík *et al.*, 2017). In 2019, Pluribus (Brown and Sandholm, 2019) defeated top-ranked professional human players in Texas hold ’em games with six players. Multiplayer games introduce some strategic concerns that we will cover in Chapter 17. Petosa and Balch (2019) implement a multiplayer version of ALPHAZERO.

**Bridge**: Smith *et al.* (1998) report on how BRIDGE BARON won the 1998 computer bridge championship, using hierarchical plans (see Chapter 11) and high-level actions, such as finessing and squeezing, that are familiar to bridge players. Ginsberg (2001) describes how his GIB program, based on Monte Carlo simulation (first proposed for bridge by Levy (1989)), won the following computer championship and did surprisingly well against expert human players. In the 21st century, the computer bridge championship has been dominated by two commercial programs, JACK and WBRIDGE5. Neither has been described in published articles, but both are believed to use Monte Carlo techniques. In general, bridge programs are at human champion level when actually playing the hands, but lag behind in the bidding phase, because they do not completely understand the conventions used by humans to communicate with their partners. Bridge programmers have concentrated more on producing

useful and educational programs that encourage people to take up the game, rather than on defeating human champions.

**Scrabble** is a game where amateur human players have difficulty coming up with high-scoring words, but for a computer, it is easy to find the highest possible score for a given hand (Gordon, 1994); the hard part is planning ahead in a partially observable, stochastic game. Nevertheless, in 2006, the QUACKLE program defeated the former world champion, David Boys, 3–2. Boys took it well, stating, “It’s still better to be a human than to be a computer.” A good description of a top program, MAVEN, is given by Sheppard (2002).

**Video games** such as **StarCraft II** involve hundreds of partially observable units moving in real time with high-dimensional near-continuous<sup>6</sup> observation and action spaces with complex rules. Oriol Vinyals, who was Spain’s StarCraft champion at age 15, described how the game can serve as a testbed and grand challenge for reinforcement learning (Vinyals *et al.*, 2017a). In 2019, Vinyals and the team at DeepMind unveiled the ALPHASTAR program, based on deep learning and reinforcement learning, which defeated expert human players 10 games to 1, and ranks in the top 0.02% of officially ranked human players (Vinyals *et al.*, 2019). ALPHASTAR took steps to limit the number of actions per minute it could perform in critical bursts, in response to critics who felt it had an unfair advantage.

Computers have defeated top humans in other popular video games such as Super Smash Bros. (Firoiu *et al.*, 2017), Quake III (Jaderberg *et al.*, 2019), and Dota 2 (Fernandez and Mahlmann, 2018), all using deep learning techniques.

**Physical games** such as **robotic soccer** (Visser *et al.*, 2008; Barrett and Stone, 2015), **billiards** (Lam and Greenspan, 2008; Archibald *et al.*, 2009), and **ping-pong** (Silva *et al.*, 2015) have attracted some attention in AI. They combine all the complications of video games with the messiness of the real world.

Computer game competitions occur annually, including the Computer Olympiads since 1989. The General Game Competition (Love *et al.*, 2006) tests programs that must learn to play an unknown game given only a logical description of the rules of the game. The International Computer Games Association (ICGA) publishes the *ICGA Journal* and runs two alternating biennial conferences, The International Conference on Computers and Games (ICCG or CG) and the International Conference on Advances in Computer Games (ACG). The IEEE publishes *IEEE Transactions on Games* and runs an annual Conference on Computational Intelligence and Games.

---

<sup>6</sup> To a human player, it appears that objects move continuously, but they are actually discrete at the level of a pixel on the screen.

# CHAPTER 7

## LOGICAL AGENTS

*In which we design agents that can form representations of a complex world, use a process of inference to derive new representations about the world, and use these new representations to deduce what to do.*

Knowledge-based  
agents  
Reasoning  
Representation

Humans, it seems, know things; and what they know helps them do things. In AI, **knowledge-based agents** use a process of **reasoning** over an internal **representation** of knowledge to decide what actions to take.

The problem-solving agents of Chapters 3 and 4 know things, but only in a very limited, inflexible sense. They know what actions are available and what the result of performing a specific action from a specific state will be, but they don't know general facts. A route-finding agent doesn't know that it is impossible for a road to be a negative number of kilometers long. An 8-puzzle agent doesn't know that two tiles cannot occupy the same space. The knowledge they have is very useful for finding a path from the start to a goal, but not for anything else.

The atomic representations used by problem-solving agents are also very limiting. In a partially observable environment, for example, a problem-solving agent's only choice for representing what it knows about the current state is to list all possible concrete states. I could give a human the goal of driving to a U.S. town with population less than 10,000, but to say that to a problem-solving agent, I could formally describe the goal only as an explicit set of the 16,000 or so towns that satisfy the description.

Chapter 5 introduced our first factored representation, whereby states are represented as assignments of values to variables; this is a step in the right direction, enabling some parts of the agent to work in a domain-independent way and allowing for more efficient algorithms. In this chapter, we take this step to its logical conclusion, so to speak—we develop **logic** as a general class of representations to support knowledge-based agents. These agents can combine and recombine information to suit myriad purposes. This can be far removed from the needs of the moment—as when a mathematician proves a theorem or an astronomer calculates the Earth's life expectancy. Knowledge-based agents can accept new tasks in the form of explicitly described goals; they can achieve competence quickly by being told or learning new knowledge about the environment; and they can adapt to changes in the environment by updating the relevant knowledge.

We begin in Section 7.1 with the overall agent design. Section 7.2 introduces a simple new environment, the wumpus world, and illustrates the operation of a knowledge-based agent without going into any technical detail. Then we explain the general principles of **logic** in Section 7.3 and the specifics of **propositional logic** in Section 7.4. Propositional logic is a factored representation; while less expressive than **first-order logic** (Chapter 8), which is the canonical structured representation, propositional logic illustrates all the basic concepts

---

```

function KB-AGENT(percept) returns an action
  persistent: KB, a knowledge base
    t, a counter, initially 0, indicating time

  TELL(KB, MAKE-PERCEPT-SENTENCE(percept, t))
  action  $\leftarrow$  ASK(KB, MAKE-ACTION-QUERY(t))
  TELL(KB, MAKE-ACTION-SENTENCE(action, t))
  t  $\leftarrow$  t + 1
  return action

```

**Figure 7.1** A generic knowledge-based agent. Given a percept, the agent adds the percept to its knowledge base, asks the knowledge base for the best action, and tells the knowledge base that it has in fact taken that action.

---

of logic. It also comes with well-developed inference technologies, which we describe in sections 7.5 and 7.6. Finally, Section 7.7 combines the concept of knowledge-based agents with the technology of propositional logic to build some simple agents for the wumpus world.

## 7.1 Knowledge-Based Agents

---

The central component of a knowledge-based agent is its **knowledge base**, or *KB*. A knowledge base is a set of **sentences**. (Here “sentence” is used as a technical term. It is related but not identical to the sentences of English and other natural languages.) Each sentence is expressed in a language called a **knowledge representation language** and represents some assertion about the world. When the sentence is taken as being given without being derived from other sentences, we call it an **axiom**.

There must be a way to add new sentences to the knowledge base and a way to query what is known. The standard names for these operations are TELL and ASK, respectively. Both operations may involve **inference**—that is, deriving new sentences from old. Inference must obey the requirement that when one ASKS a question of the knowledge base, the answer should follow from what has been told (or TELLED) to the knowledge base previously. Later in this chapter, we will be more precise about the crucial word “follow.” For now, take it to mean that the inference process should not make things up as it goes along.

Figure 7.1 shows the outline of a knowledge-based agent program. Like all our agents, it takes a percept as input and returns an action. The agent maintains a knowledge base, *KB*, which may initially contain some **background knowledge**.

Each time the agent program is called, it does three things. First, it TELLS the knowledge base what it perceives. Second, it ASKS the knowledge base what action it should perform. In the process of answering this query, extensive reasoning may be done about the current state of the world, about the outcomes of possible action sequences, and so on. Third, the agent program TELLS the knowledge base which action was chosen, and returns the action so that it can be executed.

The details of the representation language are hidden inside three functions that implement the interface between the sensors and actuators on one side and the core representation and reasoning system on the other. MAKE-PERCEPT-SENTENCE constructs a sentence as-

Knowledge base

Sentence

Knowledge representation language

Axiom

Inference

Background knowledge

serting that the agent perceived the given percept at the given time. MAKE-ACTION-QUERY constructs a sentence that asks what action should be done at the current time. Finally, MAKE-ACTION-SENTENCE constructs a sentence asserting that the chosen action was executed. The details of the inference mechanisms are hidden inside TELL and ASK. Later sections will reveal these details.

The agent in Figure 7.1 appears quite similar to the agents with internal state described in Chapter 2. Because of the definitions of TELL and ASK, however, the knowledge-based agent is not an arbitrary program for calculating actions. It is amenable to a description at the **knowledge level**, where we need specify only what the agent knows and what its goals are, in order to determine its behavior.

For example, an automated taxi might have the goal of taking a passenger from San Francisco to Marin County and might know that the Golden Gate Bridge is the only link between the two locations. Then we can expect it to cross the Golden Gate Bridge *because it knows that that will achieve its goal*. Notice that this analysis is independent of how the taxi works at the **implementation level**. It doesn't matter whether its geographical knowledge is implemented as linked lists or pixel maps, or whether it reasons by manipulating strings of symbols stored in registers or by propagating noisy signals in a network of neurons.

A knowledge-based agent can be built simply by TELLING it what it needs to know. Starting with an empty knowledge base, the agent designer can TELL sentences one by one until the agent knows how to operate in its environment. This is called the **declarative** approach to system building. In contrast, the **procedural** approach encodes desired behaviors directly as program code. In the 1970s and 1980s, advocates of the two approaches engaged in heated debates. We now understand that a successful agent often combines both declarative and procedural elements in its design, and that declarative knowledge can often be compiled into more efficient procedural code.

We can also provide a knowledge-based agent with mechanisms that allow it to learn for itself. These mechanisms, which are discussed in Chapter 19, create general knowledge about the environment from a series of percepts. A learning agent can be fully autonomous.

## 7.2 The Wumpus World

In this section we describe an environment in which knowledge-based agents can show their worth. The **wumpus world** is a cave consisting of rooms connected by passageways. Lurking somewhere in the cave is the terrible wumpus, a beast that eats anyone who enters its room. The wumpus can be shot by an agent, but the agent has only one arrow. Some rooms contain bottomless pits that will trap anyone who wanders into these rooms (except for the wumpus, which is too big to fall in). The only redeeming feature of this bleak environment is the possibility of finding a heap of gold. Although the wumpus world is rather tame by modern computer game standards, it illustrates some important points about intelligence.

A sample wumpus world is shown in Figure 7.2. The precise definition of the task environment is given, as suggested in Section 2.3, by the PEAS description:

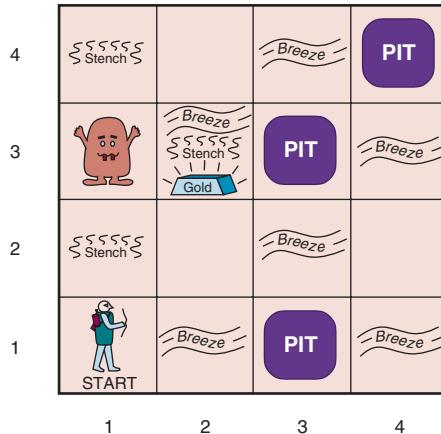

- **Performance measure:** +1000 for climbing out of the cave with the gold, -1000 for falling into a pit or being eaten by the wumpus, -1 for each action taken, and -10 for using up the arrow. The game ends either when the agent dies or when the agent climbs out of the cave.

Knowledge level

Implementation level

Declarative  
Procedural

Wumpus world

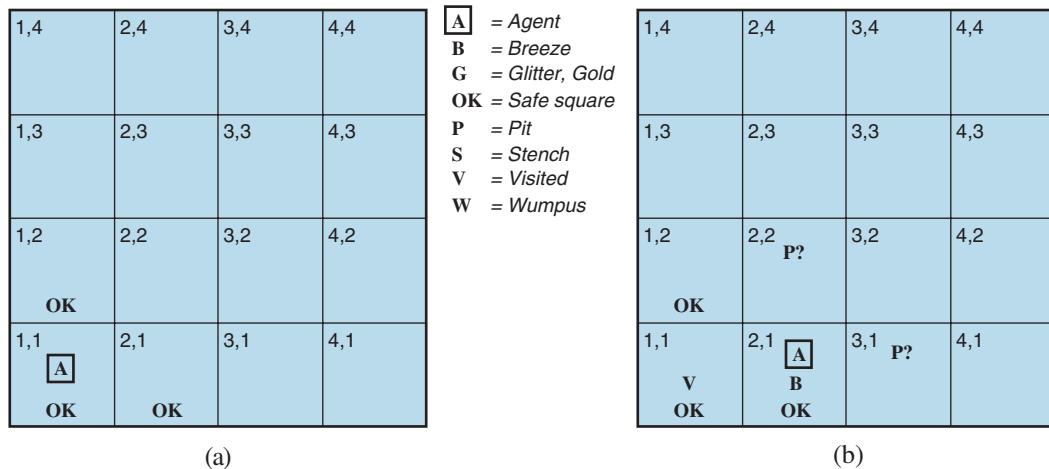

**Figure 7.2** A typical wumpus world. The agent is in the bottom left corner, facing east (rightward).

- **Environment:** A  $4 \times 4$  grid of rooms, with walls surrounding the grid. The agent always starts in the square labeled [1,1], facing to the east. The locations of the gold and the wumpus are chosen randomly, with a uniform distribution, from the squares other than the start square. In addition, each square other than the start can be a pit, with probability 0.2.
- **Actuators:** The agent can move *Forward*, *TurnLeft* by  $90^\circ$ , or *TurnRight* by  $90^\circ$ . The agent dies a miserable death if it enters a square containing a pit or a live wumpus. (It is safe, albeit smelly, to enter a square with a dead wumpus.) If an agent tries to move forward and bumps into a wall, then the agent does not move. The action *Grab* can be used to pick up the gold if it is in the same square as the agent. The action *Shoot* can be used to fire an arrow in a straight line in the direction the agent is facing. The arrow continues until it either hits (and hence kills) the wumpus or hits a wall. The agent has only one arrow, so only the first *Shoot* action has any effect. Finally, the action *Climb* can be used to climb out of the cave, but only from square [1,1].
- **Sensors:** The agent has five sensors, each of which gives a single bit of information:
  - In the squares directly (not diagonally) adjacent to the wumpus, the agent will perceive a *Stench*.<sup>1</sup>
  - In the squares directly adjacent to a pit, the agent will perceive a *Breeze*.
  - In the square where the gold is, the agent will perceive a *Glitter*.
  - When an agent walks into a wall, it will perceive a *Bump*.
  - When the wumpus is killed, it emits a woeful *Scream* that can be perceived anywhere in the cave.

The percepts will be given to the agent program in the form of a list of five symbols; for example, if there is a stench and a breeze, but no glitter, bump, or scream, the agent program will get [*Stench*, *Breeze*, *None*, *None*, *None*].

<sup>1</sup> Presumably the square containing the wumpus also has a stench, but any agent entering that square is eaten before being able to perceive anything.

**Figure 7.3** The first step taken by the agent in the wumpus world. (a) The initial situation, after percept  $[None, None, None, None, None]$ . (b) After moving to  $[2,1]$  and perceiving  $[None, Breeze, None, None, None]$ .

We can characterize the wumpus environment along the various dimensions given in Chapter 2. Clearly, it is deterministic, discrete, static, and single-agent. (The wumpus doesn't move, fortunately.) It is sequential, because rewards may come only after many actions are taken. It is partially observable, because some aspects of the state are not directly perceivable: the agent's location, the wumpus's state of health, and the availability of an arrow. As for the locations of the pits and the wumpus: we could treat them as unobserved parts of the state—in which case, the transition model for the environment is completely known, and finding the locations of pits completes the agent's knowledge of the state. Alternatively, we could say that the transition model itself is unknown because the agent doesn't know which *Forward* actions are fatal—in which case, discovering the locations of pits and wumpus completes the agent's knowledge of the transition model.

For an agent in the environment, the main challenge is its initial ignorance of the configuration of the environment; overcoming this ignorance seems to require logical reasoning. In most instances of the wumpus world, it is possible for the agent to retrieve the gold safely. Occasionally, the agent must choose between going home empty-handed and risking death to find the gold. About 21% of the environments are utterly unfair, because the gold is in a pit or surrounded by pits.

Let us watch a knowledge-based wumpus agent exploring the environment shown in Figure 7.2. We use an informal knowledge representation language consisting of writing down symbols in a grid (as in Figures 7.3 and 7.4).

The agent's initial knowledge base contains the rules of the environment, as described previously; in particular, it knows that it is in  $[1,1]$  and that  $[1,1]$  is a safe square; we denote that with an "A" and "OK," respectively, in square  $[1,1]$ .

The first percept is  $[None, None, None, None, None]$ , from which the agent can conclude that its neighboring squares,  $[1,2]$  and  $[2,1]$ , are free of dangers—they are OK. Figure 7.3(a) shows the agent's state of knowledge at this point.

1,4	2,4	3,4	4,4
1,3 W!	2,3	3,3	4,3
1,2 A S OK	2,2	3,2	4,2
1,1 V OK	2,1 B V OK	3,1 P! V OK	4,1

(a)

1,4	2,4 P?	3,4	4,4
1,3 W!	2,3 A S G B	3,3 P?	4,3
1,2 S V OK	2,2 V OK	3,2	4,2
1,1 V OK	2,1 B V OK	3,1 P! V OK	4,1

(b)

**Figure 7.4** Two later stages in the progress of the agent. (a) After moving to [1,1] and then [1,2], and perceiving [Stench, None, None, None, None]. (b) After moving to [2,2] and then [2,3], and perceiving [Stench, Breeze, Glitter, None, None].

A cautious agent will move only into a square that it knows to be OK. Let us suppose the agent decides to move forward to [2,1]. The agent perceives a breeze (denoted by “B”) in [2,1], so there must be a pit in a neighboring square. The pit cannot be in [1,1], by the rules of the game, so there must be a pit in [2,2] or [3,1] or both. The notation “P?” in Figure 7.3(b) indicates a possible pit in those squares. At this point, there is only one known square that is OK and that has not yet been visited. So the prudent agent will turn around, go back to [1,1], and then proceed to [1,2].

The agent perceives a stench in [1,2], resulting in the state of knowledge shown in Figure 7.4(a). The stench in [1,2] means that there must be a wumpus nearby. But the wumpus cannot be in [1,1], by the rules of the game, and it cannot be in [2,2] (or the agent would have detected a stench when it was in [2,1]). Therefore, the agent can infer that the wumpus is in [1,3]. The notation W! indicates this inference. Moreover, the lack of a breeze in [1,2] implies that there is no pit in [2,2]. Yet the agent has already inferred that there must be a pit in either [2,2] or [3,1], so this means it must be in [3,1]. This is a fairly difficult inference, because it combines knowledge gained at different times in different places and relies on the lack of a percept to make one crucial step.

The agent has now proved to itself that there is neither a pit nor a wumpus in [2,2], so it is OK to move there. We do not show the agent’s state of knowledge at [2,2]; we just assume that the agent turns and moves to [2,3], giving us Figure 7.4(b). In [2,3], the agent detects a glitter, so it should grab the gold and then return home.

Note that in each case for which the agent draws a conclusion from the available information, that conclusion is *guaranteed* to be correct if the available information is correct. This is a fundamental property of logical reasoning. In the rest of this chapter, we describe how to build logical agents that can represent information and draw conclusions such as those described in the preceding paragraphs.

## 7.3 Logic

---

This section summarizes the fundamental concepts of logical representation and reasoning. These beautiful ideas are independent of any of logic's particular forms. We therefore postpone the technical details of those forms until the next section, using instead the familiar example of ordinary arithmetic.

Syntax

In Section 7.1, we said that knowledge bases consist of sentences. These sentences are expressed according to the **syntax** of the representation language, which specifies all the sentences that are well formed. The notion of syntax is clear enough in ordinary arithmetic: " $x + y = 4$ " is a well-formed sentence, whereas " $x4y+ =$ " is not.

Semantics

Truth

Possible world

Model

Satisfaction

Entailment

A logic must also define the **semantics**, or meaning, of sentences. The semantics defines the **truth** of each sentence with respect to each **possible world**. For example, the semantics for arithmetic specifies that the sentence " $x + y = 4$ " is true in a world where  $x$  is 2 and  $y$  is 2, but false in a world where  $x$  is 1 and  $y$  is 1. In standard logics, every sentence must be either true or false in each possible world—there is no “in between.”<sup>2</sup>

When we need to be precise, we use the term **model** in place of “possible world.” Whereas possible worlds might be thought of as (potentially) real environments that the agent might or might not be in, models are mathematical abstractions, each of which has a fixed truth value (true or false) for every relevant sentence. Informally, we may think of a possible world as, for example, having  $x$  men and  $y$  women sitting at a table playing bridge, and the sentence  $x + y = 4$  is true when there are four people in total. Formally, the possible models are just all possible assignments of nonnegative integers to the variables  $x$  and  $y$ . Each such assignment determines the truth of any sentence of arithmetic whose variables are  $x$  and  $y$ . If a sentence  $\alpha$  is true in model  $m$ , we say that  $m$  **satisfies**  $\alpha$  or sometimes  $m$  is a **model of**  $\alpha$ . We use the notation  $M(\alpha)$  to mean the set of all models of  $\alpha$ .

Now that we have a notion of truth, we are ready to talk about logical reasoning. This involves the relation of logical **entailment** between sentences—the idea that a sentence *follows logically* from another sentence. In mathematical notation, we write

$$\alpha \models \beta$$

to mean that the sentence  $\alpha$  entails the sentence  $\beta$ . The formal definition of entailment is this:  $\alpha \models \beta$  if and only if, in every model in which  $\alpha$  is true,  $\beta$  is also true. Using the notation just introduced, we can write

$$\alpha \models \beta \text{ if and only if } M(\alpha) \subseteq M(\beta).$$

(Note the direction of the  $\subseteq$  here: if  $\alpha \models \beta$ , then  $\alpha$  is a *stronger* assertion than  $\beta$ : it rules out *more* possible worlds.) The relation of entailment is familiar from arithmetic; we are happy with the idea that the sentence  $x = 0$  entails the sentence  $xy = 0$ . Obviously, in any model where  $x$  is zero, it is the case that  $xy$  is zero (regardless of the value of  $y$ ).

We can apply the same kind of analysis to the wumpus-world reasoning example given in the preceding section. Consider the situation in Figure 7.3(b): the agent has detected nothing in [1,1] and a breeze in [2,1]. These percepts, combined with the agent's knowledge of the rules of the wumpus world, constitute the KB. The agent is interested in whether the adjacent squares [1,2], [2,2], and [3,1] contain pits. Each of the three squares might or might

<sup>2</sup> Fuzzy logic, discussed in Chapter 13, allows for degrees of truth.

**Figure 7.5** Possible models for the presence of pits in squares [1,2], [2,2], and [3,1]. The KB corresponding to the observations of nothing in [1,1] and a breeze in [2,1] is shown by the solid line. (a) Dotted line shows models of  $\alpha_1$  (no pit in [1,2]). (b) Dotted line shows models of  $\alpha_2$  (no pit in [2,2]).

not contain a pit, so (ignoring other aspects of the world for now) there are  $2^3 = 8$  possible models. These eight models are shown in Figure 7.5.<sup>3</sup>

The KB can be thought of as a set of sentences or as a single sentence that asserts all the individual sentences. The KB is false in models that contradict what the agent knows—for example, the KB is false in any model in which [1,2] contains a pit, because there is no breeze in [1,1]. There are in fact just three models in which the KB is true, and these are shown surrounded by a solid line in Figure 7.5. Now let us consider two possible conclusions:

$$\alpha_1 = \text{"There is no pit in [1,2]."} \quad \alpha_2 = \text{"There is no pit in [2,2].”}$$

We have surrounded the models of  $\alpha_1$  and  $\alpha_2$  with dotted lines in Figures 7.5(a) and 7.5(b), respectively. By inspection, we see the following:

in every model in which  $KB$  is true,  $\alpha_1$  is also true.

Hence,  $KB \models \alpha_1$ : there is no pit in [1,2]. We can also see that

in some models in which  $KB$  is true,  $\alpha_2$  is false.

Hence,  $KB$  does not entail  $\alpha_2$ : the agent *cannot* conclude that there is no pit in [2,2]. (Nor can it conclude that there *is* a pit in [2,2].)<sup>4</sup>

The preceding example not only illustrates entailment but also shows how the definition of entailment can be applied to derive conclusions—that is, to carry out **logical inference**. The inference algorithm illustrated in Figure 7.5 is called **model checking**, because it enumerates all possible models to check that  $\alpha$  is true in all models in which  $KB$  is true, that is, that  $M(KB) \subseteq M(\alpha)$ .

Logical inference  
Model checking

<sup>3</sup> Although the figure shows the models as partial wumpus worlds, they are really nothing more than assignments of *true* and *false* to the sentences “there is a pit in [1,2]” etc. Models, in the mathematical sense, do not need to have ‘orrible ’airy wumpuses in them.

<sup>4</sup> The agent can calculate the *probability* that there is a pit in [2,2]; Chapter 12 shows how.

**Figure 7.6** Sentences are physical configurations of the agent, and reasoning is a process of constructing new physical configurations from old ones. Logical reasoning should ensure that the new configurations represent aspects of the world that actually follow from the aspects that the old configurations represent.

In understanding entailment and inference, it might help to think of the set of all consequences of  $KB$  as a haystack and of  $\alpha$  as a needle. Entailment is like the needle being in the haystack; inference is like finding it. This distinction is embodied in some formal notation: if an inference algorithm  $i$  can derive  $\alpha$  from  $KB$ , we write

$$KB \vdash_i \alpha,$$

which is pronounced “ $\alpha$  is derived from  $KB$  by  $i$ ” or “ $i$  derives  $\alpha$  from  $KB$ .”

Sound  
Truth-preserving  
  
Completeness

An inference algorithm that derives only entailed sentences is called **sound** or **truth-preserving**. Soundness is a highly desirable property. An unsound inference procedure essentially makes things up as it goes along—it announces the discovery of nonexistent needles. It is easy to see that model checking, when it is applicable,<sup>5</sup> is a sound procedure.

The property of **completeness** is also desirable: an inference algorithm is complete if it can derive any sentence that is entailed. For real haystacks, which are finite in extent, it seems obvious that a systematic examination can always decide whether the needle is in the haystack. For many knowledge bases, however, the haystack of consequences is infinite, and completeness becomes an important issue.<sup>6</sup> Fortunately, there are complete inference procedures for logics that are sufficiently expressive to handle many knowledge bases.

We have described a reasoning process whose conclusions are guaranteed to be true in any world in which the premises are true; in particular, *if  $KB$  is true in the real world, then any sentence  $\alpha$  derived from  $KB$  by a sound inference procedure is also true in the real world*. So, while an inference process operates on “syntax”—internal physical configurations such as bits in registers or patterns of electrical blips in brains—the process *corresponds* to the real-world relationship whereby some aspect of the real world is the case by virtue of other aspects of the real world being the case.<sup>7</sup> This correspondence between world and representation is illustrated in Figure 7.6.

Grounding

The final issue to consider is **grounding**—the connection between logical reasoning processes and the real environment in which the agent exists. In particular, *how do we know that*

<sup>5</sup> Model checking works if the space of models is finite—for example, in wumpus worlds of fixed size. For arithmetic, on the other hand, the space of models is infinite: even if we restrict ourselves to the integers, there are infinitely many pairs of values for  $x$  and  $y$  in the sentence  $x + y = 4$ .

<sup>6</sup> Compare with the case of infinite search spaces in Chapter 3, where depth-first search is not complete.

<sup>7</sup> As Wittgenstein (1922) put it in his famous *Tractatus*: “The world is everything that is the case.”

*KB is true in the real world?* (After all, *KB* is just “syntax” inside the agent’s head.) This is a philosophical question about which many, many books have been written. (See Chapter 28.) A simple answer is that the agent’s sensors create the connection. For example, our wumpus-world agent has a smell sensor. The agent program creates a suitable sentence whenever there is a smell. Then, whenever that sentence is in the knowledge base, it is true in the real world. Thus, the meaning and truth of percept sentences are defined by the processes of sensing and sentence construction that produce them. What about the rest of the agent’s knowledge, such as its belief that wumpuses cause smells in adjacent squares? This is not a direct representation of a single percept, but a general rule—derived, perhaps, from perceptual experience but not identical to a statement of that experience. General rules like this are produced by a sentence construction process called **learning**, which is the subject of Part V. Learning is fallible. It could be the case that wumpuses cause smells *except on February 29 in leap years*, which is when they take their baths. Thus, *KB* may not be true in the real world, but with good learning procedures, there is reason for optimism.

## 7.4 Propositional Logic: A Very Simple Logic

We now present **propositional logic**. We describe its syntax (the structure of sentences) and its semantics (the way in which the truth of sentences is determined). From these, we derive a simple, syntactic algorithm for logical inference that implements the semantic notion of entailment. Everything takes place, of course, in the wumpus world.

Propositional logic

### 7.4.1 Syntax

The **syntax** of propositional logic defines the allowable sentences. The **atomic sentences** consist of a single **proposition symbol**. Each such symbol stands for a proposition that can be true or false. We use symbols that start with an uppercase letter and may contain other letters or subscripts, for example: *P*, *Q*, *R*, *W<sub>1,3</sub>* and *FacingEast*. The names are arbitrary but are often chosen to have some mnemonic value—we use *W<sub>1,3</sub>* to stand for the proposition that the wumpus is in [1,3]. (Remember that symbols such as *W<sub>1,3</sub>* are *atomic*, i.e., *W*, 1, and 3 are not meaningful parts of the symbol.) There are two proposition symbols with fixed meanings: *True* is the always-true proposition and *False* is the always-false proposition. **Complex sentences** are constructed from simpler sentences, using parentheses and operators called **logical connectives**. There are five connectives in common use:

Atomic sentences  
Proposition symbol

- ¬ (not). A sentence such as  $\neg W_{1,3}$  is called the **negation** of  $W_{1,3}$ . A **literal** is either an atomic sentence (a **positive literal**) or a negated atomic sentence (a **negative literal**). Negation  
Literal
- $\wedge$  (and). A sentence whose main connective is  $\wedge$ , such as  $W_{1,3} \wedge P_{3,1}$ , is called a **conjunction**; its parts are the **conjuncts**. (The  $\wedge$  looks like an “A” for “And.”) Conjunction
- $\vee$  (or). A sentence whose main connective is  $\vee$ , such as  $(W_{1,3} \wedge P_{3,1}) \vee W_{2,2}$ , is a **disjunction**; its parts are **disjuncts**—in this example,  $(W_{1,3} \wedge P_{3,1})$  and  $W_{2,2}$ . Disjunction
- $\Rightarrow$  (implies). A sentence such as  $(W_{1,3} \wedge P_{3,1}) \Rightarrow \neg W_{2,2}$  is called an **implication** (or conditional). Its **premise** or **antecedent** is  $(W_{1,3} \wedge P_{3,1})$ , and its **conclusion** or **consequent** is  $\neg W_{2,2}$ . Implications are also known as **rules** or **if-then** statements. The implication symbol is sometimes written in other books as  $\supset$  or  $\rightarrow$ . Implication  
Premise  
Conclusion  
Rules
- $\Leftrightarrow$  (if and only if). The sentence  $W_{1,3} \Leftrightarrow \neg W_{2,2}$  is a **biconditional**. Biconditional

```

Sentence → AtomicSentence | ComplexSentence
AtomicSentence → True | False | P | Q | R | ...
ComplexSentence → ( Sentence )
|   ¬ Sentence
|   Sentence ∧ Sentence
|   Sentence ∨ Sentence
|   Sentence ⇒ Sentence
|   Sentence ⇔ Sentence

OPERATOR PRECEDENCE : ¬, ∧, ∨, ⇒, ⇔

```

**Figure 7.7** A BNF (Backus–Naur Form) grammar of sentences in propositional logic, along with operator precedences, from highest to lowest.

---

Figure 7.7 gives a formal grammar of propositional logic. (BNF notation is explained on page 1081.) The BNF grammar is augmented with an operator precedence list to remove ambiguity when multiple operators are used. The “not” operator ( $\neg$ ) has the highest precedence, which means that in the sentence  $\neg A \wedge B$  the  $\neg$  binds most tightly, giving us the equivalent of  $(\neg A) \wedge B$  rather than  $\neg(A \wedge B)$ . (The notation for ordinary arithmetic is the same:  $-2 + 4$  is 2, not -6.) When appropriate, we also use parentheses and square brackets to clarify the intended sentence structure and improve readability.

### 7.4.2 Semantics

Truth value

Having specified the syntax of propositional logic, we now specify its semantics. The semantics defines the rules for determining the truth of a sentence with respect to a particular model. In propositional logic, a model simply sets the **truth value**—*true* or *false*—for every proposition symbol. For example, if the sentences in the knowledge base make use of the proposition symbols  $P_{1,2}$ ,  $P_{2,2}$ , and  $P_{3,1}$ , then one possible model is

$$m_1 = \{P_{1,2} = \text{false}, P_{2,2} = \text{false}, P_{3,1} = \text{true}\}.$$

With three proposition symbols, there are  $2^3 = 8$  possible models—exactly those depicted in Figure 7.5. Notice, however, that the models are purely mathematical objects with no necessary connection to wumpus worlds.  $P_{1,2}$  is just a symbol; it might mean “there is a pit in [1,2]” or “I’m in Paris today and tomorrow.”

The semantics for propositional logic must specify how to compute the truth value of *any* sentence, given a model. This is done recursively. All sentences are constructed from atomic sentences and the five connectives; therefore, we need to specify how to compute the truth of atomic sentences and how to compute the truth of sentences formed with each of the five connectives. Atomic sentences are easy:

- *True* is true in every model and *False* is false in every model.
- The truth value of every other proposition symbol must be specified directly in the model. For example, in the model  $m_1$  given earlier,  $P_{1,2}$  is false.

$P$	$Q$	$\neg P$	$P \wedge Q$	$P \vee Q$	$P \Rightarrow Q$	$P \Leftrightarrow Q$
<i>false</i>	<i>false</i>	<i>true</i>	<i>false</i>	<i>false</i>	<i>true</i>	<i>true</i>
<i>false</i>	<i>true</i>	<i>true</i>	<i>false</i>	<i>true</i>	<i>true</i>	<i>false</i>
<i>true</i>	<i>false</i>	<i>false</i>	<i>false</i>	<i>true</i>	<i>false</i>	<i>false</i>
<i>true</i>	<i>true</i>	<i>false</i>	<i>true</i>	<i>true</i>	<i>true</i>	<i>true</i>

**Figure 7.8** Truth tables for the five logical connectives. To use the table to compute, for example, the value of  $P \vee Q$  when  $P$  is true and  $Q$  is false, first look on the left for the row where  $P$  is *true* and  $Q$  is *false* (the third row). Then look in that row under the  $P \vee Q$  column to see the result: *true*.

For complex sentences, we have five rules, which hold for any subsentences  $P$  and  $Q$  (atomic or complex) in any model  $m$  (here “iff” means “if and only if”):

- $\neg P$  is true iff  $P$  is false in  $m$ .
- $P \wedge Q$  is true iff both  $P$  and  $Q$  are true in  $m$ .
- $P \vee Q$  is true iff either  $P$  or  $Q$  is true in  $m$ .
- $P \Rightarrow Q$  is true unless  $P$  is true and  $Q$  is false in  $m$ .
- $P \Leftrightarrow Q$  is true iff  $P$  and  $Q$  are both true or both false in  $m$ .

The rules can also be expressed with **truth tables** that specify the truth value of a complex sentence for each possible assignment of truth values to its components. Truth tables for the five connectives are given in Figure 7.8. From these tables, the truth value of any sentence  $s$  can be computed with respect to any model  $m$  by a simple recursive evaluation. For example, the sentence  $\neg P_{1,2} \wedge (P_{2,2} \vee P_{3,1})$ , evaluated in  $m_1$ , gives  $true \wedge (false \vee true) = true \wedge true = true$ . Exercise 7.TRUU asks you to write the algorithm PL-TRUE?( $s, m$ ), which computes the truth value of a propositional logic sentence  $s$  in a model  $m$ .

Truth table

The truth tables for “and,” “or,” and “not” are in close accord with our intuitions about the English words. The main point of possible confusion is that  $P \vee Q$  is true when  $P$  is true or  $Q$  is true *or both*. A different connective, called “exclusive or” (“xor” for short), yields false when both disjuncts are true.<sup>8</sup> There is no consensus on the symbol for exclusive or; some choices are  $\vee\vee$  or  $\neq$  or  $\oplus$ .

The truth table for  $\Rightarrow$  may not quite fit one’s intuitive understanding of “ $P$  implies  $Q$ ” or “if  $P$  then  $Q$ .” For one thing, propositional logic does not require any relation of *causation* or *relevance* between  $P$  and  $Q$ . The sentence “5 is odd implies Tokyo is the capital of Japan” is a true sentence of propositional logic (under the normal interpretation), even though it is a decidedly odd sentence of English. Another point of confusion is that any implication is true whenever its antecedent is false. For example, “5 is even implies Sam is smart” is true, regardless of whether Sam is smart. This seems bizarre, but it makes sense if you think of “ $P \Rightarrow Q$ ” as saying, “If  $P$  is true, then I am claiming that  $Q$  is true; otherwise I am making no claim.” The only way for this sentence to be *false* is if  $P$  is true but  $Q$  is false.

The biconditional,  $P \Leftrightarrow Q$ , is true whenever both  $P \Rightarrow Q$  and  $Q \Rightarrow P$  are true. In English, this is often written as “ $P$  if and only if  $Q$ .” Many of the rules of the wumpus world are best

<sup>8</sup> Latin uses two separate words: “vel” is inclusive or and “aut” is exclusive or.

written using  $\Leftrightarrow$ . For example, a square is breezy *if* a neighboring square has a pit, and a square is breezy *only if* a neighboring square has a pit. So we need a biconditional,

$$B_{1,1} \Leftrightarrow (P_{1,2} \vee P_{2,1}),$$

where  $B_{1,1}$  means that there is a breeze in [1,1].

### 7.4.3 A simple knowledge base

Now that we have defined the semantics for propositional logic, we can construct a knowledge base for the wumpus world. We focus first on the *immutable* aspects of the wumpus world, leaving the mutable aspects for a later section. For now, we need the following symbols for each  $[x,y]$  location:

$P_{x,y}$  is true if there is a pit in  $[x,y]$ .

$W_{x,y}$  is true if there is a wumpus in  $[x,y]$ , dead or alive.

$B_{x,y}$  is true if there is a breeze in  $[x,y]$ .

$S_{x,y}$  is true if there is a stench in  $[x,y]$ .

$L_{x,y}$  is true if the agent is in location  $[x,y]$ .

The sentences we write will suffice to derive  $\neg P_{1,2}$  (there is no pit in [1,2]), as was done informally in Section 7.3. We label each sentence  $R_i$  so that we can refer to them:

- There is no pit in [1,1]:

$$R_1 : \neg P_{1,1}.$$

- A square is breezy if and only if there is a pit in a neighboring square. This has to be stated for each square; for now, we include just the relevant squares:

$$R_2 : B_{1,1} \Leftrightarrow (P_{1,2} \vee P_{2,1}).$$

$$R_3 : B_{2,1} \Leftrightarrow (P_{1,1} \vee P_{2,2} \vee P_{3,1}).$$

- The preceding sentences are true in all wumpus worlds. Now we include the breeze percepts for the first two squares visited in the specific world the agent is in, leading up to the situation in Figure 7.3(b).

$$R_4 : \neg B_{1,1}.$$

$$R_5 : B_{2,1}.$$

### 7.4.4 A simple inference procedure

Our goal now is to decide whether  $KB \models \alpha$  for some sentence  $\alpha$ . For example, is  $\neg P_{1,2}$  entailed by our  $KB$ ? Our first algorithm for inference is a model-checking approach that is a direct implementation of the definition of entailment: enumerate the models, and check that  $\alpha$  is true in every model in which  $KB$  is true. Models are assignments of *true* or *false* to every proposition symbol. Returning to our wumpus-world example, the relevant proposition symbols are  $B_{1,1}, B_{2,1}, P_{1,1}, P_{1,2}, P_{2,1}, P_{2,2}$ , and  $P_{3,1}$ . With seven symbols, there are  $2^7 = 128$  possible models; in three of these,  $KB$  is true (Figure 7.9). In those three models,  $\neg P_{1,2}$  is true, hence there is no pit in [1,2]. On the other hand,  $P_{2,2}$  is true in two of the three models and false in one, so we cannot yet tell whether there is a pit in [2,2].

Figure 7.9 reproduces in a more precise form the reasoning illustrated in Figure 7.5. A general algorithm for deciding entailment in propositional logic is shown in Figure 7.10. Like the BACKTRACKING-SEARCH algorithm on page 176, TT-ENTAILS? performs a recursive

$B_{1,1}$	$B_{2,1}$	$P_{1,1}$	$P_{1,2}$	$P_{2,1}$	$P_{2,2}$	$P_{3,1}$	$R_1$	$R_2$	$R_3$	$R_4$	$R_5$	$KB$
false	true	true	true	true	false	false						
false	false	false	false	false	false	true	true	true	false	true	false	false

**Figure 7.9** A truth table constructed for the knowledge base given in the text.  $KB$  is true if  $R_1$  through  $R_5$  are true, which occurs in just 3 of the 128 rows (the ones underlined in the right-hand column). In all 3 rows,  $P_{1,2}$  is false, so there is no pit in [1,2]. On the other hand, there might (or might not) be a pit in [2,2].

```

function TT-ENTAILS?( $KB, \alpha$ ) returns true or false
  inputs:  $KB$ , the knowledge base, a sentence in propositional logic
            $\alpha$ , the query, a sentence in propositional logic
  symbols  $\leftarrow$  a list of the proposition symbols in  $KB$  and  $\alpha$ 
  return TT-CHECK-ALL( $KB, \alpha, symbols, \{\}$ )

function TT-CHECK-ALL( $KB, \alpha, symbols, model$ ) returns true or false
  if EMPTY?( $symbols$ ) then
    if PL-TRUE?( $KB, model$ ) then return PL-TRUE?( $\alpha, model$ )
    else return true // when KB is false, always return true
  else
     $P \leftarrow$  FIRST( $symbols$ )
    rest  $\leftarrow$  REST( $symbols$ )
    return (TT-CHECK-ALL( $KB, \alpha, rest, model \cup \{P = true\}$ )
           and
           TT-CHECK-ALL( $KB, \alpha, rest, model \cup \{P = false\}$ ))

```

**Figure 7.10** A truth-table enumeration algorithm for deciding propositional entailment. (TT stands for truth table.) PL-TRUE? returns *true* if a sentence holds within a model. The variable *model* represents a partial model—an assignment to some of the symbols. The keyword **and** here is an infix function symbol in the pseudocode programming language, not an operator in propositional logic; it takes two arguments and returns *true* or *false*.

enumeration of a finite space of assignments to symbols. The algorithm is **sound** because it implements directly the definition of entailment, and **complete** because it works for any  $KB$  and  $\alpha$  and always terminates—there are only finitely many models to examine.

Of course, “finitely many” is not always the same as “few.” If  $KB$  and  $\alpha$  contain  $n$  symbols in all, then there are  $2^n$  models. Thus, the time complexity of the algorithm is  $O(2^n)$ . (The space complexity is only  $O(n)$  because the enumeration is depth-first.) Later in this chapter we show algorithms that are much more efficient in many cases. Unfortunately, propositional entailment is co-NP-complete (i.e., probably no easier than NP-complete—see Appendix A), so *every known inference algorithm for propositional logic has a worst-case complexity that is exponential in the size of the input.*

## 7.5 Propositional Theorem Proving

Theorem proving

Logical equivalence

Validity

Tautology

Deduction theorem

Satisfiability

So far, we have shown how to determine entailment by *model checking*: enumerating models and showing that the sentence must hold in all models. In this section, we show how entailment can be done by **theorem proving**—applying rules of inference directly to the sentences in our knowledge base to construct a proof of the desired sentence without consulting models. If the number of models is large but the length of the proof is short, then theorem proving can be more efficient than model checking.

Before we plunge into the details of theorem-proving algorithms, we will need some additional concepts related to entailment. The first concept is **logical equivalence**: two sentences  $\alpha$  and  $\beta$  are logically equivalent if they are true in the same set of models. We write this as  $\alpha \equiv \beta$ . (Note that  $\equiv$  is used to make claims about sentences, while  $\Leftrightarrow$  is used as part of a sentence.) For example, we can easily show (using truth tables) that  $P \wedge Q$  and  $Q \wedge P$  are logically equivalent; other equivalences are shown in Figure 7.11. These equivalences play much the same role in logic as arithmetic identities do in ordinary mathematics. An alternative definition of equivalence is as follows: any two sentences  $\alpha$  and  $\beta$  are equivalent if and only if each of them entails the other:

$$\alpha \equiv \beta \text{ if and only if } \alpha \models \beta \text{ and } \beta \models \alpha.$$

The second concept we will need is **validity**. A sentence is valid if it is true in *all* models. For example, the sentence  $P \vee \neg P$  is valid. Valid sentences are also known as **tautologies**—they are *necessarily* true. Because the sentence *True* is true in all models, every valid sentence is logically equivalent to *True*. What good are valid sentences? From our definition of entailment, we can derive the **deduction theorem**, which was known to the ancient Greeks:

*For any sentences  $\alpha$  and  $\beta$ ,  $\alpha \models \beta$  if and only if the sentence  $(\alpha \Rightarrow \beta)$  is valid.*

(Exercise 7.DEDU asks for a proof.) Hence, we can decide if  $\alpha \models \beta$  by checking that  $(\alpha \Rightarrow \beta)$  is true in every model—which is essentially what the inference algorithm in Figure 7.10 does—or by proving that  $(\alpha \Rightarrow \beta)$  is equivalent to *True*. Conversely, the deduction theorem states that every valid implication sentence describes a legitimate inference.

The final concept we will need is **satisfiability**. A sentence is satisfiable if it is true in, or satisfied by, *some* model. For example, the knowledge base given earlier,  $(R_1 \wedge R_2 \wedge R_3 \wedge R_4 \wedge R_5)$ , is satisfiable because there are three models in which it is true, as shown in Figure 7.9. Satisfiability can be checked by enumerating the possible models until one is found that satisfies the sentence. The problem of determining the satisfiability of sentences

---

$$\begin{aligned}
 (\alpha \wedge \beta) &\equiv (\beta \wedge \alpha) \quad \text{commutativity of } \wedge \\
 (\alpha \vee \beta) &\equiv (\beta \vee \alpha) \quad \text{commutativity of } \vee \\
 ((\alpha \wedge \beta) \wedge \gamma) &\equiv (\alpha \wedge (\beta \wedge \gamma)) \quad \text{associativity of } \wedge \\
 ((\alpha \vee \beta) \vee \gamma) &\equiv (\alpha \vee (\beta \vee \gamma)) \quad \text{associativity of } \vee \\
 \neg(\neg \alpha) &\equiv \alpha \quad \text{double-negation elimination} \\
 (\alpha \Rightarrow \beta) &\equiv (\neg \beta \Rightarrow \neg \alpha) \quad \text{contraposition} \\
 (\alpha \Rightarrow \beta) &\equiv (\neg \alpha \vee \beta) \quad \text{implication elimination} \\
 (\alpha \Leftrightarrow \beta) &\equiv ((\alpha \Rightarrow \beta) \wedge (\beta \Rightarrow \alpha)) \quad \text{biconditional elimination} \\

 \neg(\alpha \vee \beta) &\equiv (\neg \alpha \wedge \neg \beta) \quad \text{De Morgan} \\
 (\alpha \wedge (\beta \vee \gamma)) &\equiv ((\alpha \wedge \beta) \vee (\alpha \wedge \gamma)) \quad \text{distributivity of } \wedge \text{ over } \vee \\
 (\alpha \vee (\beta \wedge \gamma)) &\equiv ((\alpha \vee \beta) \wedge (\alpha \vee \gamma)) \quad \text{distributivity of } \vee \text{ over } \wedge
 \end{aligned}$$

**Figure 7.11** Standard logical equivalences. The symbols  $\alpha$ ,  $\beta$ , and  $\gamma$  stand for arbitrary sentences of propositional logic.

in propositional logic—the **SAT** problem—was the first problem proved to be NP-complete. **SAT**  
Many problems in computer science are really satisfiability problems. For example, all the constraint satisfaction problems in Chapter 5 ask whether the constraints are satisfiable by some assignment.

Validity and satisfiability are of course connected:  $\alpha$  is valid iff  $\neg \alpha$  is unsatisfiable; contrapositively,  $\alpha$  is satisfiable iff  $\neg \alpha$  is not valid. We also have the following useful result:

$\alpha \models \beta$  if and only if the sentence  $(\alpha \wedge \neg \beta)$  is unsatisfiable.

Proving  $\beta$  from  $\alpha$  by checking the unsatisfiability of  $(\alpha \wedge \neg \beta)$  corresponds exactly to the standard mathematical proof technique of *reductio ad absurdum* (literally, “reduction to an absurd thing”). It is also called proof by **refutation** or proof by **contradiction**. One assumes a sentence  $\beta$  to be false and shows that this leads to a contradiction with known axioms  $\alpha$ . This contradiction is exactly what is meant by saying that the sentence  $(\alpha \wedge \neg \beta)$  is unsatisfiable.

Reductio ad  
absurdum  
Refutation  
Contradiction

### 7.5.1 Inference and proofs

This section covers **inference rules** that can be applied to derive a **proof**—a chain of conclusions that leads to the desired goal. The best-known rule is called **Modus Ponens** (Latin for *mode that affirms*) and is written

$$\frac{\alpha \Rightarrow \beta, \quad \alpha}{\beta}$$

Inference rules  
Proof  
Modus Ponens

The notation means that, whenever any sentences of the form  $\alpha \Rightarrow \beta$  and  $\alpha$  are given, then the sentence  $\beta$  can be inferred. For example, if  $(WumpusAhead \wedge WumpusAlive) \Rightarrow Shoot$  and  $(WumpusAhead \wedge WumpusAlive)$  are given, then  $Shoot$  can be inferred.

Another useful inference rule is **And-Elimination**, which says that, from a conjunction, **And-Elimination** any of the conjuncts can be inferred:

$$\frac{\alpha \wedge \beta}{\alpha}.$$

For example, from  $(WumpusAhead \wedge WumpusAlive)$ ,  $WumpusAlive$  can be inferred.

By considering the possible truth values of  $\alpha$  and  $\beta$ , one can easily show once and for all that Modus Ponens and And-Elimination are sound. These rules can then be used in any particular instances where they apply, generating sound inferences without the need for enumerating models.

All of the logical equivalences in Figure 7.11 can be used as inference rules. For example, the equivalence for biconditional elimination yields the two inference rules

$$\frac{\alpha \Leftrightarrow \beta}{(\alpha \Rightarrow \beta) \wedge (\beta \Rightarrow \alpha)} \quad \text{and} \quad \frac{(\alpha \Rightarrow \beta) \wedge (\beta \Rightarrow \alpha)}{\alpha \Leftrightarrow \beta}.$$

Not all inference rules work in both directions like this. For example, we cannot run Modus Ponens in the opposite direction to obtain  $\alpha \Rightarrow \beta$  and  $\alpha$  from  $\beta$ .

Let us see how these inference rules and equivalences can be used in the wumpus world. We start with the knowledge base containing  $R_1$  through  $R_5$  and show how to prove  $\neg P_{1,2}$ , that is, there is no pit in [1,2]:

1. Apply biconditional elimination to  $R_2$  to obtain

$$R_6 : (B_{1,1} \Rightarrow (P_{1,2} \vee P_{2,1})) \wedge ((P_{1,2} \vee P_{2,1}) \Rightarrow B_{1,1}).$$

2. Apply And-Elimination to  $R_6$  to obtain

$$R_7 : ((P_{1,2} \vee P_{2,1}) \Rightarrow B_{1,1}).$$

3. Logical equivalence for contrapositives gives

$$R_8 : (\neg B_{1,1} \Rightarrow \neg(P_{1,2} \vee P_{2,1})).$$

4. Apply Modus Ponens with  $R_8$  and the percept  $R_4$  (i.e.,  $\neg B_{1,1}$ ), to obtain

$$R_9 : \neg(P_{1,2} \vee P_{2,1}).$$

5. Apply De Morgan's rule, giving the conclusion

$$R_{10} : \neg P_{1,2} \wedge \neg P_{2,1}.$$

That is, neither [1,2] nor [2,1] contains a pit.

Any of the search algorithms in Chapter 3 can be used to find a sequence of steps that constitutes a proof like this. We just need to define a proof problem as follows:

- INITIAL STATE: the initial knowledge base.
- ACTIONS: the set of actions consists of all the inference rules applied to all the sentences that match the top half of the inference rule.
- RESULT: the result of an action is to add the sentence in the bottom half of the inference rule.
- GOAL: the goal is a state that contains the sentence we are trying to prove.

Thus, searching for proofs is an alternative to enumerating models. In many practical cases finding a proof can be more efficient because the proof can ignore irrelevant propositions, no matter how many of them there are. For example, the proof just given leading to  $\neg P_{1,2} \wedge \neg P_{2,1}$  does not mention the propositions  $B_{2,1}$ ,  $P_{1,1}$ ,  $P_{2,2}$ , or  $P_{3,1}$ . They can be ignored because the goal proposition,  $P_{1,2}$ , appears only in sentence  $R_2$ ; the other propositions in  $R_2$  appear only in  $R_4$  and  $R_2$ ; so  $R_1$ ,  $R_3$ , and  $R_5$  have no bearing on the proof. The same would hold even if we added a million more sentences to the knowledge base; the simple truth-table algorithm, on the other hand, would be overwhelmed by the exponential explosion of models.

One final property of logical systems is **monotonicity**, which says that the set of entailed sentences can only *increase* as information is added to the knowledge base.<sup>9</sup> For any sentences  $\alpha$  and  $\beta$ ,

$$\text{if } KB \models \alpha \text{ then } KB \wedge \beta \models \alpha.$$

For example, suppose the knowledge base contains the additional assertion  $\beta$  stating that there are exactly eight pits in the world. This knowledge might help the agent draw *additional* conclusions, but it cannot invalidate any conclusion  $\alpha$  already inferred—such as the conclusion that there is no pit in [1,2]. Monotonicity means that inference rules can be applied whenever suitable premises are found in the knowledge base—the conclusion of the rule must follow *regardless of what else is in the knowledge base*.

## 7.5.2 Proof by resolution

We have argued that the inference rules covered so far are *sound*, but we have not discussed the question of *completeness* for the inference algorithms that use them. Search algorithms such as iterative deepening search (page 99) are complete in the sense that they will find any reachable goal, but if the available inference rules are inadequate, then the goal is not reachable—no proof exists that uses only those inference rules. For example, if we removed the biconditional elimination rule, the proof in the preceding section would not go through. The current section introduces a single inference rule, **resolution**, that yields a complete inference algorithm when coupled with any complete search algorithm.

We begin by using a simple version of the resolution rule in the wumpus world. Let us consider the steps leading up to Figure 7.4(a): the agent returns from [2,1] to [1,1] and then goes to [1,2], where it perceives a stench, but no breeze. We add the following facts to the knowledge base:

$$R_{11} : \neg B_{1,2}.$$

$$R_{12} : B_{1,2} \Leftrightarrow (P_{1,1} \vee P_{2,2} \vee P_{1,3}).$$

By the same process that led to  $R_{10}$  earlier, we can now derive the absence of pits in [2,2] and [1,3] (remember that [1,1] is already known to be pitless):

$$R_{13} : \neg P_{2,2}.$$

$$R_{14} : \neg P_{1,3}.$$

We can also apply biconditional elimination to  $R_3$ , followed by Modus Ponens with  $R_5$ , to obtain the fact that there is a pit in [1,1], [2,2], or [3,1]:

$$R_{15} : P_{1,1} \vee P_{2,2} \vee P_{3,1}.$$

Now comes the first application of the resolution rule: the literal  $\neg P_{2,2}$  in  $R_{13}$  *resolves with* the literal  $P_{2,2}$  in  $R_{15}$  to give the **resolvent**

$$R_{16} : P_{1,1} \vee P_{3,1}.$$

In English: if there's a pit in one of [1,1], [2,2], and [3,1] and it's not in [2,2], then it's in [1,1] or [3,1]. Similarly, the literal  $\neg P_{1,1}$  in  $R_1$  resolves with the literal  $P_{1,1}$  in  $R_{16}$  to give

$$R_{17} : P_{3,1}.$$

In English: if there's a pit in [1,1] or [3,1] and it's not in [1,1], then it's in [3,1]. These last two inference steps are examples of the **unit resolution** inference rule

<sup>9</sup> Nonmonotonic logics, which violate the monotonicity property, capture a common property of human reasoning: changing one's mind. They are discussed in Section 10.6.

Monotonicity

Resolvent

Unit resolution

Complementary  
literals  
Clause

Unit clause  
Resolution

Factoring

$$\frac{\ell_1 \vee \cdots \vee \ell_k, \quad m}{\ell_1 \vee \cdots \vee \ell_{i-1} \vee \ell_{i+1} \vee \cdots \vee \ell_k}$$

where each  $\ell$  is a literal and  $\ell_i$  and  $m$  are **complementary literals** (i.e., one is the negation of the other). Thus, the unit resolution rule takes a **clause**—a disjunction of literals—and a literal and produces a new clause. Note that a single literal can be viewed as a disjunction of one literal, also known as a **unit clause**.

The unit resolution rule can be generalized to the full **resolution** rule

$$\frac{\ell_1 \vee \cdots \vee \ell_k, \quad m_1 \vee \cdots \vee m_n}{\ell_1 \vee \cdots \vee \ell_{i-1} \vee \ell_{i+1} \vee \cdots \vee \ell_k \vee m_1 \vee \cdots \vee m_{j-1} \vee m_{j+1} \vee \cdots \vee m_n}$$

where  $\ell_i$  and  $m_j$  are complementary literals. This says that resolution takes two clauses and produces a new clause containing all the literals of the two original clauses *except* the two complementary literals. For example, we have

$$\frac{P_{1,1} \vee P_{3,1}, \quad \neg P_{1,1} \vee \neg P_{2,2}}{P_{3,1} \vee \neg P_{2,2}}.$$

You can resolve only one pair of complementary literals at a time. For example, we can resolve  $P$  and  $\neg P$  to deduce

$$\frac{P \vee \neg Q \vee R, \quad \neg P \vee Q}{\neg Q \vee Q \vee R},$$

but you can't resolve on both  $P$  and  $Q$  at once to infer  $R$ . There is one more technical aspect of the resolution rule: the resulting clause should contain only one copy of each literal.<sup>10</sup> The removal of multiple copies of literals is called **factoring**. For example, if we resolve  $(A \vee B)$  with  $(A \vee \neg B)$ , we obtain  $(A \vee A)$ , which is reduced to just  $A$  by factoring.

The **soundness** of the resolution rule can be seen easily by considering the literal  $\ell_i$  that is complementary to literal  $m_j$  in the other clause. If  $\ell_i$  is true, then  $m_j$  is false, and hence  $m_1 \vee \cdots \vee m_{j-1} \vee m_{j+1} \vee \cdots \vee m_n$  must be true, because  $m_1 \vee \cdots \vee m_n$  is given. If  $\ell_i$  is false, then  $\ell_1 \vee \cdots \vee \ell_{i-1} \vee \ell_{i+1} \vee \cdots \vee \ell_k$  must be true because  $\ell_1 \vee \cdots \vee \ell_k$  is given. Now  $\ell_i$  is either true or false, so one or other of these conclusions holds—exactly as the resolution rule states.

What is more surprising about the resolution rule is that it forms the basis for a family of *complete* inference procedures. A *resolution-based theorem prover* can, for any sentences  $\alpha$  and  $\beta$  in propositional logic, decide whether  $\alpha \models \beta$ . The next two subsections explain how resolution accomplishes this.

### Conjunctive normal form

The resolution rule applies only to clauses (that is, disjunctions of literals), so it would seem to be relevant only to knowledge bases and queries consisting of clauses. How, then, can it lead to a complete inference procedure for all of propositional logic? The answer is that *every sentence of propositional logic is logically equivalent to a conjunction of clauses*.

A sentence expressed as a conjunction of clauses is said to be in **conjunctive normal form** or **CNF** (see Figure 7.12). We now describe a procedure for converting to CNF. We illustrate the procedure by converting the sentence  $B_{1,1} \Leftrightarrow (P_{1,2} \vee P_{2,1})$  into CNF. The steps are as follows:

Conjunctive normal  
form  
CNF

<sup>10</sup> If a clause is viewed as a *set* of literals, then this restriction is automatically respected. Using set notation for clauses makes the resolution rule much cleaner, at the cost of introducing additional notation.

---

$\text{CNFSentence} \rightarrow \text{Clause}_1 \wedge \dots \wedge \text{Clause}_n$   
 $\text{Clause} \rightarrow \text{Literal}_1 \vee \dots \vee \text{Literal}_m$   
 $\text{Fact} \rightarrow \text{Symbol}$   
 $\text{Literal} \rightarrow \text{Symbol} \mid \neg \text{Symbol}$   
 $\text{Symbol} \rightarrow P \mid Q \mid R \mid \dots$   
 $\text{HornClauseForm} \rightarrow \text{DefiniteClauseForm} \mid \text{GoalClauseForm}$   
 $\text{DefiniteClauseForm} \rightarrow \text{Fact} \mid (\text{Symbol}_1 \wedge \dots \wedge \text{Symbol}_l) \Rightarrow \text{Symbol}$   
 $\text{GoalClauseForm} \rightarrow (\text{Symbol}_1 \wedge \dots \wedge \text{Symbol}_l) \Rightarrow \text{False}$

**Figure 7.12** A grammar for conjunctive normal form, Horn clauses, and definite clauses. A CNF clause such as  $\neg A \vee \neg B \vee C$  can be written in definite clause form as  $A \wedge B \Rightarrow C$ .

---

1. Eliminate  $\Leftrightarrow$ , replacing  $\alpha \Leftrightarrow \beta$  with  $(\alpha \Rightarrow \beta) \wedge (\beta \Rightarrow \alpha)$ .

$$(B_{1,1} \Rightarrow (P_{1,2} \vee P_{2,1})) \wedge ((P_{1,2} \vee P_{2,1}) \Rightarrow B_{1,1}).$$

2. Eliminate  $\Rightarrow$ , replacing  $\alpha \Rightarrow \beta$  with  $\neg \alpha \vee \beta$ :

$$(\neg B_{1,1} \vee P_{1,2} \vee P_{2,1}) \wedge (\neg(P_{1,2} \vee P_{2,1}) \vee B_{1,1}).$$

3. CNF requires  $\neg$  to appear only in literals, so we “move  $\neg$  inwards” by repeated application of the following equivalences from Figure 7.11:

$$\begin{aligned} \neg(\neg \alpha) &\equiv \alpha && \text{(double-negation elimination)} \\ \neg(\alpha \wedge \beta) &\equiv (\neg \alpha \vee \neg \beta) && \text{(De Morgan)} \\ \neg(\alpha \vee \beta) &\equiv (\neg \alpha \wedge \neg \beta) && \text{(De Morgan)} \end{aligned}$$

In the example, we require just one application of the last rule:

$$(\neg B_{1,1} \vee P_{1,2} \vee P_{2,1}) \wedge ((\neg P_{1,2} \wedge \neg P_{2,1}) \vee B_{1,1}).$$

4. Now we have a sentence containing nested  $\wedge$  and  $\vee$  operators applied to literals. We apply the distributivity law from Figure 7.11, distributing  $\vee$  over  $\wedge$  wherever possible.

$$(\neg B_{1,1} \vee P_{1,2} \vee P_{2,1}) \wedge (\neg P_{1,2} \vee B_{1,1}) \wedge (\neg P_{2,1} \vee B_{1,1}).$$

The original sentence is now in CNF, as a conjunction of three clauses. It is much harder to read, but it can be used as input to a resolution procedure.

### A resolution algorithm

Inference procedures based on resolution work by using the principle of proof by contradiction introduced on page 241. That is, to show that  $KB \models \alpha$ , we show that  $(KB \wedge \neg \alpha)$  is unsatisfiable. We do this by proving a contradiction.

A resolution algorithm is shown in Figure 7.13. First,  $(KB \wedge \neg \alpha)$  is converted into CNF. Then, the resolution rule is applied to the resulting clauses. Each pair that contains complementary literals is resolved to produce a new clause, which is added to the set if it is not already present. The process continues until one of two things happens:

- there are no new clauses that can be added, in which case  $KB$  does not entail  $\alpha$ ; or,
- two clauses resolve to yield the *empty* clause, in which case  $KB$  entails  $\alpha$ .

---

```

function PL-RESOLUTION( $KB, \alpha$ ) returns true or false
  inputs:  $KB$ , the knowledge base, a sentence in propositional logic
            $\alpha$ , the query, a sentence in propositional logic

   $clauses \leftarrow$  the set of clauses in the CNF representation of  $KB \wedge \neg\alpha$ 
   $new \leftarrow \{\}$ 
  while true do
    for each pair of clauses  $C_i, C_j$  in  $clauses$  do
       $resolvents \leftarrow$  PL-RESOLVE( $C_i, C_j$ )
      if  $resolvents$  contains the empty clause then return true
       $new \leftarrow new \cup resolvents$ 
    if  $new \subseteq clauses$  then return false
     $clauses \leftarrow clauses \cup new$ 
  
```

**Figure 7.13** A simple resolution algorithm for propositional logic. PL-RESOLVE returns the set of all possible clauses obtained by resolving its two inputs.

---

The empty clause—a disjunction of no disjuncts—is equivalent to *False* because a disjunction is true only if at least one of its disjuncts is true. Moreover, the empty clause arises only from resolving two contradictory unit clauses such as  $P$  and  $\neg P$ .

We can apply the resolution procedure to a very simple inference in the wumpus world. When the agent is in [1,1], there is no breeze, so there can be no pits in neighboring squares. The relevant knowledge base is

$$KB = R_2 \wedge R_4 = (B_{1,1} \Leftrightarrow (P_{1,2} \vee P_{2,1})) \wedge \neg B_{1,1}$$

and we wish to prove  $\alpha$ , which is, say,  $\neg P_{1,2}$ . When we convert  $(KB \wedge \neg\alpha)$  into CNF, we obtain the clauses shown at the top of Figure 7.14. The second row of the figure shows clauses obtained by resolving pairs in the first row. Then, when  $P_{1,2}$  is resolved with  $\neg P_{1,2}$ , we obtain the empty clause, shown as a small square. Inspection of Figure 7.14 reveals that many resolution steps are pointless. For example, the clause  $B_{1,1} \vee \neg B_{1,1} \vee P_{1,2}$  is equivalent to *True*  $\vee P_{1,2}$  which is equivalent to *True*. Deducing that *True* is true is not very helpful. Therefore, any clause in which two complementary literals appear can be discarded.

### Completeness of resolution

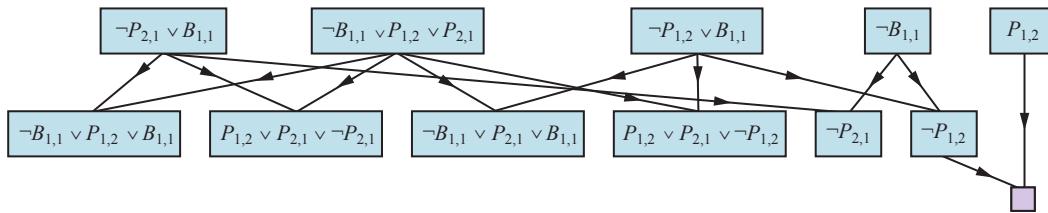

To conclude our discussion of resolution, we now show why PL-RESOLUTION is complete. To do this, we introduce the **resolution closure**  $RC(S)$  of a set of clauses  $S$ , which is the set of all clauses derivable by repeated application of the resolution rule to clauses in  $S$  or their derivatives. The resolution closure is what PL-RESOLUTION computes as the final value of the variable  $clauses$ . It is easy to see that  $RC(S)$  must be finite: thanks to the factoring step, there are only finitely many distinct clauses that can be constructed out of the symbols  $P_1, \dots, P_k$  that appear in  $S$ . Hence, PL-RESOLUTION always terminates.

The completeness theorem for resolution in propositional logic is called the **ground resolution theorem**:

If a set of clauses is unsatisfiable, then the resolution closure of those clauses contains the empty clause.

Resolution closure

Ground resolution theorem

**Figure 7.14** Partial application of PL-RESOLUTION to a simple inference in the wumpus world to prove the query  $\neg P_{1,2}$ . Each of the leftmost four clauses in the top row is paired with each of the other three, and the resolution rule is applied to yield the clauses on the bottom row. We see that the third and fourth clauses on the top row combine to yield the clause  $\neg P_{1,2}$ , which is then resolved with  $P_{1,2}$  to yield the empty clause, meaning that the query is proven.

This theorem is proved by demonstrating its contrapositive: if the closure  $RC(S)$  does *not* contain the empty clause, then  $S$  is satisfiable. In fact, we can construct a model for  $S$  with suitable truth values for  $P_1, \dots, P_k$ . The construction procedure is as follows:

For  $i$  from 1 to  $k$ ,

- If a clause in  $RC(S)$  contains the literal  $\neg P_i$  and all its other literals are false under the assignment chosen for  $P_1, \dots, P_{i-1}$ , then assign *false* to  $P_i$ .
- Otherwise, assign *true* to  $P_i$ .

This assignment to  $P_1, \dots, P_k$  is a model of  $S$ . To see this, assume the opposite—that, at some stage  $i$  in the sequence, assigning symbol  $P_i$  causes some clause  $C$  to become false. For this to happen, it must be the case that all the *other* literals in  $C$  must already have been falsified by assignments to  $P_1, \dots, P_{i-1}$ . Thus,  $C$  must now look like either  $(\text{false} \vee \text{false} \vee \dots \vee \text{false} \vee P_i)$  or like  $(\text{false} \vee \text{false} \vee \dots \vee \text{false} \vee \neg P_i)$ . If just one of these two is in  $RC(S)$ , then the algorithm will assign the appropriate truth value to  $P_i$  to make  $C$  true, so  $C$  can only be falsified if *both* of these clauses are in  $RC(S)$ .

Now, since  $RC(S)$  is closed under resolution, it will contain the resolvent of these two clauses, and that resolvent will have all of its literals already falsified by the assignments to  $P_1, \dots, P_{i-1}$ . This contradicts our assumption that the first falsified clause appears at stage  $i$ . Hence, we have proved that the construction never falsifies a clause in  $RC(S)$ ; that is, it produces a model of  $RC(S)$ . Finally, because  $S$  is contained in  $RC(S)$ , any model of  $RC(S)$  is a model of  $S$  itself.

### 7.5.3 Horn clauses and definite clauses

The completeness of resolution makes it a very important inference method. In many practical situations, however, the full power of resolution is not needed. Some real-world knowledge bases satisfy certain restrictions on the form of sentences they contain, which enables them to use a more restricted and efficient inference algorithm.

One such restricted form is the **definite clause**, which is a disjunction of literals of which *exactly one is positive*. For example, the clause  $(\neg L_{1,1} \vee \neg Breeze \vee B_{1,1})$  is a definite clause, whereas  $(\neg B_{1,1} \vee P_{1,2} \vee P_{2,1})$  is not, because it has two positive clauses.

Slightly more general is the **Horn clause**, which is a disjunction of literals of which *at*

Definite clause

Horn clause

Goal clauses

Body  
Head  
FactForward-chaining  
Backward-chaining

*most one is positive.* So all definite clauses are Horn clauses, as are clauses with no positive literals; these are called **goal clauses**. Horn clauses are closed under resolution: if you resolve two Horn clauses, you get back a Horn clause. One more class is the  $k$ -CNF sentence, which is a CNF sentence where each clause has at most  $k$  literals.

Knowledge bases containing only definite clauses are interesting for three reasons:

1. Every definite clause can be written as an implication whose premise is a conjunction of positive literals and whose conclusion is a single positive literal. (See Exercise 7.DISJ.) For example, the definite clause  $(\neg L_{1,1} \vee \neg Breeze \vee B_{1,1})$  can be written as the implication  $(L_{1,1} \wedge Breeze) \Rightarrow B_{1,1}$ . In the implication form, the sentence is easier to understand: it says that if the agent is in [1,1] and there is a breeze percept, then [1,1] is breezy. In Horn form, the premise is called the **body** and the conclusion is called the **head**. A sentence consisting of a single positive literal, such as  $L_{1,1}$ , is called a **fact**. It too can be written in implication form as  $True \Rightarrow L_{1,1}$ , but it is simpler to write just  $L_{1,1}$ .
2. Inference with Horn clauses can be done through the **forward-chaining** and **backward-chaining** algorithms, which we explain next. Both of these algorithms are natural, in that the inference steps are obvious and easy for humans to follow. This type of inference is the basis for **logic programming**, which is discussed in Chapter 9.
3. Deciding entailment with Horn clauses can be done in time that is *linear* in the size of the knowledge base—a pleasant surprise.

#### 7.5.4 Forward and backward chaining

The forward-chaining algorithm PL-FC-ENTAILS?( $KB, q$ ) determines if a single proposition symbol  $q$ —the query—is entailed by a knowledge base of definite clauses. It begins from known facts (positive literals) in the knowledge base. If all the premises of an implication are known, then its conclusion is added to the set of known facts. For example, if  $L_{1,1}$  and *Breeze* are known and  $(L_{1,1} \wedge Breeze) \Rightarrow B_{1,1}$  is in the knowledge base, then  $B_{1,1}$  can be added. This process continues until the query  $q$  is added or until no further inferences can be made. The algorithm is shown in Figure 7.15; the main point to remember is that it runs in linear time.

The best way to understand the algorithm is through an example and a picture. Figure 7.16(a) shows a simple knowledge base of Horn clauses with *A* and *B* as known facts. Figure 7.16(b) shows the same knowledge base drawn as an **AND-OR graph** (see Chapter 4). In AND-OR graphs, multiple edges joined by an arc indicate a conjunction—every edge must be proved—while multiple edges without an arc indicate a disjunction—any edge can be proved. It is easy to see how forward chaining works in the graph. The known leaves (here, *A* and *B*) are set, and inference propagates up the graph as far as possible. Wherever a conjunction appears, the propagation waits until all the conjuncts are known before proceeding. The reader is encouraged to work through the example in detail.

It is easy to see that forward chaining is **sound**: every inference is essentially an application of Modus Ponens. Forward chaining is also **complete**: every entailed atomic sentence will be derived. The easiest way to see this is to consider the final state of the *inferred* table (after the algorithm reaches a fixed point where no new inferences are possible). The table contains *true* for each symbol inferred during the process, and *false* for all other symbols. We can view the table as a logical model; moreover, *every definite clause in the original KB is true in this model.*

---

```

function PL-FC-ENTAILS?(KB, q) returns true or false
  inputs: KB, the knowledge base, a set of propositional definite clauses
           q, the query, a proposition symbol
  count  $\leftarrow$  a table, where count[c] is initially the number of symbols in clause c's premise
  inferred  $\leftarrow$  a table, where inferred[s] is initially false for all symbols
  queue  $\leftarrow$  a queue of symbols, initially symbols known to be true in KB

  while queue is not empty do
    p  $\leftarrow$  POP(queue)
    if p = q then return true
    if inferred[p] = false then
      inferred[p]  $\leftarrow$  true
      for each clause c in KB where p is in c.PREMISE do
        decrement count[c]
        if count[c] = 0 then add c.CONCLUSION to queue
  return false

```

**Figure 7.15** The forward-chaining algorithm for propositional logic. The *queue* keeps track of symbols known to be true but not yet “processed.” The *count* table keeps track of how many premises of each implication are not yet proven. Whenever a new symbol *p* from the agenda is processed, the count is reduced by one for each implication in whose premise *p* appears (easily identified in constant time with appropriate indexing.) If a count reaches zero, all the premises of the implication are known, so its conclusion can be added to the agenda. Finally, we need to keep track of which symbols have been processed; a symbol that is already in the set of inferred symbols need not be added to the agenda again. This avoids redundant work and prevents loops caused by implications such as  $P \Rightarrow Q$  and  $Q \Rightarrow P$ .

---

To see this, assume the opposite, namely that some clause  $a_1 \wedge \dots \wedge a_k \Rightarrow b$  is false in the model. Then  $a_1 \wedge \dots \wedge a_k$  must be true in the model and  $b$  must be false in the model. But this contradicts our assumption that the algorithm has reached a fixed point, because we would now be licensed to add  $b$  to the KB. We can conclude, therefore, that the set of atomic sentences inferred at the fixed point defines a model of the original KB. Furthermore, any atomic sentence *q* that is entailed by the KB must be true in all its models and in this model in particular. Hence, every entailed atomic sentence *q* must be inferred by the algorithm.

Forward chaining is an example of the general concept of **data-driven** reasoning—that is, reasoning in which the focus of attention starts with the known data. It can be used within an agent to derive conclusions from incoming percepts, often without a specific query in mind. For example, the wumpus agent might TELL its percepts to the knowledge base using an incremental forward-chaining algorithm in which new facts can be added to the agenda to initiate new inferences. In humans, a certain amount of data-driven reasoning occurs as new information arrives. For example, if I am indoors and hear rain starting to fall, it might occur to me that the picnic will be canceled. Yet it will probably not occur to me that the seventeenth petal on the largest rose in my neighbor's garden will get wet; humans keep forward chaining under careful control, lest they be swamped with irrelevant consequences.

The backward-chaining algorithm, as its name suggests, works backward from the query. If the query *q* is known to be true, then no work is needed. Otherwise, the algorithm finds

Data-driven

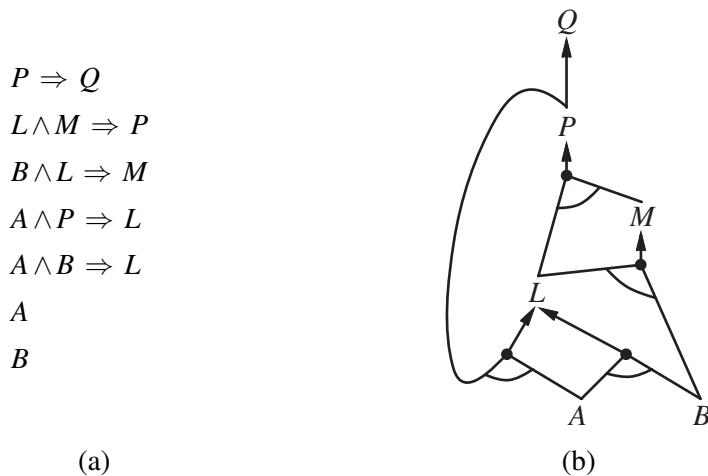

Figure 7.16 (a) A set of Horn clauses. (b) The corresponding AND-OR graph.

those implications in the knowledge base whose conclusion is  $q$ . If all the premises of one of those implications can be proved true (by backward chaining), then  $q$  is true. When applied to the query  $Q$  in Figure 7.16, it works back down the graph until it reaches a set of known facts,  $A$  and  $B$ , that forms the basis for a proof. The algorithm is essentially identical to the AND-OR-GRAF-SEARCH algorithm in Figure 4.11. As with forward chaining, an efficient implementation runs in linear time.

Goal-directed reasoning

Backward chaining is a form of **goal-directed reasoning**. It is useful for answering specific questions such as “What shall I do now?” and “Where are my keys?” Often, the cost of backward chaining is *much less* than linear in the size of the knowledge base, because the process touches only relevant facts.

## 7.6 Effective Propositional Model Checking

In this section, we describe two families of efficient algorithms for general propositional inference based on model checking: one approach based on backtracking search, and one on local hill-climbing search. These algorithms are part of the “technology” of propositional logic. This section can be skimmed on a first reading of the chapter.

The algorithms we describe are for checking satisfiability: the SAT problem. (As noted in Section 7.5, testing entailment,  $\alpha \models \beta$ , can be done by testing unsatisfiability of  $\alpha \wedge \neg\beta$ .) We mentioned on page 241 the connection between finding a satisfying model for a logical sentence and finding a solution for a constraint satisfaction problem, so it is perhaps not surprising that the two families of propositional satisfiability algorithms closely resemble the backtracking algorithms of Section 5.3 and the local search algorithms of Section 5.4. They are, however, extremely important in their own right because so many combinatorial problems in computer science can be reduced to checking the satisfiability of a propositional sentence. Any improvement in satisfiability algorithms has huge consequences for our ability to handle complexity in general.

### 7.6.1 A complete backtracking algorithm

The first algorithm we consider is often called the **Davis–Putnam algorithm**, after the seminal paper by Martin Davis and Hilary Putnam (1960). The algorithm is in fact the version described by Davis, Logemann, and Loveland (1962), so we will call it DPLL after the initials of all four authors. DPLL takes as input a sentence in conjunctive normal form—a set of clauses. Like BACKTRACKING-SEARCH and TT-ENTAILS?, it is essentially a recursive, depth-first enumeration of possible models. It embodies three improvements over the simple scheme of TT-ENTAILS?:

- *Early termination:* The algorithm detects whether the sentence must be true or false, even with a partially completed model. A clause is true if *any* literal is true, even if the other literals do not yet have truth values; hence, the sentence as a whole could be judged true even before the model is complete. For example, the sentence  $(A \vee B) \wedge (A \vee C)$  is true if  $A$  is true, regardless of the values of  $B$  and  $C$ . Similarly, a sentence is false if *any* clause is false, which occurs when each of its literals is false. Again, this can occur long before the model is complete. Early termination avoids examination of entire subtrees in the search space.
- *Pure symbol heuristic:* A **pure symbol** is a symbol that always appears with the same “sign” in all clauses. For example, in the three clauses  $(A \vee \neg B)$ ,  $(\neg B \vee \neg C)$ , and  $(C \vee A)$ , the symbol  $A$  is pure because only the positive literal appears,  $B$  is pure because only the negative literal appears, and  $C$  is impure. It is easy to see that if a sentence has a model, then it has a model with the pure symbols assigned so as to make their literals *true*, because doing so can never make a clause false. Note that, in determining the purity of a symbol, the algorithm can ignore clauses that are already known to be true in the model constructed so far. For example, if the model contains  $B = \text{false}$ , then the clause  $(\neg B \vee \neg C)$  is already true, and in the remaining clauses  $C$  appears only as a positive literal; therefore  $C$  becomes pure.
- *Unit clause heuristic:* A **unit clause** was defined earlier as a clause with just one literal. In the context of DPLL, it also means clauses in which all literals but one are already assigned *false* by the model. For example, if the model contains  $B = \text{true}$ , then  $(\neg B \vee \neg C)$  simplifies to  $\neg C$ , which is a unit clause. Obviously, for this clause to be true,  $C$  must be set to *false*. The unit clause heuristic assigns all such symbols before branching on the remainder. One important consequence of the heuristic is that any attempt to prove (by refutation) a literal that is already in the knowledge base will succeed immediately (Exercise 7.KNOW). Notice also that assigning one unit clause can create another unit clause—for example, when  $C$  is set to *false*,  $(C \vee A)$  becomes a unit clause, causing *true* to be assigned to  $A$ . This “cascade” of forced assignments is called **unit propagation**. It resembles the process of forward chaining with definite clauses, and indeed, if the CNF expression contains only definite clauses then DPLL essentially replicates forward chaining. (See Exercise 7.DPLL.)

The DPLL algorithm is shown in Figure 7.17, which gives the essential skeleton of the search process without the implementation details.

What Figure 7.17 does not show are the tricks that enable SAT solvers to scale up to large problems. It is interesting that most of these tricks are in fact rather general, and we have seen them before in other guises:

Davis–Putnam algorithm

Pure symbol

Unit propagation

---

```

function DPLL-SATISFIABLE?(s) returns true or false
  inputs: s, a sentence in propositional logic
  clauses  $\leftarrow$  the set of clauses in the CNF representation of s
  symbols  $\leftarrow$  a list of the proposition symbols in s
  return DPLL(clauses, symbols, { })

function DPLL(clauses, symbols, model) returns true or false
  if every clause in clauses is true in model then return true
  if some clause in clauses is false in model then return false
  P, value  $\leftarrow$  FIND-PURE-SYMBOL(symbols, clauses, model)
  if P is non-null then return DPLL(clauses, symbols - P, model  $\cup$  {P=valueP, value  $\leftarrow$  FIND-UNIT-CLAUSE(clauses, model)
  if P is non-null then return DPLL(clauses, symbols - P, model  $\cup$  {P=valueP  $\leftarrow$  FIRST(symbols); rest  $\leftarrow$  REST(symbols)
  return DPLL(clauses, rest, model  $\cup$  {P=true}) or
         DPLL(clauses, rest, model  $\cup$  {P=false})

```

**Figure 7.17** The DPLL algorithm for checking satisfiability of a sentence in propositional logic. The ideas behind FIND-PURE-SYMBOL and FIND-UNIT-CLAUSE are described in the text; each returns a symbol (or null) and the truth value to assign to that symbol. Like TT-ENTAILS?, DPLL operates over partial models.

---

1. **Component analysis** (as seen with Tasmania in CSPs): As DPLL assigns truth values to variables, the set of clauses may become separated into disjoint subsets, called **components**, that share no unassigned variables. Given an efficient way to detect when this occurs, a solver can gain considerable speed by working on each component separately.
2. **Variable and value ordering** (as seen in Section 5.3.1 for CSPs): Our simple implementation of DPLL uses an arbitrary variable ordering and always tries the value *true* before *false*. The **degree heuristic** (see page 177) suggests choosing the variable that appears most frequently over all remaining clauses.
3. **Intelligent backtracking** (as seen in Section 5.3.3 for CSPs): Many problems that cannot be solved in hours of run time with chronological backtracking can be solved in seconds with intelligent backtracking that backs up all the way to the relevant point of conflict. All SAT solvers that do intelligent backtracking use some form of **conflict clause learning** to record conflicts so that they won't be repeated later in the search. Usually a limited-size set of conflicts is kept, and rarely used ones are dropped.
4. **Random restarts** (as seen on page 131 for hill climbing): Sometimes a run appears not to be making progress. In this case, we can start over from the top of the search tree, rather than trying to continue. After restarting, different random choices (in variable and value selection) are made. Clauses that are learned in the first run are retained after the restart and can help prune the search space. Restarting does not guarantee that a solution will be found faster, but it does reduce the variance on the time to solution.
5. **Clever indexing** (as seen in many algorithms): The speedup methods used in DPLL itself, as well as the tricks used in modern solvers, require fast indexing of such things

---

```

function WALKSAT(clauses, p, max_flips) returns a satisfying model or failure
  inputs: clauses, a set of clauses in propositional logic
    p, the probability of choosing to do a “random walk” move, typically around 0.5
    max_flips, number of value flips allowed before giving up

  model  $\leftarrow$  a random assignment of true/false to the symbols in clauses
  for each i = 1 to max_flips do
    if model satisfies clauses then return model
    clause  $\leftarrow$  a randomly selected clause from clauses that is false in model
    if RANDOM(0, 1)  $\leq$  p then
      flip the value in model of a randomly selected symbol from clause
    else flip whichever symbol in clause maximizes the number of satisfied clauses
  return failure

```

**Figure 7.18** The WALKSAT algorithm for checking satisfiability by randomly flipping the values of variables. Many versions of the algorithm exist.

---

as “the set of clauses in which variable  $X_i$  appears as a positive literal.” This task is complicated by the fact that the algorithms are interested only in the clauses that have not yet been satisfied by previous assignments to variables, so the indexing structures must be updated dynamically as the computation proceeds.

With these enhancements, modern solvers can handle problems with tens of millions of variables. They have revolutionized areas such as hardware verification and security protocol verification, which previously required laborious, hand-guided proofs.

### 7.6.2 Local search algorithms

We have seen several local search algorithms so far in this book, including HILL-CLIMBING (page 129) and SIMULATED-ANNEALING (page 133). These algorithms can be applied directly to satisfiability problems, provided that we choose the right evaluation function. Because the goal is to find an assignment that satisfies every clause, an evaluation function that counts the number of unsatisfied clauses will do the job. In fact, this is exactly the measure used by the MIN-CONFLICTS algorithm for CSPs (page 182). All these algorithms take steps in the space of complete assignments, flipping the truth value of one symbol at a time. The space usually contains many local minima, to escape from which various forms of randomness are required. In recent years, there has been a great deal of experimentation to find a good balance between greediness and randomness.

One of the simplest and most effective algorithms to emerge from all this work is called WALKSAT (Figure 7.18). On every iteration, the algorithm picks an unsatisfied clause and picks a symbol in the clause to flip. It chooses randomly between two ways to pick which symbol to flip: (1) a “min-conflicts” step that minimizes the number of unsatisfied clauses in the new state and (2) a “random walk” step that picks the symbol randomly.

When WALKSAT returns a model, the input sentence is indeed satisfiable, but when it returns *failure*, there are two possible causes: either the sentence is unsatisfiable or we need to give the algorithm more time. If we set *max\_flips*= $\infty$  and *p* > 0, WALKSAT will eventually return a model (if one exists), because the random-walk steps will eventually hit upon the

solution. Alas, if *max\_flips* is infinity and the sentence is unsatisfiable, then the algorithm never terminates!

For this reason, WALKSAT is most useful when we expect a solution to exist—for example, the problems discussed in Chapters 3 and 5 usually have solutions. On the other hand, WALKSAT cannot always detect *unsatisfiability*, which is required for deciding entailment. For example, an agent cannot *reliably* use WALKSAT to prove that a square is safe in the wumpus world. Instead, it can say, “I thought about it for an hour and couldn’t come up with a possible world in which the square *isn’t* safe.” This may be a good empirical indicator that the square is safe, but it’s certainly not a proof.

### 7.6.3 The landscape of random SAT problems

Some SAT problems are harder than others. *Easy* problems can be solved by any old algorithm, but because we know that SAT is NP-complete, at least some problem instances must require exponential run time. In Chapter 5, we saw some surprising discoveries about certain kinds of problems. For example, the *n*-queens problem—thought to be quite tricky for backtracking search algorithms—turned out to be trivially easy for local search methods, such as min-conflicts. This is because solutions are very densely distributed in the space of assignments, and any initial assignment is guaranteed to have a solution nearby. Thus, *n*-queens is easy because it is **underconstrained**.

When we look at satisfiability problems in conjunctive normal form, an underconstrained problem is one with relatively *few* clauses constraining the variables. For example, here is a randomly generated 3-CNF sentence with five symbols and five clauses:

$$\begin{aligned} & (\neg D \vee \neg B \vee C) \wedge (B \vee \neg A \vee \neg C) \wedge (\neg C \vee \neg B \vee E) \\ & \wedge (E \vee \neg D \vee B) \wedge (B \vee E \vee \neg C). \end{aligned}$$

Sixteen of the 32 possible assignments are models of this sentence, so, on average, it would take just two random guesses to find a model. This is an easy satisfiability problem, as are most such underconstrained problems. On the other hand, an *overconstrained* problem has many clauses relative to the number of variables and is likely to have no solutions. Overconstrained problems are often easy to solve, because the constraints quickly lead either to a solution or to a dead end from which there is no escape.

To go beyond these basic intuitions, we must define exactly how random sentences are generated. The notation  $CNF_k(m, n)$  denotes a  $k$ -CNF sentence with  $m$  clauses and  $n$  symbols, where the clauses are chosen uniformly, independently, and without replacement from among all clauses with  $k$  different literals, which are positive or negative at random. (A symbol may not appear twice in a clause, nor may a clause appear twice in a sentence.)

Given a source of random sentences, we can measure the probability of satisfiability. Figure 7.19(a) plots the probability for  $CNF_3(m, 50)$ , that is, sentences with 50 variables and 3 literals per clause, as a function of the clause/symbol ratio,  $m/n$ . As we expect, for small  $m/n$  the probability of satisfiability is close to 1, and at large  $m/n$  the probability is close to 0. The probability drops fairly sharply around  $m/n=4.3$ . Empirically, we find that the “cliff” stays in roughly the same place (for  $k=3$ ) and gets sharper and sharper as  $n$  increases.

Theoretically, the **satisfiability threshold conjecture** says that for every  $k \geq 3$ , there is a threshold ratio  $r_k$  such that, as  $n$  goes to infinity, the probability that  $CNF_k(rn, n)$  is satisfiable becomes 1 for all values of  $r$  below the threshold, and 0 for all values above. The conjecture remains unproven, even for special cases like  $k = 3$ . Whether it is a theorem or not, this kind

**Underconstrained**

**Satisfiability threshold conjecture**

**Figure 7.19** (a) Graph showing the probability that a random 3-CNF sentence with  $n=50$  symbols is satisfiable, as a function of the clause/symbol ratio  $m/n$ . (b) Graph of the median run time (measured in number of iterations) for both DPLL and WALKSAT on random 3-CNF sentences. The most difficult problems have a clause/symbol ratio of about 4.3.

of thresholding effect is certainly common, for satisfiability problems as well as other types of NP-hard problems.

Now that we have a good idea where the satisfiable and unsatisfiable problems are, the next question is, where are the hard problems? It turns out that they are also often at the threshold value. Figure 7.19(b) shows that 50-symbol problems at the threshold value of 4.3 are about 20 times more difficult to solve than those at a ratio of 3.3. The underconstrained problems are easiest to solve (because it is so easy to guess a solution); the overconstrained problems are not as easy as the underconstrained, but still are much easier than the ones right at the threshold.

## 7.7 Agents Based on Propositional Logic

In this section, we bring together what we have learned so far in order to construct wumpus world agents that use propositional logic. The first step is to enable the agent to deduce, to the extent possible, the state of the world given its percept history. This requires writing down a complete logical model of the effects of actions. We then show how logical inference can be used by an agent in the wumpus world. We also show how the agent can keep track of the world efficiently without going back into the percept history for each inference. Finally, we show how the agent can use logical inference to construct plans that are guaranteed to achieve its goals, provided its knowledge base is true in the actual world.

### 7.7.1 The current state of the world

As stated at the beginning of the chapter, a logical agent operates by deducing what to do from a knowledge base of sentences about the world. The knowledge base is composed of axioms—general knowledge about how the world works—and percept sentences obtained from the agent’s experience in a particular world. In this section, we focus on the problem of deducing the current state of the wumpus world—where am I, is that square safe, and so on.

We began collecting axioms in Section 7.4.3. The agent knows that the starting square contains no pit ( $\neg P_{1,1}$ ) and no wumpus ( $\neg W_{1,1}$ ). Furthermore, for each square, it knows that the square is breezy if and only if a neighboring square has a pit; and a square is smelly if and only if a neighboring square has a wumpus. Thus, we include a large collection of sentences of the following form:

$$\begin{aligned} B_{1,1} &\Leftrightarrow (P_{1,2} \vee P_{2,1}) \\ S_{1,1} &\Leftrightarrow (W_{1,2} \vee W_{2,1}) \\ &\dots \end{aligned}$$

The agent also knows that there is exactly one wumpus. This is expressed in two parts. First, we have to say that there is *at least one* wumpus:

$$W_{1,1} \vee W_{1,2} \vee \dots \vee W_{4,3} \vee W_{4,4}.$$

Then we have to say that there is *at most one* wumpus. For each pair of locations, we add a sentence saying that at least one of them must be wumpus-free:

$$\begin{aligned} \neg W_{1,1} \vee \neg W_{1,2} \\ \neg W_{1,1} \vee \neg W_{1,3} \\ &\dots \\ \neg W_{4,3} \vee \neg W_{4,4}. \end{aligned}$$

So far, so good. Now let's consider the agent's percepts. We are using  $S_{1,1}$  to mean there is a stench in [1,1]; can we use a single proposition, *Stench* to mean that the agent perceives a stench? Unfortunately we can't: if there was no stench at the previous time step, then  $\neg Stench$  would already be asserted, and the new assertion would simply result in a contradiction. The problem is solved when we realize that a percept asserts something *only about the current time*. Thus, if the time step (as supplied to `MAKE-PERCEPT-SENTENCE` in Figure 7.1) is 4, then we add *Stench*<sup>4</sup> to the knowledge base, rather than *Stench*—neatly avoiding any contradiction with  $\neg Stench$ <sup>3</sup>. The same goes for the breeze, bump, glitter, and scream percepts.

The idea of associating propositions with time steps extends to any aspect of the world that changes over time. For example, the initial knowledge base includes  $L_{1,1}^0$ —the agent is in square [1,1] at time 0—as well as *FacingEast*<sup>0</sup>, *HaveArrow*<sup>0</sup>, and *WumpusAlive*<sup>0</sup>. We use the noun **fluent** (from the Latin *fluens*, flowing) to refer to an aspect of the world that changes. “Fluent” is a synonym for “state variable,” in the sense described in the discussion of factored representations in Section 2.4.7 on page 76. Symbols associated with permanent aspects of the world do not need a time superscript and are sometimes called **atemporal variables**.

Fluent

Atemporal variable

We can connect stench and breeze percepts directly to the properties of the squares where they are experienced as follows.<sup>11</sup> For any time step  $t$  and any square  $[x,y]$ , we assert

$$\begin{aligned} L_{x,y}^t &\Rightarrow (Breeze^t \Leftrightarrow B_{x,y}) \\ L_{x,y}^t &\Rightarrow (Stench^t \Leftrightarrow S_{x,y}). \end{aligned}$$

Now, of course, we need axioms that allow the agent to keep track of fluents such as  $L_{x,y}^t$ . These fluents change as the result of actions taken by the agent, so, in the terminology of Chapter 3, we need to write down the **transition model** of the wumpus world as a set of logical sentences.

<sup>11</sup> Section 7.4.3 conveniently glossed over this requirement.

First we need proposition symbols for the occurrences of actions. As with percepts, these symbols are indexed by time; thus, *Forward*<sup>0</sup> means that the agent executes the *Forward* action at time 0. By convention, the percept for a given time step happens first, followed by the action for that time step, followed by a transition to the next time step.

To describe how the world changes, we can try writing **effect axioms** that specify the outcome of an action at the next time step. For example, if the agent is at location [1, 1] facing east at time 0 and goes *Forward*, the result is that the agent is in square [2, 1] and no longer is in [1, 1]:

$$L_{1,1}^0 \wedge FacingEast^0 \wedge Forward^0 \Rightarrow (L_{2,1}^1 \wedge \neg L_{1,1}^1). \quad (7.1)$$

We would need one such sentence for each possible time step, for each of the 16 squares, and each of the four orientations. We would also need similar sentences for the other actions: *Grab*, *Shoot*, *Climb*, *TurnLeft*, and *TurnRight*.

Let us suppose that the agent does decide to move *Forward* at time 0 and asserts this fact into its knowledge base. Given the effect axiom in Equation (7.1), combined with the initial assertions about the state at time 0, the agent can now deduce that it is in [2, 1]. That is,  $\text{ASK}(KB, L_{2,1}^1) = \text{true}$ . So far, so good. Unfortunately, if we  $\text{ASK}(KB, \text{HaveArrow}^1)$ , the answer is *false*, that is, the agent cannot prove it still has the arrow; nor can it prove it *doesn't* have it! The information has been lost because the effect axiom fails to state what remains *unchanged* as the result of an action. The need to do this gives rise to the **frame problem**.<sup>12</sup>

One possible solution to the frame problem would be to add **frame axioms** explicitly asserting all the propositions that remain the same. For example, for each time  $t$  we would have

$$\begin{aligned} Forward^t &\Rightarrow (HaveArrow^t \Leftrightarrow HaveArrow^{t+1}) \\ Forward^t &\Rightarrow (WumpusAlive^t \Leftrightarrow WumpusAlive^{t+1}) \\ &\dots \end{aligned}$$

where we explicitly mention every proposition that stays unchanged from time  $t$  to time  $t + 1$  under the action *Forward*. Although the agent now knows that it still has the arrow after moving forward and that the wumpus hasn't died or come back to life, the proliferation of frame axioms seems remarkably inefficient. In a world with  $m$  different actions and  $n$  fluents, the set of frame axioms will be of size  $O(mn)$ . This specific manifestation of the frame problem is sometimes called the **representational frame problem**. The problem played a significant role in the history of AI; we explore it further in the notes at the end of the chapter.

The representational frame problem is significant because the real world has very many fluents, to put it mildly. Fortunately for us humans, each action typically changes no more than some small number  $k$  of those fluents—the world exhibits **locality**. Solving the representational frame problem requires defining the transition model with a set of axioms of size  $O(mk)$  rather than size  $O(mn)$ . There is also an **inferential frame problem**: the problem of projecting forward the results of a  $t$ -step plan of action in time  $O(kt)$  rather than  $O(nt)$ .

The solution to the problem involves changing one's focus from writing axioms about *actions* to writing axioms about *fluents*. Thus for each fluent  $F$ , we will have an axiom that defines the truth value of  $F^{t+1}$  in terms of fluents (including  $F$  itself) at time  $t$  and the actions that may have occurred at time  $t$ . Now, the truth value of  $F^{t+1}$  can be set in one of two ways:

<sup>12</sup> The name “frame problem” comes from “frame of reference” in physics—the assumed stationary background with respect to which motion is measured. It also has an analogy to the frames of a movie, in which normally most of the background stays constant while changes occur in the foreground.

Effect axiom

Locality

Inferential frame problem

either the action at time  $t$  causes  $F$  to be true at  $t + 1$ , or  $F$  was already true at time  $t$  and the action at time  $t$  does not cause it to be false. An axiom of this form is called a **successor-state axiom** and has this form:

$$F^{t+1} \Leftrightarrow \text{ActionCauses}F^t \vee (F^t \wedge \neg\text{ActionCausesNot}F^t).$$

One of the simplest successor-state axioms is the one for *HaveArrow*. Because there is no action for reloading, the  $\text{ActionCauses}F^t$  part goes away and we are left with

$$\text{HaveArrow}^{t+1} \Leftrightarrow (\text{HaveArrow}^t \wedge \neg\text{Shoot}^t). \quad (7.2)$$

For the agent's location, the successor-state axioms are more elaborate. For example,  $L_{1,1}^{t+1}$  is true if either (a) the agent moved *Forward* from [1, 2] when facing south, or from [2, 1] when facing west; or (b)  $L_{1,1}^t$  was already true and the action did not cause movement (either because the action was not *Forward* or because the action bumped into a wall). Written out in propositional logic, this becomes

$$\begin{aligned} L_{1,1}^{t+1} \Leftrightarrow & (L_{1,1}^t \wedge (\neg\text{Forward}^t \vee \text{Bump}^{t+1})) \\ & \vee (L_{1,2}^t \wedge (\text{FacingSouth}^t \wedge \text{Forward}^t)) \\ & \vee (L_{2,1}^t \wedge (\text{FacingWest}^t \wedge \text{Forward}^t)). \end{aligned} \quad (7.3)$$

**Exercise 7.SSAX** asks you to write out axioms for the remaining wumpus world fluents.

Given a complete set of successor-state axioms and the other axioms listed at the beginning of this section, the agent will be able to ASK and answer any answerable question about the current state of the world. For example, in Section 7.2 the initial sequence of percepts and actions is

$$\begin{aligned} & \neg\text{Stench}^0 \wedge \neg\text{Breeze}^0 \wedge \neg\text{Glitter}^0 \wedge \neg\text{Bump}^0 \wedge \neg\text{Scream}^0 ; \text{Forward}^0 \\ & \neg\text{Stench}^1 \wedge \text{Breeze}^1 \wedge \neg\text{Glitter}^1 \wedge \neg\text{Bump}^1 \wedge \neg\text{Scream}^1 ; \text{TurnRight}^1 \\ & \neg\text{Stench}^2 \wedge \text{Breeze}^2 \wedge \neg\text{Glitter}^2 \wedge \neg\text{Bump}^2 \wedge \neg\text{Scream}^2 ; \text{TurnRight}^2 \\ & \neg\text{Stench}^3 \wedge \text{Breeze}^3 \wedge \neg\text{Glitter}^3 \wedge \neg\text{Bump}^3 \wedge \neg\text{Scream}^3 ; \text{Forward}^3 \\ & \neg\text{Stench}^4 \wedge \neg\text{Breeze}^4 \wedge \neg\text{Glitter}^4 \wedge \neg\text{Bump}^4 \wedge \neg\text{Scream}^4 ; \text{TurnRight}^4 \\ & \neg\text{Stench}^5 \wedge \neg\text{Breeze}^5 \wedge \neg\text{Glitter}^5 \wedge \neg\text{Bump}^5 \wedge \neg\text{Scream}^5 ; \text{Forward}^5 \\ & \text{Stench}^6 \wedge \neg\text{Breeze}^6 \wedge \neg\text{Glitter}^6 \wedge \neg\text{Bump}^6 \wedge \neg\text{Scream}^6 \end{aligned}$$

At this point, we have  $\text{ASK}(KB, L_{1,2}^6) = \text{true}$ , so the agent knows where it is. Moreover,  $\text{ASK}(KB, W_{1,3}) = \text{true}$  and  $\text{ASK}(KB, P_{3,1}) = \text{true}$ , so the agent has found the wumpus and one of the pits. The most important question for the agent is whether a square is OK to move into—that is, whether the square is free of a pit or live wumpus. It's convenient to add axioms for this, having the form

$$OK_{x,y}^t \Leftrightarrow \neg P_{x,y} \wedge \neg(W_{x,y} \wedge \text{WumpusAlive}^t).$$

Finally,  $\text{ASK}(KB, OK_{2,2}^6) = \text{true}$ , so the square [2, 2] is OK to move into. In fact, given a sound and complete inference algorithm such as DPLL, the agent can answer any answerable question about which squares are OK—and can do so in just a few milliseconds for small-to-medium wumpus worlds.

Solving the representational and inferential frame problems is a big step forward, but a pernicious problem remains: we need to confirm that *all* the necessary preconditions of an action hold for it to have its intended effect. We said that the *Forward* action moves the agent

ahead unless there is a wall in the way, but there are many other unusual exceptions that could cause the action to fail: the agent might trip and fall, be stricken with a heart attack, be carried away by giant bats, etc. Specifying all these exceptions is called the **qualification problem**. There is no complete solution within logic; system designers have to use good judgment in deciding how detailed they want to be in specifying their model, and what details they want to leave out. We will see in Chapter 12 that probability theory allows us to summarize all the exceptions without explicitly naming them.

Qualification problem

## 7.7.2 A hybrid agent

The ability to deduce various aspects of the state of the world can be combined fairly straightforwardly with condition-action rules (see Section 2.4.2) and with problem-solving algorithms from Chapters 3 and 4 to produce a **hybrid agent** for the wumpus world. Figure 7.20 shows one possible way to do this. The agent program maintains and updates a knowledge base as well as a current plan. The initial knowledge base contains the *atemporal* axioms—those that don’t depend on  $t$ , such as the axiom relating the breeziness of squares to the presence of pits. At each time step, the new percept sentence is added along with all the axioms that depend on  $t$ , such as the successor-state axioms. (The next section explains why the agent doesn’t need axioms for *future* time steps.) Then, the agent uses logical inference, by ASKING questions of the knowledge base, to work out which squares are safe and which have yet to be visited.

Hybrid agent

The main body of the agent program constructs a plan based on a decreasing priority of goals. First, if there is a glitter, the program constructs a plan to grab the gold, follow a route back to the initial location, and climb out of the cave. Otherwise, if there is no current plan, the program plans a route to the closest safe square that it has not visited yet, making sure the route goes through only safe squares.

Route planning is done with A\* search, not with ASK. If there are no safe squares to explore, the next step—if the agent still has an arrow—is to try to make a safe square by shooting at one of the possible wumpus locations. These are determined by asking where  $\text{ASK}(KB, \neg W_{x,y})$  is false—that is, where it is *not* known that there is *not* a wumpus. The function PLAN-SHOT (not shown) uses PLAN-ROUTE to plan a sequence of actions that will line up this shot. If this fails, the program looks for a square to explore that is not provably unsafe—that is, a square for which  $\text{ASK}(KB, \neg OK^t_{x,y})$  returns false. If there is no such square, then the mission is impossible and the agent retreats to [1, 1] and climbs out of the cave.

## 7.7.3 Logical state estimation

The agent program in Figure 7.20 works quite well, but it has one major weakness: as time goes by, the computational expense involved in the calls to ASK goes up and up. This happens mainly because the required inferences have to go back further and further in time and involve more and more proposition symbols. Obviously, this is unsustainable—we cannot have an agent whose time to process each percept grows in proportion to the length of its life! What we really need is a *constant* update time—that is, independent of  $t$ . The obvious answer is to save, or **cache**, the results of inference, so that the inference process at the next time step can build on the results of earlier steps instead of having to start again from scratch.

Caching

As we saw in Section 4.4, the history of percepts and all their ramifications can be replaced by the **belief state**—that is, some representation of the set of all possible current states

---

```

function HYBRID-WUMPUS-AGENT(percept) returns an action
  inputs: percept, a list, [stench,breeze,glitter,bump,scream]
  persistent: KB, a knowledge base, initially the atemporal “wumpus physics”
    t, a counter, initially 0, indicating time
    plan, an action sequence, initially empty

  TELL(KB, MAKE-PERCEPT-SENTENCE(percept, t))
  TELL the KB the temporal “physics” sentences for time t
  safe  $\leftarrow \{[x,y] : \text{ASK}(KB, OK_{x,y}^t) = \text{true}\}$ 
  if ASK(KB, Glittert) = true then
    plan  $\leftarrow [\text{Grab}] + \text{PLAN-ROUTE}(\text{current}, \{[1,1]\}, \text{safe}) + [\text{Climb}]$ 
  if plan is empty then
    unvisited  $\leftarrow \{[x,y] : \text{ASK}(KB, L_{x,y}^{t'}) = \text{false} \text{ for all } t' \leq t\}$ 
    plan  $\leftarrow \text{PLAN-ROUTE}(\text{current}, \text{unvisited} \cap \text{safe}, \text{safe})$ 
  if plan is empty and ASK(KB, HaveArrowt) = true then
    possible_wumpus  $\leftarrow \{[x,y] : \text{ASK}(KB, \neg W_{x,y}) = \text{false}\}$ 
    plan  $\leftarrow \text{PLAN-SHOT}(\text{current}, \text{possible\_wumpus}, \text{safe})$ 
  if plan is empty then // no choice but to take a risk
    not_unsafe  $\leftarrow \{[x,y] : \text{ASK}(KB, \neg OK_{x,y}^t) = \text{false}\}$ 
    plan  $\leftarrow \text{PLAN-ROUTE}(\text{current}, \text{unvisited} \cap \text{not\_unsafe}, \text{safe})$ 
  if plan is empty then
    plan  $\leftarrow \text{PLAN-ROUTE}(\text{current}, \{[1,1]\}, \text{safe}) + [\text{Climb}]$ 
  action  $\leftarrow \text{POP}(\text{plan})$ 
  TELL(KB, MAKE-ACTION-SENTENCE(action, t))
  t  $\leftarrow t + 1$ 
  return action

function PLAN-ROUTE(current,goals,allowed) returns an action sequence
  inputs: current, the agent’s current position
    goals, a set of squares; try to plan a route to one of them
    allowed, a set of squares that can form part of the route

  problem  $\leftarrow \text{ROUTE-PROBLEM}(\text{current}, \text{goals}, \text{allowed})$ 
  return SEARCH(problem) // Any search algorithm from Chapter 3

```

**Figure 7.20** A hybrid agent program for the wumpus world. It uses a propositional knowledge base to infer the state of the world, and a combination of problem-solving search and domain-specific code to choose actions. Each time HYBRID-WUMPUS-AGENT is called, it adds the percept to the knowledge base, and then either relies on a previously-defined plan or creates a new plan, and pops off the first step of the plan as the action to do next.

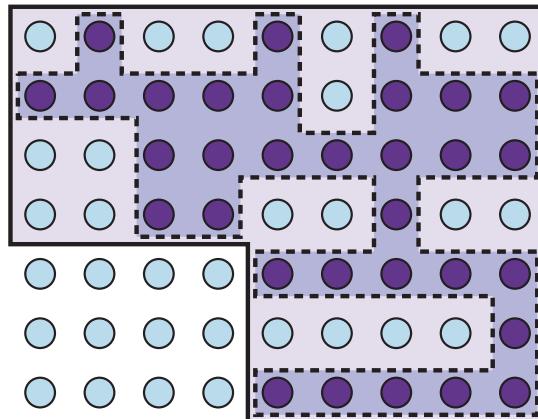

---

of the world.<sup>13</sup> The process of updating the belief state as new percepts arrive is called **state estimation** (see page 150). Whereas in Section 4.4 the belief state was an explicit list of states, here we can use a logical sentence involving the proposition symbols associated with the current time step, as well as the atemporal symbols. For example, the logical sentence

$$\text{WumpusAlive}^1 \wedge L_{2,1}^1 \wedge B_{2,1} \wedge (P_{3,1} \vee P_{2,2}) \quad (7.4)$$

---

<sup>13</sup> We can think of the percept history itself as a representation of the belief state, but one that makes inference increasingly expensive as the history gets longer.

**Figure 7.21** Depiction of a 1-CNF belief state (bold outline) as a simply representable, conservative approximation to the exact (wiggly) belief state (shaded region with dashed outline). Each possible world is shown as a circle; the shaded ones are consistent with all the percepts.

represents the set of all states at time 1 in which the wumpus is alive, the agent is at [2, 1], that square is breezy, and there is a pit in [3, 1] or [2, 2] or both.

Maintaining an exact belief state as a logical formula turns out not to be easy. If there are  $n$  fluent symbols for time  $t$ , then there are  $2^n$  possible states—that is, assignments of truth values to those symbols. Now, the set of belief states is the powerset (set of all subsets) of the set of physical states. There are  $2^n$  physical states, hence  $2^{2^n}$  belief states. Even if we used the most compact possible encoding of logical formulas, with each belief state represented by a unique binary number, we would need numbers with  $\log_2(2^{2^n}) = 2^n$  bits to label the current belief state. That is, exact state estimation may require logical formulas whose size is exponential in the number of symbols.

One very common and natural scheme for *approximate* state estimation is to represent belief states as conjunctions of literals, that is, 1-CNF formulas. To do this, the agent program simply tries to prove  $X^t$  and  $\neg X^t$  for each symbol  $X^t$  (as well as each atemporal symbol whose truth value is not yet known), given the belief state at  $t - 1$ . The conjunction of provable literals becomes the new belief state, and the previous belief state is discarded.

It is important to understand that this scheme may lose some information as time goes along. For example, if the sentence in Equation (7.4) were the true belief state, then neither  $P_{3,1}$  nor  $P_{2,2}$  would be provable individually and neither would appear in the 1-CNF belief state. (Exercise 7.HYBR explores one possible solution to this problem.) On the other hand, because every literal in the 1-CNF belief state is proved from the previous belief state, and the initial belief state is a true assertion, we know that the entire 1-CNF belief state must be true. Thus *the set of possible states represented by the 1-CNF belief state includes all states that are in fact possible given the full percept history*. As illustrated in Figure 7.21, the 1-CNF belief state acts as a simple outer envelope, or **conservative approximation**, around the exact belief state. We see this idea of conservative approximations to complicated sets as a recurring theme in many areas of AI.

---

```

function SATPLAN(init, transition, goal,  $T_{\max}$ ) returns solution or failure
  inputs: init, transition, goal, constitute a description of the problem
     $T_{\max}$ , an upper limit for plan length

  for  $t = 0$  to  $T_{\max}$  do
    cnf  $\leftarrow$  TRANSLATE-TO-SAT(init, transition, goal,  $t$ )
    model  $\leftarrow$  SAT-SOLVER(cnf)
    if model is not null then
      return EXTRACT-SOLUTION(model)
  return failure

```

**Figure 7.22** The SATPLAN algorithm. The planning problem is translated into a CNF sentence in which the goal is asserted to hold at a fixed time step  $t$  and axioms are included for each time step up to  $t$ . If the satisfiability algorithm finds a model, then a plan is extracted by looking at those proposition symbols that refer to actions and are assigned *true* in the model. If no model exists, then the process is repeated with the goal moved one step later.

---

#### 7.7.4 Making plans by propositional inference

The agent in Figure 7.20 uses logical inference to determine which squares are safe, but uses A\* search to make plans. In this section, we show how to make plans by logical inference. The basic idea is very simple:

1. Construct a sentence that includes
  - (a)  $Init^0$ , a collection of assertions about the initial state;
  - (b)  $Transition^1, \dots, Transition^t$ , the successor-state axioms for all possible actions at each time up to some maximum time  $t$ ;
  - (c) the assertion that the goal is achieved at time  $t$ :  $HaveGold^t \wedge ClimbedOut^t$ .
2. Present the whole sentence to a SAT solver. If the solver finds a satisfying model, then the goal is achievable; if the sentence is unsatisfiable, then the problem is unsolvable.
3. Assuming a model is found, extract from the model those variables that represent actions and are assigned *true*. Together they represent a plan to achieve the goals.

A propositional planning procedure, SATPLAN, is shown in Figure 7.22. It implements the basic idea just given, with one twist. Because the agent does not know how many steps it will take to reach the goal, the algorithm tries each possible number of steps  $t$ , up to some maximum conceivable plan length  $T_{\max}$ . In this way, it is guaranteed to find the shortest plan if one exists. Because of the way SATPLAN searches for a solution, this approach cannot be used in a partially observable environment; SATPLAN would just set the unobservable variables to the values it needs to create a solution.

The key step in using SATPLAN is the construction of the knowledge base. It might seem, on casual inspection, that the wumpus world axioms in Section 7.7.1 suffice for steps 1(a) and 1(b) above. There is, however, a significant difference between the requirements for entailment (as tested by ASK) and those for satisfiability.

Consider, for example, the agent's location, initially  $[1, 1]$ , and suppose the agent's unambitious goal is to be in  $[2, 1]$  at time 1. The initial knowledge base contains  $L_{1,1}^0$  and the goal is  $L_{2,1}^1$ . Using ASK, we can prove  $L_{2,1}^1$  if  $Forward^0$  is asserted, and, reassuringly, we cannot

prove  $L_{2,1}^1$  if, say,  $Shoot^0$  is asserted instead. Now, SATPLAN will find the plan [ $Forward^0$ ]; so far, so good.

Unfortunately, SATPLAN also finds the plan [ $Shoot^0$ ]. How could this be? To find out, we inspect the model that SATPLAN constructs: it includes the assignment  $L_{2,1}^0$ , that is, the agent can be in [2, 1] at time 1 by being there at time 0 and shooting. One might ask, “Didn’t we say the agent is in [1, 1] at time 0?” Yes, we did, but we didn’t tell the agent that it can’t be in two places at once! For entailment,  $L_{2,1}^0$  is unknown and cannot, therefore, be used in a proof; for satisfiability, on the other hand,  $L_{2,1}^0$  is unknown and can, therefore, be set to whatever value helps to make the goal true.

SATPLAN is a good debugging tool for knowledge bases because it reveals places where knowledge is missing. In this particular case, we can fix the knowledge base by asserting that, at each time step, the agent is in exactly one location, using a collection of sentences similar to those used to assert the existence of exactly one wumpus. Alternatively, we can assert  $\neg L_{x,y}^0$  for all locations other than [1, 1]; the successor-state axiom for location takes care of subsequent time steps. The same fixes also work to make sure the agent has one and only one orientation at a time.

SATPLAN has more surprises in store, however. The first is that it finds models with impossible actions, such as shooting with no arrow. To understand why, we need to look more carefully at what the successor-state axioms (such as Equation (7.3)) say about actions whose preconditions are not satisfied. The axioms *do* predict correctly that nothing will happen when such an action is executed (see Exercise 7.SATP), but they *do not* say that the action cannot be executed! To avoid generating plans with illegal actions, we must add **precondition axioms** stating that an action occurrence requires the preconditions to be satisfied.<sup>14</sup> For example, we need to say, for each time  $t$ , that

$$Shoot^t \Rightarrow HaveArrow^t.$$

This ensures that if a plan selects the *Shoot* action at any time, it must be the case that the agent has an arrow at that time.

SATPLAN’s second surprise is the creation of plans with multiple simultaneous actions. For example, it may come up with a model in which both  $Forward^0$  and  $Shoot^0$  are true, which is not allowed. To eliminate this problem, we introduce **action exclusion axioms**: for every pair of actions  $A_i^t$  and  $A_j^t$  we add the axiom

$$\neg A_i^t \vee \neg A_j^t.$$

It might be pointed out that walking forward and shooting at the same time is not so hard to do, whereas, say, shooting and grabbing at the same time is rather impractical. By imposing action exclusion axioms only on pairs of actions that really do interfere with each other, we can allow for plans that include multiple simultaneous actions—and because SATPLAN finds the shortest legal plan, we can be sure that it will take advantage of this capability.

To summarize, SATPLAN finds models for a sentence containing the initial state, the goal, the successor-state axioms, the precondition axioms, and the action exclusion axioms. It can be shown that this collection of axioms is sufficient, in the sense that there are no longer any spurious “solutions.” Any model satisfying the propositional sentence will be a

Precondition axioms

Action exclusion axiom

---

<sup>14</sup> Notice that the addition of precondition axioms means that we need not include preconditions for actions in the successor-state axioms.

valid plan for the original problem. Modern SAT-solving technology makes the approach quite practical. For example, a DPLL-style solver has no difficulty in generating the solution for the wumpus world instance shown in Figure 7.2.

This section has described a declarative approach to agent construction: the agent works by a combination of asserting sentences in the knowledge base and performing logical inference. This approach has some weaknesses hidden in phrases such as “for each time  $t$ ” and “for each square  $[x,y]$ . ” For any practical agent, these phrases have to be implemented by code that generates instances of the general sentence schema automatically for insertion into the knowledge base. For a wumpus world of reasonable size—one comparable to a smallish computer game—we might need a  $100 \times 100$  board and 1000 time steps, leading to knowledge bases with tens or hundreds of millions of sentences.

Not only does this become rather impractical, but it also illustrates a deeper problem: we know something about the wumpus world—namely, that the “physics” works the same way across all squares and all time steps—that we cannot express directly in the language of propositional logic. To solve this problem, we need a more expressive language, one in which phrases like “for each time  $t$ ” and “for each square  $[x,y]$ ” can be written in a natural way. First-order logic, described in Chapter 8, is such a language; in first-order logic a wumpus world of any size and duration can be described in about ten logic sentences rather than ten million or ten trillion.

## Summary

---

We have introduced knowledge-based agents and have shown how to define a logic with which such agents can reason about the world. The main points are as follows:

- Intelligent agents need knowledge about the world in order to reach good decisions.
- Knowledge is contained in agents in the form of **sentences** in a **knowledge representation language** that are stored in a **knowledge base**.
- A knowledge-based agent is composed of a knowledge base and an inference mechanism. It operates by storing sentences about the world in its knowledge base, using the inference mechanism to infer new sentences, and using these sentences to decide what action to take.
- A representation language is defined by its **syntax**, which specifies the structure of sentences, and its **semantics**, which defines the **truth** of each sentence in each **possible world or model**.
- The relationship of **entailment** between sentences is crucial to our understanding of reasoning. A sentence  $\alpha$  entails another sentence  $\beta$  if  $\beta$  is true in all worlds where  $\alpha$  is true. Equivalent definitions include the **validity** of the sentence  $\alpha \Rightarrow \beta$  and the **unsatisfiability** of the sentence  $\alpha \wedge \neg\beta$ .
- Inference is the process of deriving new sentences from old ones. **Sound** inference algorithms derive *only* sentences that are entailed; **complete** algorithms derive *all* sentences that are entailed.
- **Propositional logic** is a simple language consisting of **proposition symbols** and **logical connectives**. It can handle propositions that are known to be true, known to be false, or completely unknown.

- The set of possible models, given a fixed propositional vocabulary, is finite, so entailment can be checked by enumerating models. Efficient **model-checking** inference algorithms for propositional logic include backtracking and local search methods and can often solve large problems quickly.
- **Inference rules** are patterns of sound inference that can be used to find proofs. The **resolution** rule yields a complete inference algorithm for knowledge bases that are expressed in **conjunctive normal form**. **Forward chaining** and **backward chaining** are very natural reasoning algorithms for knowledge bases in **Horn form**.
- **Local search** methods such as WALKSAT can be used to find solutions. Such algorithms are sound but not complete.
- Logical **state estimation** involves maintaining a logical sentence that describes the set of possible states consistent with the observation history. Each update step requires inference using the transition model of the environment, which is built from **successor-state axioms** that specify how each **fluent** changes.
- Decisions within a logical agent can be made by SAT solving: finding possible models specifying future action sequences that reach the goal. This approach works only for fully observable or sensorless environments.
- Propositional logic does not scale to environments of unbounded size because it lacks the expressive power to deal concisely with time, space, and universal patterns of relationships among objects.

## Bibliographical and Historical Notes

---

John McCarthy's paper "Programs with Common Sense" (McCarthy, 1958, 1968) promulgated the notion of agents that use logical reasoning to mediate between percepts and actions. It also raised the flag of declarativism, pointing out that telling an agent what it needs to know is an elegant way to build software. Allen Newell's (1982) article "The Knowledge Level" makes the case that rational agents can be described and analyzed at an abstract level defined by the knowledge they possess rather than the programs they run.

Logic itself had its origins in ancient Greek philosophy and mathematics. Plato discussed the syntactic structure of sentences, their truth and falsity, their meaning, and the validity of logical arguments. The first known systematic study of logic was Aristotle's Organon. His **syllogisms** were what we now call inference rules, although they lacked the compositionality of our current rules.

The Megarian and Stoic schools began the systematic study of the basic logical connectives in the fifth century BCE. Truth tables are due to Philo of Megara. The Stoics took five basic inference rules as valid without proof, including the rule we now call Modus Ponens. They derived a number of other rules from these five, using, among other principles, the deduction theorem (page 240) and were clearer about proof than was Aristotle (Mates, 1953).

The idea of reducing logical inference to a purely mechanical process is due to Wilhelm Leibniz (1646–1716). George Boole (1847) introduced the first comprehensive and workable system of formal logic in his book *The Mathematical Analysis of Logic*. Boole's logic was closely modeled on the ordinary algebra of real numbers and used substitution of logically equivalent expressions as its primary inference method. Although it didn't handle all of

Syllogism

propositional logic, other mathematicians soon filled in the missing pieces. Schröder (1877) described conjunctive normal form, while Horn form was introduced much later by Alfred Horn (1951). The first comprehensive exposition of modern propositional logic (and first-order logic) is found in Gottlob Frege’s (1879) *Begriffschrift* (“Concept Writing” or “Conceptual Notation”).

The first mechanical device to carry out logical inferences was the Stanhope Demonstrator, constructed by the third Earl of Stanhope (1753–1816). William Stanley Jevons, one of the mathematicians who extended Boole’s work, constructed his “logical piano” in 1869 to do inferences in Boolean logic. An entertaining history of these early mechanical inference devices is given by Martin Gardner (1968). The first computer programs for logical inference were Martin Davis’s 1954 program for proofs in Presburger arithmetic (Davis, 1957), and the Logic Theorist of Newell, Shaw, and Simon (1957).

Emil Post (1921) and Ludwig Wittgenstein (1922) independently used truth tables as a method of testing validity of propositional logic sentences. The Davis–Putnam algorithm (Davis and Putnam, 1960) was the first algorithm for propositional resolution, and the improved DPLL backtracking algorithm (Davis *et al.*, 1962) proved to be more efficient. The resolution rule and a proof of its completeness were developed in full generality for first-order logic by J. A. Robinson (1965).

Stephen Cook (1971) showed that deciding satisfiability of a sentence in propositional logic (the SAT problem) is NP-complete. Many subsets of propositional logic are known for which the satisfiability problem is polynomially solvable; Horn clauses are one such subset.

Early investigations showed that DPLL has polynomial average-case complexity for certain natural distributions of problems. Even better, Franco and Paull (1983) showed that the same problems could be solved in *constant* time simply by guessing random assignments. Motivated by the empirical success of local search, Koutsoupias and Papadimitriou (1992) showed that a simple hill-climbing algorithm can solve *almost all* satisfiability problem instances very quickly, suggesting that hard problems are rare. Schöning (1999) exhibited a randomized hill-climbing algorithm whose *worst-case* expected run time on 3-SAT problems is  $O(1.333^n)$ —still exponential, but substantially faster than previous worst-case bounds. The current record is  $O(1.32216^n)$  (Rolf, 2006).

#### Watched literal

Efficiency gains in propositional solvers have been rapid. Given ten minutes of computing time, the original DPLL algorithm on 1962 hardware could solve only problems with 10 or 15 variables (on a 2019 laptop it would be about 30 variables). By 1995 the SATZ solver (Li and Anbulagan, 1997) could handle 1,000 variables, thanks to optimized data structures for indexing variables. Two crucial contributions were the **watched literal** indexing technique of Zhang and Stickel (1996), which makes unit propagation very efficient, and the introduction of clause (i.e., constraint) learning techniques from the CSP community by Bayardo and Schrag (1997). Using these ideas, and spurred by the prospect of solving industrial-scale circuit verification problems, Moskewicz *et al.* (2001) developed the CHAFF solver, which could handle problems with millions of variables. Beginning in 2002, annual SAT competitions have been held; most of the winning entries have been variants of CHAFF. The landscape of solvers is surveyed by Gomes *et al.* (2008).

Local search algorithms for satisfiability were tried by various authors throughout the 1980s, based on the idea of minimizing the number of unsatisfied clauses (Hansen and Jau-mard, 1990). A particularly effective algorithm was developed by Gu (1989) and indepen-

dently by Selman *et al.* (1992), who called it GSAT and showed that it was capable of solving a wide range of very hard problems very quickly. The WALKSAT algorithm described in this chapter is due to Selman *et al.* (1996).

The “phase transition” in satisfiability of random  $k$ -SAT problems was first observed by Simon and Dubois (1989) and has given rise to a great deal of theoretical and empirical research—due, in part, to the connection to phase transition phenomena in statistical physics. Crawford and Auton (1993) located the 3-SAT transition at a clause/variable ratio of around 4.26, noting that this coincides with a sharp peak in the run time of their SAT solver. Cook and Mitchell (1997) provide an excellent summary of the early literature on the problem. Algorithms such as **survey propagation** (Parisi and Zecchina, 2002; Maneva *et al.*, 2007) take advantage of special properties of random SAT instances near the satisfiability threshold and greatly outperform general SAT solvers on such instances. The current state of theoretical understanding is summarized by Achlioptas (2009).

Good sources for information on satisfiability, both theoretical and practical, include the *Handbook of Satisfiability* (Biere *et al.*, 2009), Donald Knuth’s (2015) fascicle on satisfiability, and the regular *International Conferences on Theory and Applications of Satisfiability Testing*, known as SAT.

The idea of building agents with propositional logic can be traced back to the seminal paper of McCulloch and Pitts (1943), which is well known for initiating the field of neural networks, but actually was concerned with the implementation of a Boolean circuit-based agent design in the brain. Stan Rosenschein (Rosenschein, 1985; Kaelbling and Rosenschein, 1990) developed ways to compile circuit-based agents from declarative descriptions of the task environment. Rod Brooks (1986, 1989) demonstrates the effectiveness of circuit-based designs for controlling robots (see Chapter 26). Brooks (1991) argues that circuit-based designs are *all* that is needed for AI—that representation and reasoning are cumbersome, expensive, and unnecessary. In our view, both reasoning and circuits are necessary. Williams *et al.* (2003) describe a hybrid agent—not too different from our wumpus agent—that controls NASA spacecraft, planning sequences of actions and diagnosing and recovering from faults.

The general problem of keeping track of a partially observable environment was introduced for state-based representations in Chapter 4. Its instantiation for propositional representations was studied by Amir and Russell (2003), who identified several classes of environments that admit efficient state-estimation algorithms and showed that for several other classes the problem is intractable. The **temporal-projection** problem, which involves determining what propositions hold true after an action sequence is executed, can be seen as a special case of state estimation with empty percepts. Many authors have studied this problem because of its importance in planning; some important hardness results were established by Liberatore (1997). The idea of representing a belief state with propositions can be traced to Wittgenstein (1922).

The approach to logical state estimation using temporal indexes on propositional variables was proposed by Kautz and Selman (1992). Later generations of SATPLAN were able to take advantage of the advances in SAT solvers and remain among the most effective ways of solving difficult planning problems (Kautz, 2006).

The **frame problem** was first recognized by McCarthy and Hayes (1969). Many researchers considered the problem unsolvable within first-order logic, and it spurred a great deal of research into nonmonotonic logics. Philosophers from Dreyfus (1972) to Crockett

[Survey propagation](#)

[Temporal-projection](#)

(1994) have cited the frame problem as one symptom of the inevitable failure of the entire AI enterprise. The solution of the frame problem with successor-state axioms is due to Ray Reiter (1991). Thielscher (1999) identifies the inferential frame problem as a separate idea and provides a solution. In retrospect, one can see that Rosenschein's (1985) agents were using circuits that implemented successor-state axioms, but Rosenschein did not notice that the frame problem was thereby largely solved.

Modern propositional solvers have been applied to a variety of industrial applications, such as the synthesis of computer hardware (Nowick *et al.*, 1993). The SATMC satisfiability checker was used to detect a previously unknown vulnerability in a Web browser sign-on protocol (Armando *et al.*, 2008).

The wumpus world was invented as a game by Gregory Yob (1975). Ironically, Yob developed it because he was bored with games played on a rectangular grid: he put his wumpus on a dodecahedron, and we put it back onto the boring old grid. Michael Genesereth suggested that the wumpus world be used as an agent testbed.

# CHAPTER 8

## FIRST-ORDER LOGIC

*In which we notice that the world is blessed with many objects, some of which are related to other objects, and in which we endeavor to reason about them.*

Propositional logic sufficed to illustrate the basic concepts of logic, inference, and knowledge-based agents. Unfortunately, propositional logic is limited in what it can say. In this chapter, we examine **first-order logic**,<sup>1</sup> which can concisely represent much more. We begin in Section 8.1 with a discussion of representation languages in general; Section 8.2 covers the syntax and semantics of first-order logic; Sections 8.3 and 8.4 illustrate the use of first-order logic for simple representations.

[First-order logic](#)

### 8.1 Representation Revisited

In this section, we discuss the nature of representation languages. Programming languages (such as C++ or Java or Python) are the largest class of formal languages in common use. Data structures within programs can be used to represent facts; for example, a program could use a  $4 \times 4$  array to represent the contents of the wumpus world. Thus, the programming language statement  $World[2,2] \leftarrow Pit$  is a fairly natural way to assert that there is a pit in square [2,2]. Putting together a string of such statements is sufficient for running a simulation of the wumpus world.

What programming languages lack is a general mechanism for deriving facts from other facts; each update to a data structure is done by a domain-specific procedure whose details are derived by the programmer from his or her own knowledge of the domain. This procedural approach can be contrasted with the **declarative** nature of propositional logic, in which knowledge and inference are separate, and inference is entirely domain independent. SQL databases take a mix of declarative and procedural knowledge.

A second drawback of data structures in programs (and of databases) is the lack of any easy way to say, for example, “There is a pit in [2,2] or [3,1]” or “If the wumpus is in [1,1] then he is not in [2,2].” Programs can store a single value for each variable, and some systems allow the value to be “unknown,” but they lack the expressiveness required to directly handle partial information.

Propositional logic is a declarative language because its semantics is based on a truth relation between sentences and possible worlds. It also has sufficient expressive power to deal with partial information, using disjunction and negation. Propositional logic has a third property that is desirable in representation languages, namely, **compositionality**. In a compositional language, the meaning of a sentence is a function of the meaning of its parts. For

[Compositionality](#)

<sup>1</sup> First-order logic is also called **first-order predicate calculus**; it may be abbreviated as **FOL** or **FOPC**.

example, the meaning of “ $S_{1,4} \wedge S_{1,2}$ ” is related to the meanings of “ $S_{1,4}$ ” and “ $S_{1,2}$ .” It would be very strange if “ $S_{1,4}$ ” meant that there is a stench in square [1,4] and “ $S_{1,2}$ ” meant that there is a stench in square [1,2], but “ $S_{1,4} \wedge S_{1,2}$ ” meant that France and Poland drew 1–1 in last week’s ice hockey qualifying match.

However, propositional logic, as a factored representation, lacks the expressive power to *concisely* describe an environment with many objects. For example, we were forced to write a separate rule about breezes and pits for each square, such as

$$B_{1,1} \Leftrightarrow (P_{1,2} \vee P_{2,1}).$$

In English, on the other hand, it seems easy enough to say, once and for all, “Squares adjacent to pits are breezy.” The syntax and semantics of English make it possible to describe the environment concisely: English, like first-order logic, is a structured representation.

### 8.1.1 The language of thought

Natural languages (such as English or Spanish) are very expressive indeed. We managed to write almost this whole book in natural language, with only occasional lapses into other languages (mainly mathematics and diagrams). There is a long tradition in linguistics and the philosophy of language that views natural language as a declarative knowledge representation language. If we could uncover the rules for natural language, we could use them in representation and reasoning systems and gain the benefit of the billions of pages that have been written in natural language.

The modern view of natural language is that it serves as a medium for *communication* rather than pure representation. When a speaker points and says, “Look!” the listener comes to know that, say, Superman has finally appeared over the rooftops. Yet we would not want to say that the sentence “Look!” represents that fact. Rather, the meaning of the sentence depends both on the sentence itself and on the *context* in which the sentence was spoken. Clearly, one could not store a sentence such as “Look!” in a knowledge base and expect to recover its meaning without also storing a representation of the context—which raises the question of how the context itself can be represented.

Natural languages also suffer from *ambiguity*, a problem for a representation language. As Pinker (1995) puts it: “When people think about *spring*, surely they are not confused as to whether they are thinking about a season or something that goes *boing*—and if one word can correspond to two thoughts, thoughts can’t be words.”

The famous **Sapir–Whorf hypothesis** (Whorf, 1956) claims that our understanding of the world is strongly influenced by the language we speak. It is certainly true that different speech communities divide up the world differently. The French have two words “chaise” and “fauteuil,” for a concept that English speakers cover with one: “chair.” But English speakers can easily recognize the category *fauteuil* and give it a name—roughly “open-arm chair”—so does language really make a difference? Whorf relied mainly on intuition and speculation, and his ideas have been largely dismissed, but in the intervening years we actually have real data from anthropological, psychological, and neurological studies.

For example, can you remember which of the following two phrases formed the opening of Section 8.1?

“In this section, we discuss the nature of representation languages . . .”

“This section covers the topic of knowledge representation languages . . .”

Wanner (1974) did a similar experiment and found that subjects made the right choice at chance level—about 50% of the time—but remembered the content of what they read with better than 90% accuracy. This suggests that people interpret the words they read and form an internal *nonverbal* representation, and that the exact words are not consequential.

More interesting is the case in which a concept is completely absent in a language. Speakers of the Australian aboriginal language Guugu Yimithirr have no words for relative (or *egocentric*) directions, such as front, back, right, or left. Instead they use absolute directions, saying, for example, the equivalent of “I have a pain in my north arm.” This difference in language makes a difference in behavior: Guugu Yimithirr speakers are better at navigating in open terrain, while English speakers are better at placing the fork to the right of the plate.

Language also seems to influence thought through seemingly arbitrary grammatical features such as the gender of nouns. For example, “bridge” is masculine in Spanish and feminine in German. Boroditsky (2003) asked subjects to choose English adjectives to describe a photograph of a particular bridge. Spanish speakers chose *big, dangerous, strong, and towering*, whereas German speakers chose *beautiful, elegant, fragile, and slender*.

Words can serve as anchor points that affect how we perceive the world. Loftus and Palmer (1974) showed experimental subjects a movie of an auto accident. Subjects who were asked “How fast were the cars going when they contacted each other?” reported an average of 32 mph, while subjects who were asked the question with the word “smashed” instead of “contacted” reported 41 mph for the same cars in the same movie. Overall, there are measurable but small differences in cognitive processing by speakers of different languages, but no convincing evidence that this leads to a major difference in world view.

In a logical reasoning system that uses conjunctive normal form (CNF), we can see that the linguistic forms “ $\neg(A \vee B)$ ” and “ $\neg A \wedge \neg B$ ” are the same because we can look inside the system and see that the two sentences are stored as the same canonical CNF form. It is starting to become possible to do something similar with the human brain. Mitchell *et al.* (2008) put subjects in a functional magnetic resonance imaging (fMRI) machine, showed them words such as “celery,” and imaged their brains. A machine learning program trained on (word, image) pairs was able to predict correctly 77% of the time on binary choice tasks (e.g., “celery” or “airplane”). The system can even predict at above-chance levels for words it has never seen an fMRI image of before (by considering the images of related words) and for people it has never seen before (proving that fMRI reveals some level of common representation across people). This type of work is still in its infancy, but fMRI (and other imaging technology such as intracranial electrophysiology (Sahin *et al.*, 2009)) promises to give us much more concrete ideas of what human knowledge representations are like.

From the viewpoint of formal logic, representing the same knowledge in two different ways makes absolutely no difference; the same facts will be derivable from either representation. In practice, however, one representation might require fewer steps to derive a conclusion, meaning that a reasoner with limited resources could get to the conclusion using one representation but not the other. For *nondeductive* tasks such as learning from experience, outcomes are *necessarily* dependent on the form of the representations used. We show in Chapter 19 that when a learning program considers two possible theories of the world, both of which are consistent with all the data, the most common way of breaking the tie is to choose the most succinct theory—and that depends on the language used to represent theories. Thus, the influence of language on thought is unavoidable for any agent that does learning.

Object  
Relation  
Function

Property

Ontological commitment

### 8.1.2 Combining the best of formal and natural languages

We can adopt the foundation of propositional logic—a declarative, compositional semantics that is context-independent and unambiguous—and build a more expressive logic on that foundation, borrowing representational ideas from natural language while avoiding its drawbacks. When we look at the syntax of natural language, the most obvious elements are nouns and noun phrases that refer to **objects** (squares, pits, wumpuses) and verbs and verb phrases along with adjectives and adverbs that refer to **relations** among objects (is breezy, is adjacent to, shoots). Some of these relations are **functions**—relations in which there is only one “value” for a given “input.” It is easy to start listing examples of objects, relations, and functions:

- Objects: people, houses, numbers, theories, Ronald McDonald, colors, baseball games, wars, centuries ...
- Relations: these can be unary relations or **properties** such as red, round, bogus, prime, multistoried ..., or more general  $n$ -ary relations such as brother of, bigger than, inside, part of, has color, occurred after, owns, comes between, ...
- Functions: father of, best friend, third inning of, one more than, beginning of ...

Indeed, almost any assertion can be thought of as referring to objects and properties or relations. Some examples follow:

- “One plus two equals three.”  
Objects: one, two, three, one plus two; Relation: equals; Function: plus. (“One plus two” is a name for the object that is obtained by applying the function “plus” to the objects “one” and “two.” “Three” is another name for this object.)
- “Squares neighboring the wumpus are smelly.”  
Objects: wumpus, squares; Property: smelly; Relation: neighboring.
- “Evil King John ruled England in 1200.”  
Objects: John, England, 1200; Relation: ruled during; Properties: evil, king.

The language of **first-order logic**, whose syntax and semantics we define in the next section, is built around objects and relations. It has been important to mathematics, philosophy, and artificial intelligence precisely because those fields—and indeed, much of everyday human existence—can be usefully thought of as dealing with objects and the relations among them. First-order logic can also express facts about *some* or *all* of the objects in the universe. This enables one to represent general laws or rules, such as the statement “Squares neighboring the wumpus are smelly.”

The primary difference between propositional and first-order logic lies in the **ontological commitment** made by each language—that is, what it assumes about the nature of *reality*. Mathematically, this commitment is expressed through the nature of the formal models with respect to which the truth of sentences is defined. For example, propositional logic assumes that there are facts that either hold or do not hold in the world. Each fact can be in one of two states—true or false—and each model assigns *true* or *false* to each proposition symbol (see Section 7.4.2). First-order logic assumes more; namely, that the world consists of objects with certain relations among them that do or do not hold. (See Figure 8.1.) The formal models are correspondingly more complicated than those for propositional logic.

Language	Ontological Commitment (What exists in the world)	Epistemological Commitment (What an agent believes about facts)
Propositional logic	facts	true/false/unknown
First-order logic	facts, objects, relations	true/false/unknown
Temporal logic	facts, objects, relations, times	true/false/unknown
Probability theory	facts	degree of belief $\in [0, 1]$
Fuzzy logic	facts with degree of truth $\in [0, 1]$	known interval value

**Figure 8.1** Formal languages and their ontological and epistemological commitments.

This ontological commitment is a great strength of logic (both propositional and first-order), because it allows us to start with true statements and infer other true statements. It is especially powerful in domains where every proposition has clear boundaries, such as mathematics or the wumpus world, where a square either does or doesn't have a pit; there is no possibility of a square with a vaguely pit-like indentation. But in the real world, many propositions have vague boundaries: Is Vienna a large city? Does this restaurant serve delicious food? Is that person tall? It depends who you ask, and their answer might be “kind of.”

One response is to refine the representation: if a crude line dividing cities into “large” and “not large” leaves out too much information for the application in question, then one can increase the number of size categories or use a *Population* function symbol. Another proposed solution comes from **Fuzzy logic**, which makes the ontological commitment that propositions have a **degree of truth** between 0 and 1. For example, the sentence “Vienna is a large city” might be true to degree 0.8 in fuzzy logic, while “Paris is a large city” might be true to degree 0.9. This corresponds better to our intuitive conception of the world, but it makes it harder to do inference: instead of one rule to determine the truth of  $A \wedge B$ , fuzzy logic needs different rules depending on the domain. Another possibility, covered in Section 25.1, is to assign each concept to a point in a multidimensional space, and then measure the distance between the concept “large city” and the concept “Vienna” or “Paris.”

Various special-purpose logics make still further ontological commitments; for example, **temporal logic** assumes that facts hold at particular *times* and that those times (which may be points or intervals) are ordered. Thus, special-purpose logics give certain kinds of objects (and the axioms about them) “first class” status within the logic, rather than simply defining them within the knowledge base. **Higher-order logic** views the relations and functions referred to by first-order logic as objects in themselves. This allows one to make assertions about *all* relations—for example, one could wish to define what it means for a relation to be transitive. Unlike most special-purpose logics, higher-order logic is strictly more expressive than first-order logic, in the sense that some sentences of higher-order logic cannot be expressed by any finite number of first-order logic sentences.

A logic can also be characterized by its **epistemological commitments**—the possible states of knowledge that it allows with respect to each fact. In both propositional and first-order logic, a sentence represents a fact and the agent either believes the sentence to be true, believes it to be false, or has no opinion. These logics therefore have three possible states of knowledge regarding any sentence.

Fuzzy logic  
Degree of truth

Temporal logic

Higher-order logic

Epistemological commitment

Systems using **probability theory**, on the other hand, can have any *degree of belief*, or *subjective likelihood*, ranging from 0 (total disbelief) to 1 (total belief). It is important not to confuse the degree of belief in probability theory with the degree of truth in fuzzy logic. Indeed, some fuzzy systems allow uncertainty (degree of belief) about degrees of truth. For example, a probabilistic wumpus-world agent might believe that the wumpus is in [1,3] with probability 0.75 and in [2, 3] with probability 0.25 (although the wumpus is definitely in one particular square).

## 8.2 Syntax and Semantics of First-Order Logic

We begin this section by specifying more precisely the way in which the possible worlds of first-order logic reflect the ontological commitment to objects and relations. Then we introduce the various elements of the language, explaining their semantics as we go along. The main points are how the language facilitates concise representations and how its semantics leads to sound reasoning procedures.

### 8.2.1 Models for first-order logic

Chapter 7 said that the models of a logical language are the formal structures that constitute the possible worlds under consideration. Each model links the vocabulary of the logical sentences to elements of the possible world, so that the truth of any sentence can be determined. Thus, models for propositional logic link proposition symbols to predefined truth values.

Models for first-order logic are much more interesting. First, they have objects in them! The **domain** of a model is the set of objects or **domain elements** it contains. The domain is required to be *nonempty*—every possible world must contain at least one object. (See Exercise 8.EMPT for a discussion of empty worlds.) Mathematically speaking, it doesn’t matter *what* these objects are—all that matters is *how many* there are in each particular model—but for pedagogical purposes we’ll use a concrete example. Figure 8.2 shows a model with five objects: Richard the Lionheart, King of England from 1189 to 1199; his younger brother, the evil King John, who ruled from 1199 to 1215; the left legs of Richard and John; and a crown.

The objects in the model may be *related* in various ways. In the figure, Richard and John are brothers. Formally speaking, a relation is just the set of **tuples** of objects that are related. (A tuple is a collection of objects arranged in a fixed order and is written with angle brackets surrounding the objects.) Thus, the brotherhood relation in this model is the set

$$\{ \langle \text{Richard the Lionheart}, \text{King John} \rangle, \langle \text{King John}, \text{Richard the Lionheart} \rangle \}. \quad (8.1)$$

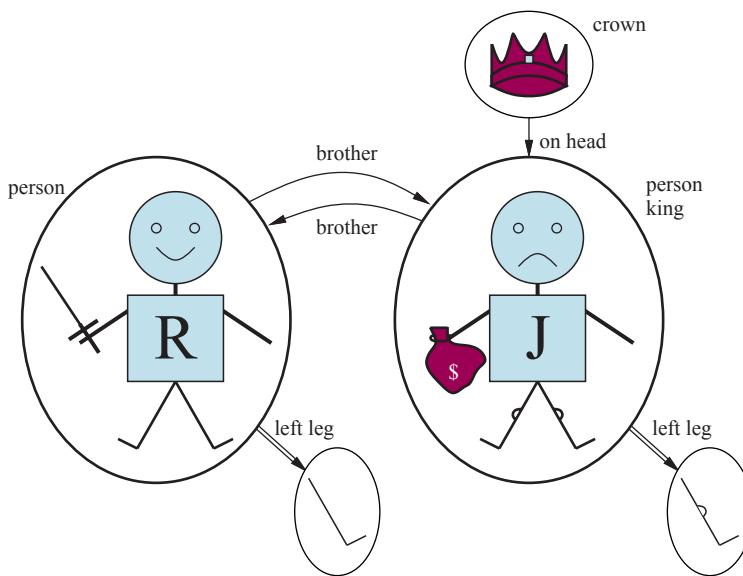

(Here we have named the objects in English, but you may, if you wish, mentally substitute the pictures for the names.) The crown is on King John’s head, so the “on head” relation contains just one tuple,  $\langle \text{the crown}, \text{King John} \rangle$ . The “brother” and “on head” relations are binary relations—that is, they relate pairs of objects. The model also contains unary relations, or properties: the “person” property is true of both Richard and John; the “king” property is true only of John (presumably because Richard is dead at this point); and the “crown” property is true only of the crown.

Certain kinds of relationships are best considered as functions, in that a given object must be related to exactly one object in this way. For example, each person has one left leg, so the model has a unary “left leg” function—a mapping from a one-element tuple to an object—that

Domain

Domain elements

Tuple

**Figure 8.2** A model containing five objects, two binary relations (brother and on-head), three unary relations (person, king, and crown), and one unary function (left-leg).

includes the following mappings:

$$\begin{aligned} \langle \text{Richard the Lionheart} \rangle &\rightarrow \text{Richard's left leg} \\ \langle \text{King John} \rangle &\rightarrow \text{John's left leg}. \end{aligned} \tag{8.2}$$

Strictly speaking, models in first-order logic require **total functions**, that is, there must be a value for every input tuple. Thus the crown must have a left leg and so must each of the left legs. There is a technical solution to this awkward problem involving an additional “invisible” object that is the left leg of everything that has no left leg, including itself. Fortunately, as long as one makes no assertions about the left legs of things that have no left legs, these technicalities are of no import.

So far, we have described the elements that populate models for first-order logic. The other essential part of a model is the link between those elements and the vocabulary of the logical sentences, which we explain next.

### 8.2.2 Symbols and interpretations

We turn now to the syntax of first-order logic. The impatient reader can obtain a complete description from the formal grammar in Figure 8.3.

The basic syntactic elements of first-order logic are the symbols that stand for objects, relations, and functions. The symbols, therefore, come in three kinds: **constant symbols**, which stand for objects; **predicate symbols**, which stand for relations; and **function symbols**, which stand for functions. We adopt the convention that these symbols will begin with uppercase letters. For example, we might use the constant symbols *Richard* and *John*; the predicate symbols *Brother*, *OnHead*, *Person*, *King*, and *Crown*; and the function symbol *LeftLeg*. As with proposition symbols, the choice of names is entirely up to the user. Each predicate and function symbol comes with an **arity** that fixes the number of arguments.

\end{array}$$

```

**Figure 8.3** The syntax of first-order logic with equality, specified in Backus–Naur form (see page 1081 if you are not familiar with this notation). Operator precedences are specified, from highest to lowest. The precedence of quantifiers is such that a quantifier holds over everything to the right of it.

---

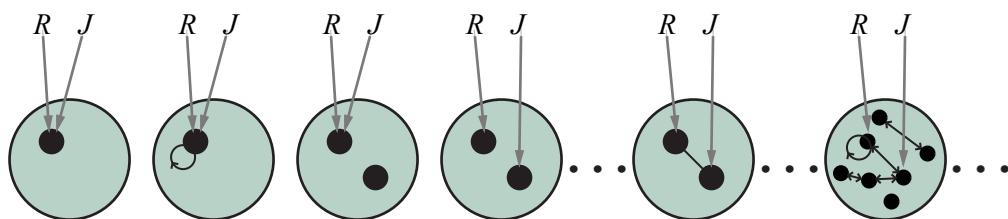

## Interpretation

## Intended interpretation

Every model must provide the information required to determine if any given sentence is true or false. Thus, in addition to its objects, relations, and functions, each model includes an **interpretation** that specifies exactly which objects, relations and functions are referred to by the constant, predicate, and function symbols. One possible interpretation for our example—which a logician would call the **intended interpretation**—is as follows:

- *Richard* refers to Richard the Lionheart and *John* refers to the evil King John.
- *Brother* refers to the brotherhood relation—that is, the set of tuples of objects given in Equation (8.1); *OnHead* is a relation that holds between the crown and King John; *Person*, *King*, and *Crown* are unary relations that identify persons, kings, and crowns.
- *LeftLeg* refers to the “left leg” function as defined in Equation (8.2).

There are many other possible interpretations, of course. For example, one interpretation maps *Richard* to the crown and *John* to King John’s left leg. There are five objects in the model, so there are 25 possible interpretations just for the constant symbols *Richard* and *John*.

**Figure 8.4** Some members of the set of all models for a language with two constant symbols,  $R$  and  $J$ , and one binary relation symbol. The interpretation of each constant symbol is shown by a gray arrow. Within each model, the related objects are connected by arrows.

Notice that not all the objects need have a name—for example, the intended interpretation does not name the crown or the legs. It is also possible for an object to have several names; there is an interpretation under which both *Richard* and *John* refer to the crown.<sup>2</sup> If you find this possibility confusing, remember that, in propositional logic, it is perfectly possible to have a model in which *Cloudy* and *Sunny* are both true; it is the job of the knowledge base to rule out models that are inconsistent with our knowledge.

In summary, a model in first-order logic consists of a set of objects and an interpretation that maps constant symbols to objects, function symbols to functions on those objects, and predicate symbols to relations. Just as with propositional logic, entailment, validity, and so on are defined in terms of *all possible models*. To get an idea of what the set of all possible models looks like, see Figure 8.4. It shows that models vary in how many objects they contain—from one to infinity—and in the way the constant symbols map to objects.

Because the number of first-order models is unbounded, we cannot check entailment by enumerating them all (as we did for propositional logic). Even if the number of objects is restricted, the number of combinations can be very large. (See Exercise 8.MCNT.) For the example in Figure 8.4, there are 137,506,194,466 models with six or fewer objects.

### 8.2.3 Terms

A **term** is a logical expression that refers to an object. Constant symbols are terms, but it is not always convenient to have a distinct symbol to name every object. In English we might use the expression “King John’s left leg” rather than giving a name to his leg. This is what function symbols are for: instead of using a constant symbol, we use  $\text{LeftLeg}(\text{John})$ .<sup>3</sup>

In the general case, a complex term is formed by a function symbol followed by a parenthesized list of terms as arguments to the function symbol. It is important to remember that a complex term is just a complicated kind of name. It is not a “subroutine call” that “returns a value.” There is no *LeftLeg* subroutine that takes a person as input and returns a leg. We can reason about left legs (e.g., stating the general rule that everyone has one and then deducing

<sup>2</sup> Later, in Section 8.2.8, we examine a semantics in which every object must have exactly one name.

<sup>3</sup>  $\lambda$ -expressions (lambda expressions) provide a useful notation in which new function symbols are constructed “on the fly.” For example, the function that squares its argument can be written as  $(\lambda x : x \times x)$  and can be applied to arguments just like any other function symbol. A  $\lambda$ -expression can also be defined and used as a predicate symbol. The `lambda` operator in Lisp and Python plays exactly the same role. Notice that the use of  $\lambda$  in this way does *not* increase the formal expressive power of first-order logic, because any sentence that includes a  $\lambda$ -expression can be rewritten by “plugging in” its arguments to yield an equivalent sentence.

that John must have one) without ever providing a definition of *LeftLeg*. This is something that cannot be done with subroutines in programming languages.

The formal semantics of terms is straightforward. Consider a term  $f(t_1, \dots, t_n)$ . The function symbol  $f$  refers to some function in the model (call it  $F$ ); the argument terms refer to objects in the domain (call them  $d_1, \dots, d_n$ ); and the term as a whole refers to the object that is the value of the function  $F$  applied to  $d_1, \dots, d_n$ . For example, suppose the *LeftLeg* function symbol refers to the function shown in Equation (8.2) and *John* refers to King John, then  $\text{LeftLeg}(\text{John})$  refers to King John's left leg. In this way, the interpretation fixes the referent of every term.

### 8.2.4 Atomic sentences

Atomic sentence  
Atom

Now that we have terms for referring to objects and predicate symbols for referring to relations, we can combine them to make **atomic sentences** that state facts. An **atomic sentence** (or **atom** for short) is formed from a predicate symbol optionally followed by a parenthesized list of terms, such as

$\text{Brother}(\text{Richard}, \text{John}).$

This states, under the intended interpretation given earlier, that Richard the Lionheart is the brother of King John.<sup>4</sup> Atomic sentences can have complex terms as arguments. Thus,

$\text{Married}(\text{Father}(\text{Richard}), \text{Mother}(\text{John}))$

states that Richard the Lionheart's father is married to King John's mother (again, under a suitable interpretation).<sup>5</sup>

► *An atomic sentence is **true** in a given model if the relation referred to by the predicate symbol holds among the objects referred to by the arguments.*

### 8.2.5 Complex sentences

Quantifier

We can use **logical connectives** to construct more complex sentences, with the same syntax and semantics as in propositional calculus. Here are four sentences that are true in the model of Figure 8.2 under our intended interpretation:

$\neg\text{Brother}(\text{LeftLeg}(\text{Richard}), \text{John})$   
 $\text{Brother}(\text{Richard}, \text{John}) \wedge \text{Brother}(\text{John}, \text{Richard})$   
 $\text{King}(\text{Richard}) \vee \text{King}(\text{John})$   
 $\neg\text{King}(\text{Richard}) \Rightarrow \text{King}(\text{John}).$

### 8.2.6 Quantifiers

Once we have a logic that allows objects, it is only natural to want to express properties of entire collections of objects, instead of enumerating the objects by name. **Quantifiers** let us do this. First-order logic contains two standard quantifiers, called *universal* and *existential*.

#### Universal quantification ( $\forall$ )

Recall the difficulty we had in Chapter 7 with the expression of general rules in propositional logic. Rules such as “Squares neighboring the wumpus are smelly” and “All kings

<sup>4</sup> We usually follow the argument-ordering convention that  $P(x, y)$  is read as “ $x$  is a  $P$  of  $y$ .”

<sup>5</sup> This ontology only recognizes one father and one mother for each person. A more complex ontology could recognize biological mother, birth mother, adoptive mother, etc.

are persons” are the bread and butter of first-order logic. We deal with the first of these in Section 8.3. The second rule, “All kings are persons,” is written in first-order logic as

$$\forall x \text{ King}(x) \Rightarrow \text{Person}(x).$$

The **universal quantifier**  $\forall$  is usually pronounced “For all . . .”. (Remember that the upside-down A stands for “all.”) Thus, the sentence says, “For all  $x$ , if  $x$  is a king, then  $x$  is a person.” The symbol  $x$  is called a **variable**. By convention, variables are lowercase letters. A variable is a term all by itself, and as such can also serve as the argument of a function—for example,  $\text{LeftLeg}(x)$ . A term with no variables is called a **ground term**.

Universal quantifier

Variable

Ground term

Intuitively, the sentence  $\forall x P$ , where  $P$  is any logical sentence, says that  $P$  is true for every object  $x$ . More precisely,  $\forall x P$  is true in a given model if  $P$  is true in all possible **extended interpretations** constructed from the interpretation given in the model, where each extended interpretation specifies a domain element to which  $x$  refers.

Extended interpretation

This sounds complicated, but it is really just a careful way of stating the intuitive meaning of universal quantification. Consider the model shown in Figure 8.2 and the intended interpretation that goes with it. We can extend the interpretation in five ways:

- $x \rightarrow$  Richard the Lionheart,
- $x \rightarrow$  King John,
- $x \rightarrow$  Richard’s left leg,
- $x \rightarrow$  John’s left leg,
- $x \rightarrow$  the crown.

The universally quantified sentence  $\forall x \text{ King}(x) \Rightarrow \text{Person}(x)$  is true in the original model if the sentence  $\text{King}(x) \Rightarrow \text{Person}(x)$  is true under each of the five extended interpretations. That is, the universally quantified sentence is equivalent to asserting the following five sentences:

- Richard the Lionheart is a king  $\Rightarrow$  Richard the Lionheart is a person.
- King John is a king  $\Rightarrow$  King John is a person.
- Richard’s left leg is a king  $\Rightarrow$  Richard’s left leg is a person.
- John’s left leg is a king  $\Rightarrow$  John’s left leg is a person.
- The crown is a king  $\Rightarrow$  the crown is a person.

Let us look carefully at this set of assertions. Since, in our model, King John is the only king, the second sentence asserts that he is a person, as we would hope. But what about the other four sentences, which appear to make claims about legs and crowns? Is that part of the meaning of “All kings are persons”? In fact, the other four assertions are true in the model, but make no claim whatsoever about the personhood qualifications of legs, crowns, or indeed Richard. This is because none of these objects is a king. Looking at the truth table for  $\Rightarrow$  (Figure 7.8 on page 237), we see that the implication is true whenever its premise is false—*regardless* of the truth of the conclusion. Thus, by asserting the universally quantified sentence, which is equivalent to asserting a whole list of individual implications, we end up asserting the conclusion of the rule just for those objects for which the premise is true and saying nothing at all about those objects for which the premise is false. Thus, the truth-table definition of  $\Rightarrow$  turns out to be perfect for writing general rules with universal quantifiers.

A common mistake, made frequently even by diligent readers who have read this paragraph several times, is to use conjunction instead of implication. The sentence

$$\forall x \text{ King}(x) \wedge \text{Person}(x)$$

would be equivalent to asserting

Richard the Lionheart is a king  $\wedge$  Richard the Lionheart is a person,  
 King John is a king  $\wedge$  King John is a person,  
 Richard's left leg is a king  $\wedge$  Richard's left leg is a person,

and so on. Obviously, this does not capture what we want.

**Existential quantifier**

Universal quantification makes statements about every object. Similarly, we can make a statement about *some* object without naming it, by using an **existential quantifier**. To say, for example, that King John has a crown on his head, we write

$$\exists x \ Crown(x) \wedge OnHead(x, John).$$

$\exists x$  is pronounced “There exists an  $x$  such that . . .” or “For some  $x$  . . .”.

Intuitively, the sentence  $\exists x P$  says that  $P$  is true for at least one object  $x$ . More precisely,  $\exists x P$  is true in a given model if  $P$  is true in *at least one* extended interpretation that assigns  $x$  to a domain element. That is, at least one of the following is true:

Richard the Lionheart is a crown  $\wedge$  Richard the Lionheart is on John's head;  
 King John is a crown  $\wedge$  King John is on John's head;  
 Richard's left leg is a crown  $\wedge$  Richard's left leg is on John's head;  
 John's left leg is a crown  $\wedge$  John's left leg is on John's head;  
 The crown is a crown  $\wedge$  the crown is on John's head.

The fifth assertion is true in the model, so the original existentially quantified sentence is true in the model. Notice that, by our definition, the sentence would also be true in a model in which King John was wearing two crowns. This is entirely consistent with the original sentence “King John has a crown on his head.”<sup>6</sup>

Just as  $\Rightarrow$  appears to be the natural connective to use with  $\forall$ ,  $\wedge$  is the natural connective to use with  $\exists$ . Using  $\wedge$  as the main connective with  $\forall$  led to an overly strong statement in the example in the previous section; using  $\Rightarrow$  with  $\exists$  usually leads to a very weak statement, indeed. Consider the following sentence:

$$\exists x \ Crown(x) \Rightarrow OnHead(x, John).$$

On the surface, this might look like a reasonable rendition of our sentence. Applying the semantics, we see that the sentence says that at least one of the following assertions is true:

Richard the Lionheart is a crown  $\Rightarrow$  Richard the Lionheart is on John's head;  
 King John is a crown  $\Rightarrow$  King John is on John's head;  
 Richard's left leg is a crown  $\Rightarrow$  Richard's left leg is on John's head;

and so on. An implication is true if both premise and conclusion are true, *or if its premise is false*; so if Richard the Lionheart is not a crown, then the first assertion is true and the existential is satisfied. So, an existentially quantified implication sentence is true whenever *any* object fails to satisfy the premise; hence such sentences really do not say much at all.

---

<sup>6</sup> There is a variant of the existential quantifier, usually written  $\exists^1$  or  $\exists!$ , that means “There exists exactly one.” The same meaning can be expressed using equality statements.

### Nested quantifiers

We will often want to express more complex sentences using multiple quantifiers. The simplest case is where the quantifiers are of the same type. For example, “Brothers are siblings” can be written as

$$\forall x \forall y \text{Brother}(x,y) \Rightarrow \text{Sibling}(x,y).$$

Consecutive quantifiers of the same type can be written as one quantifier with several variables. For example, to say that siblinghood is a symmetric relationship, we can write

$$\forall x, y \text{Sibling}(x,y) \Leftrightarrow \text{Sibling}(y,x).$$

In other cases we will have mixtures. “Everybody loves somebody” means that for every person, there is someone that person loves:

$$\forall x \exists y \text{Loves}(x,y).$$

On the other hand, to say “There is someone who is loved by everyone,” we write

$$\exists y \forall x \text{Loves}(x,y).$$

The order of quantification is therefore very important. It becomes clearer if we insert parentheses.  $\forall x (\exists y \text{Loves}(x,y))$  says that *everyone* has a particular property, namely, the property that they love someone. On the other hand,  $\exists y (\forall x \text{Loves}(x,y))$  says that *someone* in the world has a particular property, namely the property of being loved by everybody.

Some confusion can arise when two quantifiers are used with the same variable name. Consider the sentence

$$\forall x (\text{Crown}(x) \vee (\exists x \text{Brother}(\text{Richard},x))).$$

Here the  $x$  in  $\text{Brother}(\text{Richard},x)$  is *existentially* quantified. The rule is that the variable belongs to the innermost quantifier that mentions it; then it will not be subject to any other quantification. Another way to think of it is this:  $\exists x \text{Brother}(\text{Richard},x)$  is a sentence about Richard (that he has a brother), not about  $x$ ; so putting a  $\forall x$  outside it has no effect. It could equally well have been written  $\exists z \text{Brother}(\text{Richard},z)$ . Because this can be a source of confusion, we will always use different variable names with nested quantifiers.

### Connections between $\forall$ and $\exists$

The two quantifiers are actually intimately connected with each other, through negation. Asserting that everyone dislikes parsnips is the same as asserting there does not exist someone who likes them, and vice versa:

$$\forall x \neg \text{Likes}(x, \text{Parsnips}) \text{ is equivalent to } \neg \exists x \text{ Likes}(x, \text{Parsnips}).$$

We can go one step further: “Everyone likes ice cream” means that there is no one who does not like ice cream:

$$\forall x \text{ Likes}(x, \text{IceCream}) \text{ is equivalent to } \neg \exists x \neg \text{Likes}(x, \text{IceCream}).$$

Because  $\forall$  is really a conjunction over the universe of objects and  $\exists$  is a disjunction, it should not be surprising that they obey De Morgan’s rules. The De Morgan rules for quantified and unquantified sentences are as follows:

$$\begin{array}{ll} \neg \exists x P & \equiv \forall x \neg P \\ \neg \forall x P & \equiv \exists x \neg P \\ \forall x P & \equiv \neg \exists x \neg P \\ \exists x P & \equiv \neg \forall x \neg P \end{array} \quad \begin{array}{ll} \neg(P \vee Q) & \equiv \neg P \wedge \neg Q \\ \neg(P \wedge Q) & \equiv \neg P \vee \neg Q \\ P \wedge Q & \equiv \neg(\neg P \vee \neg Q) \\ P \vee Q & \equiv \neg(\neg P \wedge \neg Q). \end{array}$$

Thus, we do not really need both  $\forall$  and  $\exists$ , just as we do not really need both  $\wedge$  and  $\vee$ . Still, readability is more important than parsimony, so we will keep both of the quantifiers.

### 8.2.7 Equality

[Equality symbol](#)

First-order logic includes one more way to make atomic sentences, other than using a predicate and terms as described earlier. We can use the **equality symbol** to signify that two terms refer to the same object. For example,

$$\text{Father}(\text{John}) = \text{Henry}$$

says that the object referred to by *Father(John)* and the object referred to by *Henry* are the same. Because an interpretation fixes the referent of any term, determining the truth of an equality sentence is simply a matter of seeing that the referents of the two terms are the same object.

The equality symbol can be used to state facts about a given function, as we just did for the *Father* symbol. It can also be used with negation to insist that two terms are not the same object. To say that Richard has at least two brothers, we would write

$$\exists x, y \text{ Brother}(x, \text{Richard}) \wedge \text{Brother}(y, \text{Richard}) \wedge \neg(x = y).$$

The sentence

$$\exists x, y \text{ Brother}(x, \text{Richard}) \wedge \text{Brother}(y, \text{Richard})$$

does not have the intended meaning. In particular, it is true in the model of Figure 8.2, where Richard has only one brother. To see this, consider the extended interpretation in which both  $x$  and  $y$  are assigned to King John. The addition of  $\neg(x = y)$  rules out such models. The notation  $x \neq y$  is sometimes used as an abbreviation for  $\neg(x = y)$ .

### 8.2.8 Database semantics

Continuing the example from the previous section, suppose that we believe that Richard has two brothers, John and Geoffrey.<sup>7</sup> We could write

$$\text{Brother}(\text{John}, \text{Richard}) \wedge \text{Brother}(\text{Geoffrey}, \text{Richard}), \tag{8.3}$$

but that wouldn't completely capture the state of affairs. First, this assertion is true in a model where Richard has only one brother—we need to add  $\text{John} \neq \text{Geoffrey}$ . Second, the sentence doesn't rule out models in which Richard has many more brothers besides John and Geoffrey. Thus, the correct translation of “Richard's brothers are John and Geoffrey” is as follows:

$$\begin{aligned} &\text{Brother}(\text{John}, \text{Richard}) \wedge \text{Brother}(\text{Geoffrey}, \text{Richard}) \wedge \text{John} \neq \text{Geoffrey} \\ &\wedge \forall x \text{ Brother}(x, \text{Richard}) \Rightarrow (x = \text{John} \vee x = \text{Geoffrey}). \end{aligned}$$

This logical sentence seems much more cumbersome than the corresponding English sentence. But if we fail to translate the English properly, our logical reasoning system will make mistakes. Can we devise a semantics that allows a more straightforward logical sentence?

One proposal that is very popular in database systems works as follows. First, we insist that every constant symbol refer to a distinct object—the **unique-names assumption**. Second, we assume that atomic sentences not known to be true are in fact false—the **closed-world assumption**. Finally, we invoke **domain closure**, meaning that each model contains no more domain elements than those named by the constant symbols.

[Unique-names assumption](#)

[Closed-world assumption](#)

[Domain closure](#)

<sup>7</sup> Actually he had four, the others being William and Henry.

**Figure 8.5** Some members of the set of all models for a language with two constant symbols,  $R$  and  $J$ , and one binary relation symbol, under database semantics. The interpretation of the constant symbols is fixed, and there is a distinct object for each constant symbol.

Under the resulting semantics, Equation (8.3) does indeed state that Richard has exactly two brothers, John and Geoffrey. We call this **database semantics** to distinguish it from the standard semantics of first-order logic. Database semantics is also used in logic programming systems, as explained in Section 9.4.4.

It is instructive to consider the set of all possible models under database semantics for the same case as shown in Figure 8.4 (page 277). Figure 8.5 shows some of the models, ranging from the model with no tuples satisfying the relation to the model with all tuples satisfying the relation. With two objects, there are four possible two-element tuples, so there are  $2^4 = 16$  different subsets of tuples that can satisfy the relation. Thus, there are 16 possible models in all—a lot fewer than the infinitely many models for the standard first-order semantics. On the other hand, the database semantics requires definite knowledge of what the world contains.

This example brings up an important point: there is no one “correct” semantics for logic. The usefulness of any proposed semantics depends on how concise and intuitive it makes the expression of the kinds of knowledge we want to write down, and on how easy and natural it is to develop the corresponding rules of inference. Database semantics is most useful when we are certain about the identity of all the objects described in the knowledge base and when we have all the facts at hand; in other cases, it is quite awkward. For the rest of this chapter, we assume the standard semantics while noting instances in which this choice leads to cumbersome expressions.

## 8.3 Using First-Order Logic

Now that we have defined an expressive logical language, let’s learn how to use it. In this section, we provide example sentences in some simple **domains**. In knowledge representation, a domain is just some part of the world about which we wish to express some knowledge.

We begin with a brief description of the TELL/ASK interface for first-order knowledge bases. Then we look at the domains of family relationships, numbers, sets, and lists, and at the wumpus world. Section 8.4.2 contains a more substantial example (electronic circuits) and Chapter 10 covers everything in the universe.

### 8.3.1 Assertions and queries in first-order logic

Sentences are added to a knowledge base using TELL, exactly as in propositional logic. Such sentences are called **assertions**. For example, we can assert that John is a king, Richard is a

Database semantics

Domain

Assertion

person, and all kings are persons:

$$\begin{aligned} \text{TELL}(KB, \text{King}(John)). \\ \text{TELL}(KB, \text{Person}(Richard)). \\ \text{TELL}(KB, \forall x \text{ King}(x) \Rightarrow \text{Person}(x)). \end{aligned}$$

We can ask questions of the knowledge base using ASK. For example,

$$\text{ASK}(KB, \text{King}(John))$$

returns *true*. Questions asked with ASK are called **queries** or **goals**. Generally speaking, any query that is logically entailed by the knowledge base should be answered affirmatively. For example, given the three assertions above, the query

$$\text{ASK}(KB, \text{Person}(John))$$

should also return *true*. We can ask quantified queries, such as

$$\text{ASK}(KB, \exists x \text{ Person}(x)).$$

The answer is *true*, but this is perhaps not as helpful as we would like. It is rather like answering “Can you tell me the time?” with “Yes.” If we want to know what value of  $x$  makes the sentence true, we will need a different function, which we call ASKVARS,

$$\text{ASKVARS}(KB, \text{Person}(x))$$

Substitution  
Binding list

and which yields a stream of answers. In this case there will be two answers:  $\{x/John\}$  and  $\{x/Richard\}$ . Such an answer is called a **substitution** or **binding list**. ASKVARS is usually reserved for knowledge bases consisting solely of Horn clauses, because in such knowledge bases every way of making the query true will bind the variables to specific values. That is not the case with first-order logic; in a  $KB$  that has been told only that  $\text{King}(John) \vee \text{King}(Richard)$  there is no single binding to  $x$  that makes the query  $\exists x \text{ King}(x)$  true, even though the query is in fact true.

### 8.3.2 The kinship domain

The first example we consider is the domain of family relationships, or kinship. This domain includes facts such as “Elizabeth is the mother of Charles” and “Charles is the father of William” and rules such as “One’s grandmother is the mother of one’s parent.”

Clearly, the objects in our domain are people. Unary predicates include *Male* and *Female*, among others. Kinship relations—parenthood, brotherhood, marriage, and so on—are represented by binary predicates: *Parent*, *Sibling*, *Brother*, *Sister*, *Child*, *Daughter*, *Son*, *Spouse*, *Wife*, *Husband*, *Grandparent*, *Grandchild*, *Cousin*, *Aunt*, and *Uncle*. We use functions for *Mother* and *Father*, because every person has exactly one of each of these, biologically (although we could introduce additional functions for adoptive mothers, surrogate mothers, etc.).

We can go through each function and predicate, writing down what we know in terms of the other symbols. For example, one’s mother is one’s parent who is female:

$$\forall m, c \text{ Mother}(c) = m \Leftrightarrow \text{Female}(m) \wedge \text{Parent}(m, c).$$

One’s husband is one’s male spouse:

$$\forall w, h \text{ Husband}(h, w) \Leftrightarrow \text{Male}(h) \wedge \text{Spouse}(h, w).$$

Parent and child are inverse relations:

$$\forall p, c \text{ Parent}(p, c) \Leftrightarrow \text{Child}(c, p).$$

A grandparent is a parent of one's parent:

$$\forall g, c \text{ Grandparent}(g, c) \Leftrightarrow \exists p \text{ Parent}(g, p) \wedge \text{Parent}(p, c).$$

A sibling is another child of one's parent:

$$\forall x, y \text{ Sibling}(x, y) \Leftrightarrow x \neq y \wedge \exists p \text{ Parent}(p, x) \wedge \text{Parent}(p, y).$$

We could go on for several more pages like this, and Exercise 8.KINS asks you to do just that.

Each of these sentences can be viewed as an **axiom** of the kinship domain, as explained in Section 7.1. Axioms are commonly associated with purely mathematical domains—we will see some axioms for numbers shortly—but they are needed in all domains. They provide the basic factual information from which useful conclusions can be derived. Our kinship axioms are also **definitions**; they have the form  $\forall x, y P(x, y) \Leftrightarrow \dots$ . The axioms define the *Mother* function and the *Husband*, *Male*, *Parent*, *Grandparent*, and *Sibling* predicates in terms of other predicates. Our definitions “bottom out” at a basic set of predicates (*Child*, *Female*, etc.) in terms of which the others are ultimately defined. Definition

This is a natural way in which to build up the representation of a domain, and it is analogous to the way in which software packages are built up by successive definitions of subroutines from primitive library functions. Notice that there is not necessarily a unique set of primitive predicates; we could equally well have used *Parent* instead of *Child*. In some domains, as we show, there is no clearly identifiable basic set.

Not all logical sentences about a domain are axioms. Some are **theorems**—that is, they are entailed by the axioms. For example, consider the assertion that siblinghood is symmetric: Theorem

$$\forall x, y \text{ Sibling}(x, y) \Leftrightarrow \text{Sibling}(y, x).$$

Is this an axiom or a theorem? In fact, it is a theorem that follows logically from the axiom that defines siblinghood. If we ASK the knowledge base this sentence, it should return *true*.

From a purely logical point of view, a knowledge base need contain only axioms and no theorems, because the theorems do not increase the set of conclusions that follow from the knowledge base. From a practical point of view, theorems are essential to reduce the computational cost of deriving new sentences. Without them, a reasoning system has to start from first principles every time, rather like a physicist having to rederive the rules of calculus for every new problem.

Not all axioms are definitions. Some provide more general information about certain predicates without constituting a definition. Indeed, some predicates have no complete definition because we do not know enough to characterize them fully. For example, there is no obvious definitive way to complete the sentence

$$\forall x \text{ Person}(x) \Leftrightarrow \dots$$

Fortunately, first-order logic allows us to make use of the *Person* predicate without completely defining it. Instead, we can write partial specifications of properties that every person has and properties that make something a person:

$$\forall x \text{ Person}(x) \Rightarrow \dots$$

$$\forall x \dots \Rightarrow \text{Person}(x).$$

Axioms can also be “just plain facts,” such as *Male(Jim)* and *Spouse(Jim, Laura)*. Such facts form the descriptions of specific problem instances, enabling specific questions to be

answered. If all goes well, the answers to these questions will then be theorems that follow from the axioms.

Often, one finds that the expected answers are not forthcoming—for example, from  $\text{Spouse}(\text{Jim}, \text{Laura})$  one expects (under the laws of many countries) to be able to infer that  $\neg\text{Spouse}(\text{George}, \text{Laura})$ ; but this does not follow from the axioms given earlier—even after we add  $\text{Jim} \neq \text{George}$  as suggested in Section 8.2.8. This is a sign that an axiom is missing. Exercise 8.HILL asks the reader to supply it.

### 8.3.3 Numbers, sets, and lists

Natural numbers

Peano axioms

Numbers are perhaps the most vivid example of how a large theory can be built up from a tiny kernel of axioms. We describe here the theory of **natural numbers** or nonnegative integers. We need a predicate  $\text{NatNum}$  that will be true of natural numbers; we need one constant symbol, 0; and we need one function symbol,  $S$  (successor). The **Peano axioms** define natural numbers and addition.<sup>8</sup> Natural numbers are defined recursively:

$$\begin{aligned} &\text{NatNum}(0). \\ &\forall n \text{ NatNum}(n) \Rightarrow \text{NatNum}(S(n)). \end{aligned}$$

That is, 0 is a natural number, and for every object  $n$ , if  $n$  is a natural number, then  $S(n)$  is a natural number. So the natural numbers are 0,  $S(0)$ ,  $S(S(0))$ , and so on. We also need axioms to constrain the successor function:

$$\begin{aligned} &\forall n \ 0 \neq S(n). \\ &\forall m, n \ m \neq n \Rightarrow S(m) \neq S(n). \end{aligned}$$

Now we can define addition in terms of the successor function:

$$\begin{aligned} &\forall m \text{ NatNum}(m) \Rightarrow + (0, m) = m. \\ &\forall m, n \text{ NatNum}(m) \wedge \text{NatNum}(n) \Rightarrow + (S(m), n) = S(+ (m, n)). \end{aligned}$$

The first of these axioms says that adding 0 to any natural number  $m$  gives  $m$  itself. Notice the use of the binary function symbol “+” in the term  $+(m, 0)$ ; in ordinary mathematics, the term would be written  $m + 0$  using **infix** notation. (The notation we have used for first-order logic is called **prefix**.) To make our sentences about numbers easier to read, we allow the use of infix notation. We can also write  $S(n)$  as  $n + 1$ , so the second axiom becomes

$$\forall m, n \text{ NatNum}(m) \wedge \text{NatNum}(n) \Rightarrow (m + 1) + n = (m + n) + 1.$$

This axiom reduces addition to repeated application of the successor function.

Infix

Prefix

Syntactic sugar

The use of infix notation is an example of **syntactic sugar**, that is, an extension to or abbreviation of the standard syntax that does not change the semantics. Any sentence that uses sugar can be “desugared” to produce an equivalent sentence in ordinary first-order logic. Another example is using square brackets rather than parentheses to make it easier to see what left bracket matches with what right bracket. Yet another example is collapsing quantifiers: replacing  $\forall x \ \forall y \ P(x, y)$  with  $\forall x, y \ P(x, y)$ .

Once we have addition, it is straightforward to define multiplication as repeated addition, exponentiation as repeated multiplication, integer division and remainders, prime numbers, and so on. Thus, the whole of number theory (including cryptography) can be built up from one constant, one function, one predicate and four axioms.

<sup>8</sup> The Peano axioms also include the principle of induction, which is a sentence of second-order logic rather than of first-order logic. The importance of this distinction is explained in Chapter 9.

The domain of **sets** is also fundamental to mathematics as well as to commonsense reasoning. (In fact, it is possible to define number theory in terms of set theory.) We want to be able to represent individual sets, including the empty set. We need a way to build up sets from elements or from operations on other sets. We will want to know whether an element is a member of a set and we will want to distinguish sets from objects that are not sets.

We will use the normal vocabulary of set theory as syntactic sugar. The empty set is a constant written as  $\{\}$ . There is one unary predicate, *Set*, which is true of sets. The binary predicates are  $x \in s$  ( $x$  is a member of set  $s$ ) and  $s_1 \subseteq s_2$  (set  $s_1$  is a subset of  $s_2$ , possibly equal to  $s_2$ ). The binary functions are  $s_1 \cap s_2$  (intersection),  $s_1 \cup s_2$  (union), and  $Add(x, s)$  (the set resulting from adding element  $x$  to set  $s$ ). One possible set of axioms is as follows:

1. The only sets are the empty set and those made by adding something to a set:

$$\forall s \ Set(s) \Leftrightarrow (s = \{\}) \vee (\exists x, s_2 \ Set(s_2) \wedge s = Add(x, s_2)).$$

2. The empty set has no elements added into it. In other words, there is no way to decompose  $\{\}$  into a smaller set and an element:

$$\neg \exists x, s \ Add(x, s) = \{\}.$$

3. Adding an element already in the set has no effect:

$$\forall x, s \ x \in s \Leftrightarrow s = Add(x, s).$$

4. The only members of a set are the elements that were added into it. We express this recursively, saying that  $x$  is a member of  $s$  if and only if  $s$  is equal to some element  $y$  added to some set  $s_2$ , where either  $y$  is the same as  $x$  or  $x$  is a member of  $s_2$ :

$$\forall x, s \ x \in s \Leftrightarrow \exists y, s_2 \ (s = Add(y, s_2) \wedge (x = y \vee x \in s_2)).$$

5. A set is a subset of another set if and only if all of the first set's members are members of the second set:

$$\forall s_1, s_2 \ s_1 \subseteq s_2 \Leftrightarrow (\forall x \ x \in s_1 \Rightarrow x \in s_2).$$

6. Two sets are equal if and only if each is a subset of the other:

$$\forall s_1, s_2 \ (s_1 = s_2) \Leftrightarrow (s_1 \subseteq s_2 \wedge s_2 \subseteq s_1).$$

7. An object is in the intersection of two sets if and only if it is a member of both sets:

$$\forall x, s_1, s_2 \ x \in (s_1 \cap s_2) \Leftrightarrow (x \in s_1 \wedge x \in s_2).$$

8. An object is in the union of two sets if and only if it is a member of either set:

$$\forall x, s_1, s_2 \ x \in (s_1 \cup s_2) \Leftrightarrow (x \in s_1 \vee x \in s_2).$$

**Lists** are similar to sets. The differences are that lists are ordered and the same element can appear more than once in a list. We can use the vocabulary of Lisp for lists: *Nil* is the constant list with no elements; *Cons*, *Append*, *First*, and *Rest* are functions; and *Find* is the predicate that does for lists what *Member* does for sets. *List* is a predicate that is true only of lists. As with sets, it is common to use syntactic sugar in logical sentences involving lists. The empty list is  $[]$ . The term *Cons*( $x$ , *Nil*) (i.e., the list containing the element  $x$  followed by nothing) is written as  $[x]$ . A list of several elements, such as  $[A, B, C]$ , corresponds to the nested term *Cons*( $A$ , *Cons*( $B$ , *Cons*( $C$ , *Nil*))). Exercise 8.LIST asks you to write out the axioms for lists.

### 8.3.4 The wumpus world

Some propositional logic axioms for the wumpus world were given in Chapter 7. The first-order axioms in this section are much more concise, capturing in a natural way exactly what we want to say.

Recall that the wumpus agent receives a percept vector with five elements. The corresponding first-order sentence stored in the knowledge base must include both the percept and the time at which it occurred; otherwise, the agent will get confused about when it saw what. We use integers for time steps. A typical percept sentence would be

$$\text{Percept}([Stench, Breeze, Glitter, None, None], 5).$$

Here, *Percept* is a binary predicate, and *Stench* and so on are constants placed in a list. The actions in the wumpus world can be represented by logical terms:

$$\text{Turn}(Right), \text{ Turn}(Left), \text{ Forward}, \text{ Shoot}, \text{ Grab}, \text{ Climb}.$$

To determine which is best, the agent program executes the query

$$\text{ASKVARS}(KB, \text{BestAction}(a, 5)),$$

which returns a binding list such as  $\{a/\text{Grab}\}$ . The agent program can then return *Grab* as the action to take. The raw percept data implies certain facts about the current state. For example:

$$\begin{aligned} \forall t, s, g, w, c \text{ Percept}([s, Breeze, g, w, c], t) &\Rightarrow Breeze(t) \\ \forall t, s, g, w, c \text{ Percept}([s, None, g, w, c], t) &\Rightarrow \neg Breeze(t) \\ \forall t, s, b, w, c \text{ Percept}([s, b, Glitter, w, c], t) &\Rightarrow Glitter(t) \\ \forall t, s, b, w, c \text{ Percept}([s, b, None, w, c], t) &\Rightarrow \neg Glitter(t) \end{aligned}$$

and so on. These rules exhibit a trivial form of the reasoning process called **perception**, which we study in depth in Chapter 27. Notice the quantification over time  $t$ . In propositional logic, we would need copies of each sentence for each time step.

Simple “reflex” behavior can also be implemented by quantified implication sentences. For example, we have

$$\forall t \text{ Glitter}(t) \Rightarrow \text{BestAction}(Grab, t).$$

Given the percept and rules from the preceding paragraphs, this would yield the desired conclusion *BestAction(Grab, 5)*—that is, *Grab* is the right thing to do.

We have represented the agent’s inputs and outputs; now it is time to represent the environment itself. Let us begin with objects. Obvious candidates are squares, pits, and the wumpus. We could name each square—*Square*<sub>1,2</sub> and so on—but then the fact that *Square*<sub>1,2</sub> and *Square*<sub>1,3</sub> are adjacent would have to be an “extra” fact, and we would need one such fact for each pair of squares. It is better to use a complex term in which the row and column appear as integers; for example, we can simply use the list term [1, 2]. Adjacency of any two squares can be defined as

$$\begin{aligned} \forall x, y, a, b \text{ Adjacent}([x, y], [a, b]) &\Leftrightarrow \\ (x = a \wedge (y = b - 1 \vee y = b + 1)) \vee (y = b \wedge (x = a - 1 \vee x = a + 1)). \end{aligned}$$

We could name each pit, but this would be inappropriate for a different reason: there is no

reason to distinguish among pits.<sup>9</sup> It is simpler to use a unary predicate *Pit* that is true of squares containing pits. Finally, since there is exactly one wumpus, a constant *Wumpus* is just as good as a unary predicate (and perhaps more dignified from the wumpus's viewpoint).

The agent's location changes over time, so we write  $At(Agent, s, t)$  to mean that the agent is at square  $s$  at time  $t$ . We can fix the wumpus to a specific location forever with  $\forall t At(Wumpus, [1, 3], t)$ . We can then say that objects can be at only one location at a time:

$$\forall x, s_1, s_2, t \ At(x, s_1, t) \wedge At(x, s_2, t) \Rightarrow s_1 = s_2.$$

Given its current location, the agent can infer properties of the square from properties of its current percept. For example, if the agent is at a square and perceives a breeze, then that square is breezy:

$$\forall s, t \ At(Agent, s, t) \wedge Breeze(t) \Rightarrow Breezy(s).$$

It is useful to know that a *square* is breezy because we know that the pits cannot move about. Notice that *Breezy* has no time argument.

Having discovered which places are breezy (or smelly) and, very importantly, *not* breezy (or *not* smelly), the agent can deduce where the pits are (and where the wumpus is). Whereas propositional logic necessitates a separate axiom for each square (see  $R_2$  and  $R_3$  on page 238) and would need a different set of axioms for each geographical layout of the world, first-order logic just needs one axiom:

$$\forall s \ Breezy(s) \Leftrightarrow \exists r \ Adjacent(r, s) \wedge Pit(r). \quad (8.4)$$

Similarly, in first-order logic we can quantify over time, so we need just one successor-state axiom for each predicate, rather than a different copy for each time step. For example, the axiom for the arrow (Equation (7.2) on page 258) becomes

$$\forall t \ HaveArrow(t + 1) \Leftrightarrow (HaveArrow(t) \wedge \neg Action(Shoot, t)).$$

From these two example sentences, we can see that the first-order logic formulation is no less concise than the original English-language description given in Chapter 7. The reader is invited to construct analogous axioms for the agent's location and orientation; in these cases, the axioms quantify over both space and time. As in the case of propositional state estimation, an agent can use logical inference with axioms of this kind to keep track of aspects of the world that are not directly observed. Chapter 11 goes into more depth on the subject of first-order successor-state axioms and their uses for constructing plans.

## 8.4 Knowledge Engineering in First-Order Logic

The preceding section illustrated the use of first-order logic to represent knowledge in three simple domains. This section describes the general process of knowledge-base construction—a process called **knowledge engineering**. A knowledge engineer is someone who investigates a particular domain, learns what concepts are important in that domain, and creates a formal representation of the objects and relations in the domain. We illustrate the knowledge engineering process in an electronic circuit domain. The approach we take is suitable for developing *special-purpose* knowledge bases whose domain is carefully circumscribed and

Knowledge  
engineering

<sup>9</sup> Similarly, most of us do not name each bird that flies overhead as it migrates to warmer regions in winter. An ornithologist wishing to study migration patterns, survival rates, and so on *does* name each bird, by means of a ring on its leg, because individual birds must be tracked.

whose range of queries is known in advance. *General-purpose* knowledge bases, which cover a broad range of human knowledge and are intended to support tasks such as natural language understanding, are discussed in Chapter 10.

### 8.4.1 The knowledge engineering process

Knowledge engineering projects vary widely in content, scope, and difficulty, but all such projects include the following steps:

1. *Identify the questions.* The knowledge engineer must delineate the range of questions that the knowledge base will support and the kinds of facts that will be available for each specific problem instance. For example, does the wumpus knowledge base need to be able to choose actions, or is it required only to answer questions about the contents of the environment? Will the sensor facts include the current location? The task will determine what knowledge must be represented in order to connect problem instances to answers. This step is analogous to the PEAS process for designing agents in Chapter 2.
2. *Assemble the relevant knowledge.* The knowledge engineer might already be an expert in the domain, or might need to work with real experts to extract what they know—a process called **knowledge acquisition**. At this stage, the knowledge is not represented formally. The idea is to understand the scope of the knowledge base, as determined by the task, and to understand how the domain actually works.

For the wumpus world, which is defined by an artificial set of rules, the relevant knowledge is easy to identify. (Notice, however, that the definition of adjacency was not supplied explicitly in the wumpus-world rules.) For real domains, the issue of relevance can be quite difficult—for example, a system for simulating VLSI designs might or might not need to take into account stray capacitances and skin effects.

3. *Decide on a vocabulary of predicates, functions, and constants.* That is, translate the important domain-level concepts into logic-level names. This involves many questions of knowledge-engineering *style*. Like programming style, this can have a significant impact on the eventual success of the project. For example, should pits be represented by objects or by a unary predicate on squares? Should the agent's orientation be a function or a predicate? Should the wumpus's location depend on time? Once the choices have been made, the result is a vocabulary that is known as the **ontology** of the domain. The word *ontology* means a particular theory of the nature of being or existence. The ontology determines what kinds of things exist, but does not determine their specific properties and interrelationships.
4. *Encode general knowledge about the domain.* The knowledge engineer writes down the axioms for all the vocabulary terms. This pins down (to the extent possible) the meaning of the terms, enabling the expert to check the content. Often, this step reveals misconceptions or gaps in the vocabulary that must be fixed by returning to step 3 and iterating through the process.
5. *Encode a description of the problem instance.* If the ontology is well thought out, this step is easy. It involves writing simple atomic sentences about instances of concepts that are already part of the ontology. For a logical agent, problem instances are supplied by the sensors, whereas a “disembodied” knowledge base is given sentences in the same way that traditional programs are given input data.

Knowledge  
acquisition

Ontology

6. *Pose queries to the inference procedure and get answers.* This is where the reward is: we can let the inference procedure operate on the axioms and problem-specific facts to derive the facts we are interested in knowing. Thus, we avoid the need for writing an application-specific solution algorithm.
7. *Debug and evaluate the knowledge base.* Alas, the answers to queries will seldom be correct on the first try. More precisely, the answers will be correct *for the knowledge base as written*, assuming that the inference procedure is sound, but they will not be the ones that the user is expecting. For example, if an axiom is missing, some queries will not be answerable from the knowledge base. A considerable debugging process could ensue. Missing axioms or axioms that are too weak can be easily identified by noticing places where the chain of reasoning stops unexpectedly. For example, if the knowledge base includes a diagnostic rule (see Exercise 8.WUMD) for finding the wumpus,

$$\forall s \text{ Smelly}(s) \Rightarrow \text{Adjacent}(\text{Home}(\text{Wumpus}), s),$$

instead of the biconditional, then the agent will never be able to prove the *absence* of wumpuses. Incorrect axioms can be identified because they are false statements about the world. For example, the sentence

$$\forall x \text{ NumOfLegs}(x, 4) \Rightarrow \text{Mammal}(x)$$

is false for reptiles, amphibians, and tables. *The falsehood of this sentence can be determined independently of the rest of the knowledge base.* In contrast, a typical error in a program looks like this:

```
offset = position + 1.
```

It is impossible to tell whether `offset` should be `position` or `position + 1` without understanding the surrounding context.

When you get to the point where there are no obvious errors in your knowledge base, it is tempting to declare success. But unless there are obviously no errors, it is better to formally evaluate your system by running it on a test suite of queries and measuring how many you get right. Without objective measurement, it is too easy to convince yourself that the job is done. To understand this seven-step process better, we now apply it to an extended example—the domain of electronic circuits.

### 8.4.2 The electronic circuits domain

We will develop an ontology and knowledge base that allow us to reason about digital circuits of the kind shown in Figure 8.6. We follow the seven-step process for knowledge engineering.

#### Identify the questions

There are many reasoning tasks associated with digital circuits. At the highest level, one analyzes the circuit's functionality. For example, does the circuit in Figure 8.6 actually add properly? If all the inputs are high, what is the output of gate A2? Questions about the circuit's structure are also interesting. For example, what are all the gates connected to the first input terminal? Does the circuit contain feedback loops? These will be our tasks in this section. There are more detailed levels of analysis, including those related to timing delays, circuit area, power consumption, production cost, and so on. Each of these levels would require additional knowledge.

### Assemble the relevant knowledge

What do we know about digital circuits? For our purposes, they are composed of wires and gates. Signals flow along wires to the input terminals of gates, and each gate produces a signal on the output terminal that flows along another wire. To determine what these signals will be, we need to know how the gates transform their input signals. There are four types of gates: AND, OR, and XOR gates have two input terminals, and NOT gates have one. All gates have one output terminal. Circuits, like gates, have input and output terminals.

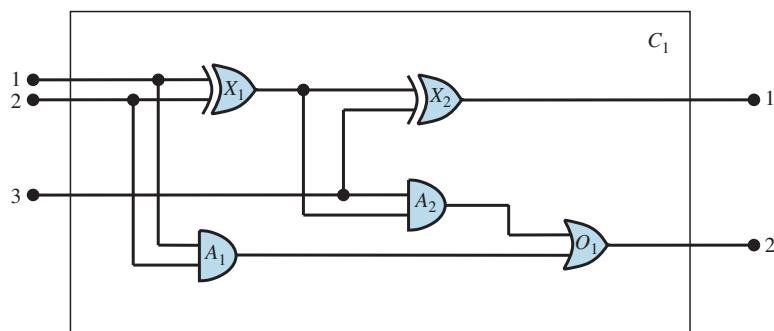

To reason about functionality and connectivity, we do not need to talk about the wires themselves, the paths they take, or the junctions where they come together. All that matters is the connections between terminals—we can say that one output terminal is connected to another input terminal without having to say what actually connects them. Other factors such as the size, shape, color, or cost of the various components are irrelevant to our analysis.

If our purpose were something other than verifying designs at the gate level, the ontology would be different. For example, if we were interested in debugging faulty circuits, then it would probably be a good idea to include the wires in the ontology, because a faulty wire can corrupt the signal flowing along it. For resolving timing faults, we would need to include gate delays. If we were interested in designing a product that would be profitable, then the cost of the circuit and its speed relative to other products on the market would be important.

### Decide on a vocabulary

We now know that we want to talk about circuits, terminals, signals, and gates. The next step is to choose functions, predicates, and constants to represent them. First, we need to be able to distinguish gates from each other and from other objects. Each gate is represented as an object named by a constant, about which we assert that it is a gate with, say,  $\text{Gate}(X_1)$ . The behavior of each gate is determined by its type: one of the constants  $\text{AND}$ ,  $\text{OR}$ ,  $\text{XOR}$ , or  $\text{NOT}$ . Because a gate has exactly one type, a function is appropriate:  $\text{Type}(X_1) = \text{XOR}$ . Circuits, like gates, are identified by a predicate:  $\text{Circuit}(C_1)$ .

Next we consider terminals, which are identified by the predicate  $\text{Terminal}(x)$ . A circuit can have one or more input terminals and one or more output terminals. We use the function

**Figure 8.6** A digital circuit  $C_1$ , purporting to be a one-bit full adder. The first two inputs are the two bits to be added, and the third input is a carry bit. The first output is the sum, and the second output is a carry bit for the next adder. The circuit contains two XOR gates, two AND gates, and one OR gate.

$In(1, X_1)$  to denote the first input terminal for circuit  $X_1$ . A similar function  $Out(n, c)$  is used for output terminals. The predicate  $Arity(c, i, j)$  says that circuit  $c$  has  $i$  input and  $j$  output terminals. The connectivity between gates can be represented by a predicate,  $Connected$ , which takes two terminals as arguments, as in  $Connected(Out(1, X_1), In(1, X_2))$ .

Finally, we need to know whether a signal is on or off. One possibility is to use a unary predicate,  $On(t)$ , which is true when the signal at a terminal is on. This makes it a little difficult, however, to pose questions such as “What are all the possible values of the signals at the output terminals of circuit  $C_1$ ?” We therefore introduce as objects two signal values, 1 and 0, representing “on” and “off” respectively, and a function  $Signal(t)$  that denotes the signal value for the terminal  $t$ .

### Encode general knowledge of the domain

One sign that we have a good ontology is that we require only a few general rules, which can be stated clearly and concisely. These are all the axioms we will need:

1. If two terminals are connected, then they have the same signal:

$$\forall t_1, t_2 \ Terminal(t_1) \wedge Terminal(t_2) \wedge Connected(t_1, t_2) \Rightarrow \\ Signal(t_1) = Signal(t_2).$$

2. The signal at every terminal is either 1 or 0:

$$\forall t \ Terminal(t) \Rightarrow Signal(t) = 1 \vee Signal(t) = 0.$$

3.  $Connected$  is commutative:

$$\forall t_1, t_2 \ Connected(t_1, t_2) \Leftrightarrow Connected(t_2, t_1).$$

4. There are four types of gates:

$$\forall g \ Gate(g) \wedge k = Type(g) \Rightarrow k = AND \vee k = OR \vee k = XOR \vee k = NOT.$$

5. An AND gate’s output is 0 if and only if any of its inputs is 0:

$$\forall g \ Gate(g) \wedge Type(g) = AND \Rightarrow \\ Signal(Out(1, g)) = 0 \Leftrightarrow \exists n \ Signal(In(n, g)) = 0.$$

6. An OR gate’s output is 1 if and only if any of its inputs is 1:

$$\forall g \ Gate(g) \wedge Type(g) = OR \Rightarrow \\ Signal(Out(1, g)) = 1 \Leftrightarrow \exists n \ Signal(In(n, g)) = 1.$$

7. An XOR gate’s output is 1 if and only if its inputs are different:

$$\forall g \ Gate(g) \wedge Type(g) = XOR \Rightarrow \\ Signal(Out(1, g)) = 1 \Leftrightarrow Signal(In(1, g)) \neq Signal(In(2, g)).$$

8. A NOT gate’s output is different from its input:

$$\forall g \ Gate(g) \wedge Type(g) = NOT \Rightarrow \\ Signal(Out(1, g)) \neq Signal(In(1, g)).$$

9. The gates (except for NOT) have two inputs and one output.

$$\forall g \ Gate(g) \wedge Type(g) = NOT \Rightarrow Arity(g, 1, 1). \\ \forall g \ Gate(g) \wedge k = Type(g) \wedge (k = AND \vee k = OR \vee k = XOR) \Rightarrow \\ Arity(g, 2, 1)$$

10. A circuit has terminals, up to its input and output arity, and nothing beyond its arity:

$$\forall c, i, j \ Circuit(c) \wedge Arity(c, i, j) \Rightarrow \\ \forall n \ (n \leq i \Rightarrow Terminal(In(n, c))) \wedge (n > i \Rightarrow In(n, c) = Nothing) \wedge \\ \forall n \ (n \leq j \Rightarrow Terminal(Out(n, c))) \wedge (n > j \Rightarrow Out(n, c) = Nothing)$$

11. Gates, terminals, and signals are all distinct.

$$\forall g, t, s \text{ } Gate(g) \wedge Terminal(t) \wedge Signal(s) \Rightarrow \\ g \neq t \wedge g \neq s \wedge t \neq s.$$

12. Gates are circuits.

$$\forall g \text{ } Gate(g) \Rightarrow Circuit(g)$$

### Encode the specific problem instance

The circuit shown in Figure 8.6 is encoded as circuit  $C_1$  with the following description. First we categorize the circuit and its component gates:

$$\begin{aligned} & Circuit(C_1) \wedge Arity(C_1, 3, 2) \\ & Gate(X_1) \wedge Type(X_1) = XOR \\ & Gate(X_2) \wedge Type(X_2) = XOR \\ & Gate(A_1) \wedge Type(A_1) = AND \\ & Gate(A_2) \wedge Type(A_2) = AND \\ & Gate(O_1) \wedge Type(O_1) = OR. \end{aligned}$$

Then we show the connections between them:

$$\begin{aligned} & Connected(Out(1, X_1), In(1, X_2)) \quad Connected(In(1, C_1), In(1, X_1)) \\ & Connected(Out(1, X_1), In(2, A_2)) \quad Connected(In(1, C_1), In(1, A_1)) \\ & Connected(Out(1, A_2), In(1, O_1)) \quad Connected(In(2, C_1), In(2, X_1)) \\ & Connected(Out(1, A_1), In(2, O_1)) \quad Connected(In(2, C_1), In(2, A_1)) \\ & Connected(Out(1, X_2), Out(1, C_1)) \quad Connected(In(3, C_1), In(2, X_2)) \\ & Connected(Out(1, O_1), Out(2, C_1)) \quad Connected(In(3, C_1), In(1, A_2)). \end{aligned}$$

### Pose queries to the inference procedure

What combinations of inputs would cause the first output of  $C_1$  (the sum bit) to be 0 and the second output of  $C_1$  (the carry bit) to be 1?

$$\begin{aligned} \exists i_1, i_2, i_3 \text{ } Signal(In(1, C_1)) = i_1 \wedge Signal(In(2, C_1)) = i_2 \wedge Signal(In(3, C_1)) = i_3 \\ \wedge Signal(Out(1, C_1)) = 0 \wedge Signal(Out(2, C_1)) = 1. \end{aligned}$$

The answers are substitutions for the variables  $i_1$ ,  $i_2$ , and  $i_3$  such that the resulting sentence is entailed by the knowledge base. ASK VARS will give us three such substitutions:

$$\{i_1/1, i_2/1, i_3/0\} \quad \{i_1/1, i_2/0, i_3/1\} \quad \{i_1/0, i_2/1, i_3/1\}.$$

What are the possible sets of values of all the terminals for the adder circuit?

$$\begin{aligned} \exists i_1, i_2, i_3, o_1, o_2 \text{ } Signal(In(1, C_1)) = i_1 \wedge Signal(In(2, C_1)) = i_2 \\ \wedge Signal(In(3, C_1)) = i_3 \wedge Signal(Out(1, C_1)) = o_1 \wedge Signal(Out(2, C_1)) = o_2. \end{aligned}$$

This final query will return a complete input–output table for the device, which can be used to check that it does in fact add its inputs correctly. This is a simple example of **circuit verification**. We can also use the definition of the circuit to build larger digital systems, for which the same kind of verification procedure can be carried out. (See Exercise 8.ADDR.) Many domains are amenable to the same kind of structured knowledge-base development, in which more complex concepts are defined on top of simpler concepts.

## Debug the knowledge base

We can perturb the knowledge base in various ways to see what kinds of erroneous behaviors emerge. For example, suppose we fail to read Section 8.2.8 and hence forget to assert that  $1 \neq 0$ . Suppose we find that the system is unable to prove any outputs for the circuit, except for the input cases 000 and 110. We can pinpoint the problem by asking for the outputs of each gate. For example, we can ask

$$\exists i_1, i_2, o \ Signal(In(1, C_1)) = i_1 \wedge Signal(In(2, C_1)) = i_2 \wedge Signal(Out(1, X_1)) = o,$$

which reveals that no outputs are known at  $X_1$  for the input cases 10 and 01. Then, we look at the axiom for XOR gates, as applied to  $X_1$ :

$$Signal(Out(1, X_1)) = 1 \Leftrightarrow Signal(In(1, X_1)) \neq Signal(In(2, X_1)).$$

If the inputs are known to be, say, 1 and 0, then this reduces to

$$Signal(Out(1, X_1)) = 1 \Leftrightarrow 1 \neq 0.$$

Now the problem is apparent: the system is unable to infer that  $Signal(Out(1, X_1)) = 1$ , so we need to tell it that  $1 \neq 0$ .

## Summary

---

This chapter has introduced **first-order logic**, a representation language that is far more powerful than propositional logic. The important points are as follows:

- Knowledge representation languages should be declarative, compositional, expressive, context independent, and unambiguous.
- Logics differ in their **ontological commitments** and **epistemological commitments**. While propositional logic commits only to the existence of facts, first-order logic commits to the existence of objects and relations and thereby gains expressive power, appropriate for domains such as the wumpus world and electronic circuits.
- Both propositional logic and first-order logic share a difficulty in representing vague propositions. This difficulty limits their applicability in domains that require personal judgments, like politics or cuisine.
- The syntax of first-order logic builds on that of propositional logic. It adds terms to represent objects, and has universal and existential quantifiers to construct assertions about all or some of the possible values of the quantified variables.
- A **possible world**, or **model**, for first-order logic includes a set of objects and an **interpretation** that maps constant symbols to objects, predicate symbols to relations among objects, and function symbols to functions on objects.
- An atomic sentence is true only when the relation named by the predicate holds between the objects named by the terms. **Extended interpretations**, which map quantifier variables to objects in the model, define the truth of quantified sentences.
- Developing a knowledge base in first-order logic requires a careful process of analyzing the domain, choosing a vocabulary, and encoding the axioms required to support the desired inferences.

## Bibliographical and Historical Notes

---

Although Aristotle's logic dealt with generalizations over objects, it fell far short of the expressive power of first-order logic. A major barrier to its further development was its concentration on one-place predicates to the exclusion of many-place relational predicates. The first systematic treatment of relations was given by Augustus De Morgan (1864), who cited the following example to show the sorts of inferences that Aristotle's logic could not handle: "All horses are animals; therefore, the head of a horse is the head of an animal." This inference is inaccessible to Aristotle because any valid rule that can support this inference must first analyze the sentence using the two-place predicate " $x$  is the head of  $y$ ." The logic of relations was studied in depth by Charles Sanders Peirce (Peirce, 1870; Misak, 2004).

True first-order logic dates from the introduction of quantifiers in Gottlob Frege's (1879) *Begriffschrift* ("Concept Writing" or "Conceptual Notation"). Peirce (1883) also developed first-order logic independently of Frege, although slightly later. Frege's ability to nest quantifiers was a big step forward, but he used an awkward notation. The present notation for first-order logic is due substantially to Giuseppe Peano (1889), but the semantics is virtually identical to Frege's. Oddly enough, Peano's axioms were due in large measure to Grassmann (1861) and Dedekind (1888).

Leopold Löwenheim (1915) gave a systematic treatment of model theory for first-order logic, including the first proper treatment of the equality symbol. Löwenheim's results were further extended by Thoralf Skolem (1920). Alfred Tarski (1935, 1956) gave an explicit definition of truth and model-theoretic satisfaction in first-order logic, using set theory.

John McCarthy (1958) was primarily responsible for the introduction of first-order logic as a tool for building AI systems. The prospects for logic-based AI were advanced significantly by Robinson's (1965) development of resolution, a complete procedure for first-order inference. The logicist approach took root at Stanford University. Cordell Green (1969a, 1969b) developed a first-order reasoning system, QA3, leading to the first attempts to build a logical robot at SRI (Fikes and Nilsson, 1971). First-order logic was applied by Zohar Manna and Richard Waldinger (1971) for reasoning about programs and later by Michael Genesereth (1984) for reasoning about circuits. In Europe, logic programming (a restricted form of first-order reasoning) was developed for linguistic analysis (Colmerauer *et al.*, 1973) and for general declarative systems (Kowalski, 1974). Computational logic was also well entrenched at Edinburgh through the LCF (Logic for Computable Functions) project (Gordon *et al.*, 1979). These developments are chronicled further in Chapters 9 and 10.

Practical applications built with first-order logic include a system for evaluating the manufacturing requirements for electronic products (Mannion, 2002), a system for reasoning about policies for file access and digital rights management (Halpern and Weissman, 2008), and a system for the automated composition of Web services (McIlraith and Zeng, 2001).

Reactions to the Whorf hypothesis (Whorf, 1956) and the problem of language and thought in general, appear in multiple books (Pullum, 1991; Pinker, 2003) including the seemingly opposing titles *Why the World Looks Different in Other Languages* (Deutscher, 2010) and *Why The World Looks the Same in Any Language* (McWhorter, 2014) (although both authors agree that there are differences and the differences are small). The "theory" theory (Gopnik and Glymour, 2002; Tenenbaum *et al.*, 2007) views children's learning about the world as analogous to the construction of scientific theories. Just as the predictions of a ma-

chine learning algorithm depend strongly on the vocabulary supplied to it, so will the child's formulation of theories depend on the linguistic environment in which learning occurs.

There are a number of good introductory texts on first-order logic, including some by leading figures in the history of logic: Alfred Tarski (1941), Alonzo Church (1956), and W.V. Quine (1982) (which is one of the most readable). Enderton (1972) gives a more mathematically oriented perspective. A highly formal treatment of first-order logic, along with many more advanced topics in logic, is provided by Bell and Machover (1977). Manna and Waldinger (1985) give a readable introduction to logic from a computer science perspective, as do Huth and Ryan (2004), who concentrate on program verification. Barwise and Etchemendy (2002) take an approach similar to the one used here. Smullyan (1995) presents results concisely, using the tableau format. Gallier (1986) provides an extremely rigorous mathematical exposition of first-order logic, along with a great deal of material on its use in automated reasoning. *Logical Foundations of Artificial Intelligence* (Genesereth and Nilsson, 1987) is both a solid introduction to logic and the first systematic treatment of logical agents with percepts and actions, and there are two good handbooks: van Benthem and ter Meulen (1997) and Robinson and Voronkov (2001). The journal of record for the field of pure mathematical logic is the *Journal of Symbolic Logic*, whereas the *Journal of Applied Logic* deals with concerns closer to those of artificial intelligence.

# CHAPTER 9

## INFERENCE IN FIRST-ORDER LOGIC

*In which we define effective procedures for answering questions posed in first-order logic.*

In this chapter, we describe algorithms that can answer any answerable first-order logic question. Section 9.1 introduces inference rules for quantifiers and shows how to reduce first-order inference to propositional inference, albeit at potentially great expense. Section 9.2 describes how **unification** can be used to construct inference rules that work directly with first-order sentences. We then discuss three major families of first-order inference algorithms: **forward chaining** (Section 9.3), **backward chaining** (Section 9.4), and **resolution-based theorem proving** (Section 9.5).

### 9.1 Propositional vs. First-Order Inference

One way to do first-order inference is to convert the first-order knowledge base to propositional logic and use propositional inference, which we already know how to do. A first step is eliminating universal quantifiers. For example, suppose our knowledge base contains the standard folkloric axiom that all greedy kings are evil:

$$\forall x \text{ King}(x) \wedge \text{Greedy}(x) \Rightarrow \text{Evil}(x).$$

From that we can infer any of the following sentences:

$$\begin{aligned} & \text{King(John)} \wedge \text{Greedy(John)} \Rightarrow \text{Evil(John)} \\ & \text{King(Richard)} \wedge \text{Greedy(Richard)} \Rightarrow \text{Evil(Richard)} \\ & \text{King(Father(John))} \wedge \text{Greedy(Father(John))} \Rightarrow \text{Evil(Father(John))}. \\ & \vdots \end{aligned}$$

Universal  
Instantiation

In general, the rule of **Universal Instantiation** (**UI** for short) says that we can infer any sentence obtained by substituting a **ground term** (a term without variables) for a universally quantified variable.<sup>1</sup>

To write out the inference rule formally, we use the notion of **substitutions** introduced in Section 8.3. Let  $\text{SUBST}(\theta, \alpha)$  denote the result of applying the substitution  $\theta$  to the sentence  $\alpha$ . Then the rule is written

$$\frac{\forall v \ \alpha}{\text{SUBST}(\{v/g\}, \alpha)}$$

for any variable  $v$  and ground term  $g$ . For example, the three sentences given earlier are obtained with the substitutions  $\{x/\text{John}\}$ ,  $\{x/\text{Richard}\}$ , and  $\{x/\text{Father(John)}\}$ .

<sup>1</sup> Do not confuse these substitutions with the extended interpretations used to define the semantics of quantifiers in Section 8.2.6. The substitution replaces a variable with a term (a piece of syntax) to produce a new sentence, whereas an interpretation maps a variable to an object in the domain.

Similarly, the rule of **Existential Instantiation** replaces an existentially quantified variable with a single *new constant symbol*. The formal statement is as follows: for any sentence  $\alpha$ , variable  $v$ , and constant symbol  $k$  that does not appear elsewhere in the knowledge base,

$$\frac{\exists v \ \alpha}{\text{SUBST}(\{v/k\}, \alpha)}.$$

For example, from the sentence

$$\exists x \ Crown(x) \wedge OnHead(x, John)$$

we can infer the sentence

$$Crown(C_1) \wedge OnHead(C_1, John)$$

as long as  $C_1$  does not appear elsewhere in the knowledge base. Basically, the existential sentence says there is some object satisfying a condition, and applying the existential instantiation rule just gives a name to that object. Of course, that name must not already belong to another object. Mathematics provides a nice example: suppose we discover that there is a number that is a little bigger than 2.71828 and that satisfies the equation  $d(x^y)/dy = x^y$  for  $x$ . We can give this number the name  $e$ , but it would be a mistake to give it the name of an existing object, such as  $\pi$ . In logic, the new name is called a **Skolem constant**.

Whereas Universal Instantiation can be applied many times to the same axiom to produce many different consequences, Existential Instantiation need only be applied once, and then the existentially quantified sentence can be discarded. For example, we no longer need  $\exists x \ Kill(x, \text{Victim})$  once we have added the sentence  $Kill(\text{Murderer}, \text{Victim})$ .

Skolem constant

### 9.1.1 Reduction to propositional inference

We now show how to convert any first-order knowledge base into a propositional knowledge base. The first idea is that, just as an existentially quantified sentence can be replaced by one instantiation, a universally quantified sentence can be replaced by the set of *all possible* instantiations. For example, suppose our knowledge base contains just the sentences

$$\begin{aligned} & \forall x \ King(x) \wedge Greedy(x) \Rightarrow Evil(x) \\ & King(John) \\ & Greedy(John) \\ & Brother(Richard, John). \end{aligned} \tag{9.1}$$

and that the only objects are *John* and *Richard*. We apply UI to the first sentence using all possible substitutions,  $\{x/John\}$  and  $\{x/Richard\}$ . We obtain

$$\begin{aligned} & King(John) \wedge Greedy(John) \Rightarrow Evil(John) \\ & King(Richard) \wedge Greedy(Richard) \Rightarrow Evil(Richard). \end{aligned}$$

Next replace ground atomic sentences, such as *King(John)*, with proposition symbols, such as *JohnIsKing*. Finally, apply any of the complete propositional algorithms in Chapter 7 to obtain conclusions such as *JohnIsEvil*, which is equivalent to *Evil(John)*.

This technique of **propositionalization** can be made completely general, as we show in Section 9.5. However, there is a problem: when the knowledge base includes a function symbol, the set of possible ground-term substitutions is infinite! For example, if the knowledge base mentions the *Father* symbol, then infinitely many nested terms such as *Father(Father(Father(John)))* can be constructed.

Propositionalization

Fortunately, there is a famous theorem due to Jacques Herbrand (1930) to the effect that if a sentence is entailed by the original, first-order knowledge base, then there is a proof involving just a *finite* subset of the propositionalized knowledge base. Since any such subset has a maximum depth of nesting among its ground terms, we can find the subset by first generating all the instantiations with constant symbols (*Richard* and *John*), then all terms of depth 1 (*Father(Richard)* and *Father(John)*), then all terms of depth 2, and so on, until we are able to construct a propositional proof of the entailed sentence.

We have sketched an approach to first-order inference via propositionalization that is **complete**—that is, any entailed sentence can be proved. This is a major achievement, given that the space of possible models is infinite. On the other hand, we do not know until the proof is done that the sentence *is* entailed! What happens when the sentence is *not* entailed? Can we tell? Well, for first-order logic, it turns out that we cannot. Our proof procedure can go on and on, generating more and more deeply nested terms, but we will not know whether it is stuck in a hopeless loop or whether the proof is just about to pop out. This is very much like the halting problem for Turing machines. Alan Turing (1936) and Alonzo Church (1936) both proved, in rather different ways, the inevitability of this state of affairs. *The question of entailment for first-order logic is semidecidable—that is, algorithms exist that say yes to every entailed sentence, but no algorithm exists that also says no to every nonentailed sentence.*

## 9.2 Unification and First-Order Inference

---

The sharp-eyed reader will have noticed that the propositionalization approach generates many unnecessary instantiations of universally quantified sentences. We'd rather have an approach that uses just the one rule, reasoning that  $\{x/John\}$  solves the query *Evil(x)* as follows: given the rule that greedy kings are evil, find some  $x$  such that  $x$  is a king and  $x$  is greedy, and then infer that this  $x$  is evil. More generally, if there is some substitution  $\theta$  that makes each of the conjuncts of the premise of the implication identical to sentences already in the knowledge base, then we can assert the conclusion of the implication, after applying  $\theta$ . In this case, the substitution  $\theta = \{x/John\}$  achieves that aim. Now suppose that instead of knowing *Greedy(John)*, we know that *everyone* is greedy:

$$\forall y \text{ Greedy}(y). \quad (9.2)$$

Then we would still like to be able to conclude that *Evil(John)*, because we know that John is a king (given) and John is greedy (because everyone is greedy). What we need for this to work is to find a substitution for both the variables in the implication sentence and the variables in the sentences that are in the knowledge base. In this case, applying the substitution  $\{x/John, y/John\}$  to the implication premises *King(x)* and *Greedy(x)* and the knowledge-base sentences *King(John)* and *Greedy(y)* will make them identical. Thus, we can infer the consequent of the implication.

This inference process can be captured as a single inference rule that we call **Generalized Modus Ponens**:<sup>2</sup> For atomic sentences  $p_i$ ,  $p'_i$ , and  $q$ , where there is a substitution  $\theta$  such that

Generalized Modus Ponens

<sup>2</sup> Generalized Modus Ponens is more general than Modus Ponens (page 241) in the sense that the known facts and the premise of the implication need match only up to a substitution, rather than exactly. On the other hand, Modus Ponens allows any sentence  $\alpha$  as the premise, rather than just a conjunction of atomic sentences.

$\text{SUBST}(\theta, p'_i) = \text{SUBST}(\theta, p_i)$ , for all  $i$ ,

$$\frac{p'_1, p'_2, \dots, p'_n, (p_1 \wedge p_2 \wedge \dots \wedge p_n \Rightarrow q)}{\text{SUBST}(\theta, q)}.$$

There are  $n + 1$  premises to this rule: the  $n$  atomic sentences  $p'_i$  and the one implication. The conclusion is the result of applying the substitution  $\theta$  to the consequent  $q$ . For our example:

$$\begin{array}{ll} p'_1 \text{ is } \text{King}(John) & p_1 \text{ is } \text{King}(x) \\ p'_2 \text{ is } \text{Greedy}(y) & p_2 \text{ is } \text{Greedy}(x) \\ \theta \text{ is } \{x/John, y/John\} & q \text{ is } \text{Evil}(x) \\ \text{SUBST}(\theta, q) \text{ is } \text{Evil}(John). & \end{array}$$

It is easy to show that Generalized Modus Ponens is a sound inference rule. First, we observe that, for any sentence  $p$  (whose variables are assumed to be universally quantified) and for any substitution  $\theta$ ,

$$p \models \text{SUBST}(\theta, p)$$

is true by Universal Instantiation. It is true in particular for a  $\theta$  that satisfies the conditions of the Generalized Modus Ponens rule. Thus, from  $p'_1, \dots, p'_n$  we can infer

$$\text{SUBST}(\theta, p'_1) \wedge \dots \wedge \text{SUBST}(\theta, p'_n)$$

and from the implication  $p_1 \wedge \dots \wedge p_n \Rightarrow q$  we can infer

$$\text{SUBST}(\theta, p_1) \wedge \dots \wedge \text{SUBST}(\theta, p_n) \Rightarrow \text{SUBST}(\theta, q).$$

Now,  $\theta$  in Generalized Modus Ponens is defined so that  $\text{SUBST}(\theta, p'_i) = \text{SUBST}(\theta, p_i)$ , for all  $i$ ; therefore the first of these two sentences matches the premise of the second exactly. Hence,  $\text{SUBST}(\theta, q)$  follows by Modus Ponens.

Generalized Modus Ponens is a **lifted** version of Modus Ponens—it raises Modus Ponens from ground (variable-free) propositional logic to first-order logic. We will see in the rest of this chapter that we can develop lifted versions of the forward chaining, backward chaining, and resolution algorithms introduced in Chapter 7. The key advantage of lifted inference rules over propositionalization is that they make only those substitutions that are required to allow particular inferences to proceed.

### 9.2.1 Unification

Lifted inference rules require finding substitutions that make different logical expressions look identical. This process is called **unification** and is a key component of all first-order inference algorithms. The UNIFY algorithm takes two sentences and returns a **unifier** for them (a substitution) if one exists:

$$\text{UNIFY}(p, q) = \theta \text{ where } \text{SUBST}(\theta, p) = \text{SUBST}(\theta, q).$$

Let us look at some examples of how UNIFY should behave. Suppose we have a query  $\text{AskVars}(\text{Knows}(John, x))$ : whom does John know? Answers to this query can be found by finding all sentences in the knowledge base that unify with  $\text{Knows}(John, x)$ . Here are the results of unification with four different sentences that might be in the knowledge base:

$$\begin{aligned} \text{UNIFY}(\text{Knows}(John, x), \text{Knows}(John, Jane)) &= \{x/Jane\} \\ \text{UNIFY}(\text{Knows}(John, x), \text{Knows}(y, Bill)) &= \{x/Bill, y/John\} \\ \text{UNIFY}(\text{Knows}(John, x), \text{Knows}(y, \text{Mother}(y))) &= \{y/John, x/\text{Mother}(John)\} \\ \text{UNIFY}(\text{Knows}(John, x), \text{Knows}(x, Elizabeth)) &= \text{failure}. \end{aligned}$$

Standardizing apart

The last unification fails because  $x$  cannot take on the values *John* and *Elizabeth* at the same time. Now, remember that  $\text{Knows}(x, \text{Elizabeth})$  means “Everyone knows Elizabeth,” so we *should* be able to infer that John knows Elizabeth. The problem arises only because the two sentences happen to use the same variable name,  $x$ . The problem can be avoided by **standardizing apart** one of the two sentences being unified, which means renaming its variables to avoid name clashes. For example, we can rename  $x$  in  $\text{Knows}(x, \text{Elizabeth})$  to  $x_{17}$  (a new variable name) without changing its meaning. Now the unification will work:

$$\text{UNIFY}(\text{Knows}(\text{John}, x), \text{Knows}(x_{17}, \text{Elizabeth})) = \{x/\text{Elizabeth}, x_{17}/\text{John}\}.$$

Exercise 9.STAN delves further into the need for standardizing apart.

There is one more complication: we said that UNIFY should return a substitution that makes the two arguments look the same. But there could be more than one such unifier. For example,  $\text{UNIFY}(\text{Knows}(\text{John}, x), \text{Knows}(y, z))$  could return  $\{y/\text{John}, x/z\}$  or could return  $\{y/\text{John}, x/\text{John}, z/\text{John}\}$ . The first unifier gives  $\text{Knows}(\text{John}, z)$  as the result of unification, whereas the second gives  $\text{Knows}(\text{John}, \text{John})$ . The second result could be obtained from the first by an additional substitution  $\{z/\text{John}\}$ ; we say that the first unifier is *more general* than the second, because it places fewer restrictions on the values of the variables.

Most general unifier (MGU)

Every unifiable pair of expressions has a single **most general unifier (MGU)** that is unique up to renaming and substitution of variables. For example,  $\{x/\text{John}\}$  and  $\{y/\text{John}\}$  are considered equivalent, as are  $\{x/\text{John}, y/\text{John}\}$  and  $\{x/\text{John}, y/x\}$ .

Occur check

An algorithm for computing most general unifiers is shown in Figure 9.1. The process is simple: recursively explore the two expressions simultaneously “side by side,” building up a unifier along the way, but failing if two corresponding points in the structures do not match. There is one expensive step: when matching a variable against a complex term, one must check whether the variable itself occurs inside the term; if it does, the match fails because no consistent unifier can be constructed. For example,  $S(x)$  can’t unify with  $S(S(x))$ . This so-called **occur check** makes the complexity of the entire algorithm quadratic in the size of the expressions being unified. Some systems, including many logic programming systems, simply omit the occur check and put the onus on the user to avoid making unsound inferences as a result. Other systems use more complex unification algorithms with linear-time complexity.

### 9.2.2 Storage and retrieval

Underlying the TELL, ASK, and ASKVARS functions used to inform and interrogate a knowledge base are the more primitive STORE and FETCH functions. STORE( $s$ ) stores a sentence  $s$  into the knowledge base and FETCH( $q$ ) returns all unifiers such that the query  $q$  unifies with some sentence in the knowledge base. The problem we used to illustrate unification—finding all facts that unify with  $\text{Knows}(\text{John}, x)$ —is an instance of FETCHing.

The simplest way to implement STORE and FETCH is to keep all the facts in one long list and unify each query against every element of the list. Such a process is inefficient, but it works. The remainder of this section outlines ways to make retrieval more efficient.

Indexing

Predicate indexing

We can make FETCH more efficient by ensuring that unifications are attempted only with sentences that have *some* chance of unifying. For example, there is no point in trying to unify  $\text{Knows}(\text{John}, x)$  with  $\text{Brother}(\text{Richard}, \text{John})$ . We can avoid such unifications by **indexing** the facts in the knowledge base. A simple scheme called **predicate indexing** puts all the

---

```

function UNIFY( $x, y, \theta = \text{empty}$ ) returns a substitution to make  $x$  and  $y$  identical, or failure
  if  $\theta = \text{failure}$  then return failure
  else if  $x = y$  then return  $\theta$ 
  else if VARIABLE?( $x$ ) then return UNIFY-VAR( $x, y, \theta$ )
  else if VARIABLE?( $y$ ) then return UNIFY-VAR( $y, x, \theta$ )
  else if COMPOUND?( $x$ ) and COMPOUND?( $y$ ) then
    return UNIFY(ARGS( $x$ ), ARGS( $y$ ), UNIFY(OP( $x$ ), OP( $y$ ),  $\theta$ ))
  else if LIST?( $x$ ) and LIST?( $y$ ) then
    return UNIFY(REST( $x$ ), REST( $y$ ), UNIFY(FIRST( $x$ ), FIRST( $y$ ),  $\theta$ ))
  else return failure

function UNIFY-VAR( $var, x, \theta$ ) returns a substitution
  if  $\{var/val\} \in \theta$  for some  $val$  then return UNIFY( $val, x, \theta$ )
  else if  $\{x/val\} \in \theta$  for some  $val$  then return UNIFY( $var, val, \theta$ )
  else if OCCUR-CHECK?( $var, x$ ) then return failure
  else return add  $\{var/x\}$  to  $\theta$ 

```

**Figure 9.1** The unification algorithm. The arguments  $x$  and  $y$  can be any expression: a constant or variable, or a compound expression such as a complex sentence or term, or a list of expressions. The argument  $\theta$  is a substitution, initially the empty substitution, but with  $\{var/val\}$  pairs added to it as we recurse through the inputs, comparing the expressions element by element. In a compound expression such as  $F(A, B)$ , OP( $x$ ) field picks out the function symbol  $F$  and ARGS( $x$ ) field picks out the argument list ( $A, B$ ).

---

*Knows* facts in one bucket and all the *Brother* facts in another. The buckets can be stored in a hash table for efficient access.

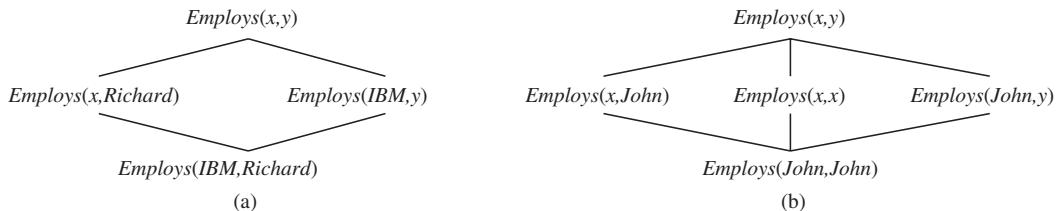

Predicate indexing is useful when there are many predicate symbols but only a few clauses for each symbol. Sometimes, however, a predicate has many clauses. For example, suppose that the tax authorities want to keep track of who employs whom, using a predicate *Employs*( $x, y$ ). This would be a very large bucket with perhaps millions of employers and tens of millions of employees. Answering a query such as *Employs*( $x, Richard$ ) with predicate indexing would require scanning the entire bucket.

For this particular query, it would help if facts were indexed both by predicate and by second argument, perhaps using a combined hash table key. Then we could simply construct the key from the query and retrieve exactly those facts that unify with the query. For other queries, such as *Employs*(*IBM*,  $y$ ), we would need to have indexed the facts by combining the predicate with the first argument. Therefore, facts can be stored under multiple index keys, rendering them instantly accessible to various queries that they might unify with.

Given a sentence to be stored, it is possible to construct indices for *all possible* queries that unify with it. For the fact *Employs*(*IBM*, *Richard*), the queries are

<i>Employs</i> ( <i>IBM</i> , <i>Richard</i> )	Does IBM employ Richard?
<i>Employs</i> ( $x$ , <i>Richard</i> )	Who employs Richard?
<i>Employs</i> ( <i>IBM</i> , $y$ )	Whom does IBM employ?
<i>Employs</i> ( $x$ , $y$ )	Who employs whom?

These queries form a **subsumption lattice**, as shown in Figure 9.2(a). The lattice has some [Subsumption lattice](#)

**Figure 9.2** (a) The subsumption lattice whose lowest node is *Employs(IBM, Richard)*. (b) The subsumption lattice for the sentence *Employs(John, John)*.

interesting properties. The child of any node in the lattice is obtained from its parent by a single substitution; and the “highest” common descendant of any two nodes is the result of applying their most general unifier. A sentence with repeated constants has a slightly different lattice, as shown in Figure 9.2(b). Although function symbols are not shown in the figure, they too can be incorporated into the lattice structure.

For predicates with a small number of arguments, it is a good tradeoff to create an index for every point in the subsumption lattice. That requires a little more work at storage time, but speeds up retrieval time. However, for a predicate with  $n$  arguments, the lattice contains  $O(2^n)$  nodes. If function symbols are allowed, the number of nodes is also exponential in the size of the terms in the sentence to be stored. This can lead to a huge number of indices.

We have to somehow limit the indices to ones that are likely to be used frequently in queries; otherwise we will waste more time in creating the indices than we save by having them. We could adopt a fixed policy, such as maintaining indices only on keys composed of a predicate plus a single argument. Or we could learn an adaptive policy that creates indices to meet the demands of the kinds of queries being asked. For commercial databases where facts number in the billions, the problem has been the subject of intensive study, technology development, and continual optimization.

### 9.3 Forward Chaining

In Section 7.5 we showed a forward-chaining algorithm for knowledge bases of propositional definite clauses. Here we expand that idea to cover first-order definite clauses.

Of course there are some logical sentences that cannot be stated as a definite clause, and thus cannot be handled by this approach. But rules of the form *Antecedent*  $\Rightarrow$  *Consequent* are sufficient to cover a wide variety of interesting real-world systems.

### 9.3.1 First-order definite clauses

First-order definite clauses are disjunctions of literals of which *exactly one is positive*. That means a definite clause is either atomic, or is an implication whose antecedent is a conjunction of positive literals and whose consequent is a single positive literal. Existential quantifiers are not allowed, and universal quantifiers are left implicit: if you see an  $x$  in a definite clause, that means there is an implicit  $\forall x$  quantifier. A typical first-order definite clause looks like this:

$$King(x) \wedge Greedy(x) \Rightarrow Evil(x),$$

but the literals *King*(*John*) and *Greedy*(*v*) also count as definite clauses. First-order liter-

als can include variables, so  $\text{Greedy}(y)$  is interpreted as “everyone is greedy” (the universal quantifier is implicit).

Let us put definite clauses to work in representing the following problem:

The law says that it is a crime for an American to sell weapons to hostile nations. The country Nono, an enemy of America, has some missiles, and all of its missiles were sold to it by Colonel West, who is American.

First, we will represent these facts as first-order definite clauses:

“... it is a crime for an American to sell weapons to hostile nations”:

$$\text{American}(x) \wedge \text{Weapon}(y) \wedge \text{Sells}(x,y,z) \wedge \text{Hostile}(z) \Rightarrow \text{Criminal}(x). \quad (9.3)$$

“Nono ... has some missiles.” The sentence  $\exists x \text{ Owns}(\text{Nono},x) \wedge \text{Missile}(x)$  is transformed into two definite clauses by Existential Instantiation, introducing a new constant  $M_1$ :

$$\text{Owns}(\text{Nono},M_1) \quad (9.4)$$

$$\text{Missile}(M_1) \quad (9.5)$$

“All of its missiles were sold to it by Colonel West”:

$$\text{Missile}(x) \wedge \text{Owns}(\text{Nono},x) \Rightarrow \text{Sells}(\text{West},x,\text{Nono}). \quad (9.6)$$

We will also need to know that missiles are weapons:

$$\text{Missile}(x) \Rightarrow \text{Weapon}(x) \quad (9.7)$$

and we must know that an enemy of America counts as “hostile”:

$$\text{Enemy}(x,\text{America}) \Rightarrow \text{Hostile}(x). \quad (9.8)$$

“West, who is American ...”:

$$\text{American}(\text{West}). \quad (9.9)$$

“The country Nono, an enemy of America ...”:

$$\text{Enemy}(\text{Nono},\text{America}). \quad (9.10)$$

This knowledge base happens to be a **Datalog** knowledge base: Datalog is a language consisting of first-order definite clauses with no function symbols. Datalog gets its name because it can represent the type of statements typically made in relational databases. The absence of function symbols makes inference much easier.

Datalog

### 9.3.2 A simple forward-chaining algorithm

Figure 9.3 shows a simple forward chaining inference algorithm. Starting from the known facts, it triggers all the rules whose premises are satisfied, adding their conclusions to the known facts. The process repeats until the query is answered (assuming that just one answer is required) or no new facts are added. Notice that a fact is not “new” if it is just a **renaming** of a known fact—a sentence is a renaming of another if they are identical except for the names of the variables. For example,  $\text{Likes}(x,\text{IceCream})$  and  $\text{Likes}(y,\text{IceCream})$  are renamings of each other. They both mean the same thing: “Everyone likes ice cream.”

Renaming

We use our crime problem to illustrate FOL-FC-ASK. The implication sentences available for chaining are (9.3), (9.6), (9.7), and (9.8). Two iterations are required:

---

```

function FOL-FC-ASK( $KB, \alpha$ ) returns a substitution or false
  inputs:  $KB$ , the knowledge base, a set of first-order definite clauses
            $\alpha$ , the query, an atomic sentence

  while true do
     $new \leftarrow \{\}$       // The set of new sentences inferred on each iteration
    for each rule in  $KB$  do
       $(p_1 \wedge \dots \wedge p_n \Rightarrow q) \leftarrow \text{STANDARDIZE-VARIABLES}(rule)$ 
      for each  $\theta$  such that  $\text{SUBST}(\theta, p_1 \wedge \dots \wedge p_n) = \text{SUBST}(\theta, p'_1 \wedge \dots \wedge p'_n)$ 
        for some  $p'_1, \dots, p'_n$  in  $KB$ 
         $q' \leftarrow \text{SUBST}(\theta, q)$ 
        if  $q'$  does not unify with some sentence already in  $KB$  or  $new$  then
          add  $q'$  to  $new$ 
           $\phi \leftarrow \text{UNIFY}(q', \alpha)$ 
          if  $\phi$  is not failure then return  $\phi$ 
        if  $new = \{\}$  then return false
        add  $new$  to  $KB$ 
  
```

**Figure 9.3** A conceptually straightforward, but inefficient, forward-chaining algorithm. On each iteration, it adds to  $KB$  all the atomic sentences that can be inferred in one step from the implication sentences and the atomic sentences already in  $KB$ . The function STANDARDIZE-VARIABLES replaces all variables in its arguments with new ones that have not been used before.

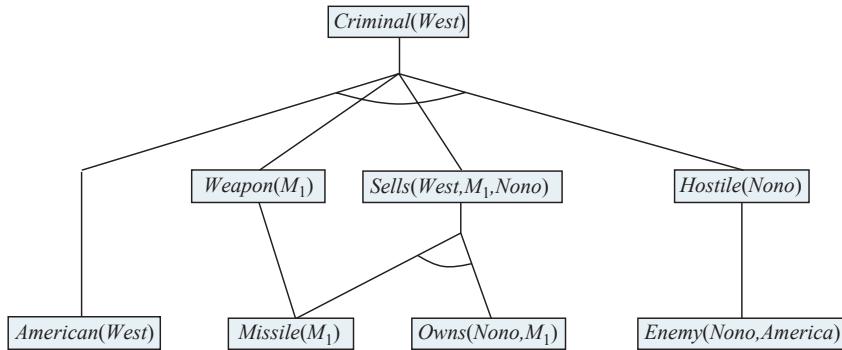

---

- On the first iteration, rule (9.3) has unsatisfied premises.  
Rule (9.6) is satisfied with  $\{x/M_1\}$ , and *Sells(West, M<sub>1</sub>, Nono)* is added.  
Rule (9.7) is satisfied with  $\{x/M_1\}$ , and *Weapon(M<sub>1</sub>)* is added.  
Rule (9.8) is satisfied with  $\{x/Nono\}$ , and *Hostile(Nono)* is added.
- On the second iteration, rule (9.3) is satisfied with  $\{x/West, y/M_1, z/Nono\}$ , and the inference *Criminal(West)* is added.

Figure 9.4 shows the proof tree that is generated. Notice that no new inferences are possible at this point because every sentence that could be concluded by forward chaining is already contained explicitly in the KB. Such a knowledge base is called a **fixed point** of the inference process. Fixed points reached by forward chaining with first-order definite clauses are similar to those for propositional forward chaining (page 249); the principal difference is that a first-order fixed point can include universally quantified atomic sentences.

FOL-FC-ASK is easy to analyze. First, it is **sound**, because every inference is just an application of Generalized Modus Ponens, which is sound. Second, it is **complete** for definite clause knowledge bases; that is, it answers every query whose answers are entailed by any knowledge base of definite clauses.

For Datalog knowledge bases, which contain no function symbols, the proof of completeness is fairly easy. We begin by counting the number of possible facts that can be added, which determines the maximum number of iterations. Let  $k$  be the maximum **arity** (number of arguments) of any predicate,  $p$  be the number of predicates, and  $n$  be the number of constant symbols. Clearly, there can be no more than  $pn^k$  distinct ground facts, so after this many iterations the algorithm must have reached a fixed point. Then we can make an argument very

**Figure 9.4** The proof tree generated by forward chaining on the crime example. The initial facts appear at the bottom level, facts inferred on the first iteration in the middle level, and facts inferred on the second iteration at the top level.

similar to the proof of completeness for propositional forward chaining. (See page 249.) The details of how to make the transition from propositional to first-order completeness are given for the resolution algorithm in Section 9.5.

For general definite clauses with function symbols, FOL-FC-ASK can generate infinitely many new facts, so we need to be more careful. For the case in which an answer to the query sentence  $q$  is entailed, we must appeal to Herbrand's theorem (page 300) to establish that the algorithm will find a proof. (See Section 9.5 for the resolution case.) If the query has no answer, the algorithm could fail to terminate in some cases. For example, if the knowledge base includes the Peano axioms

$$\begin{aligned} &\text{NatNum}(0) \\ &\forall n \text{ NatNum}(n) \Rightarrow \text{NatNum}(S(n)), \end{aligned}$$

then forward chaining adds  $\text{NatNum}(S(0))$ ,  $\text{NatNum}(S(S(0)))$ ,  $\text{NatNum}(S(S(S(0))))$ , and so on. This problem is unavoidable in general. As with general first-order logic, entailment with definite clauses is semidecidable.

### 9.3.3 Efficient forward chaining

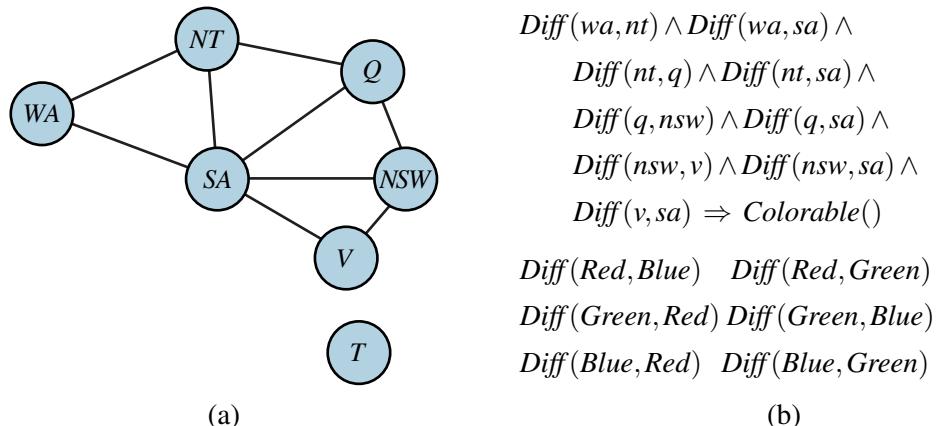

The forward-chaining algorithm in Figure 9.3 is designed for ease of understanding, not efficiency. There are three sources of inefficiency. First, the inner loop of the algorithm tries to match every rule against every fact in the knowledge base. Second, the algorithm rechecks every rule on every iteration, even if very few additions have been made to the knowledge base. Third, the algorithm can generate many facts that are irrelevant to the goal. We address each of these issues in turn.

#### Matching rules against known facts

The problem of matching the premise of a rule against the facts in the knowledge base might seem simple enough. For example, suppose we want to apply the rule

$$\text{Missile}(x) \Rightarrow \text{Weapon}(x).$$

Then we need to find all the facts that unify with  $\text{Missile}(x)$ ; in a suitably indexed knowledge

**Figure 9.5** (a) Constraint graph for coloring the map of Australia. (b) The map-coloring CSP expressed as a single definite clause. Each map region is represented as a variable whose value can be one of the constants *Red*, *Green*, or *Blue* (which are declared *Diff*).

base, this can be done in constant time per fact. Now consider a rule such as

$$\text{Missile}(x) \wedge \text{Owns}(\text{Nono}, x) \Rightarrow \text{Sells}(\text{West}, x, \text{Nono}).$$

Again, we can find all the objects owned by Nono in constant time per object; then, for each object, we could check whether it is a missile. However, if the knowledge base contains many objects owned by Nono and very few missiles, then it would be better to find all the missiles first and then check whether they are owned by Nono. This is the **conjunction ordering** problem: find an ordering to solve the conjuncts of the rule premise so that the total cost is minimized. It turns out that finding the optimal ordering is NP-hard, but good heuristics are available. For example, the **minimum-remaining-values** (MRV) heuristic used for CSPs in Chapter 5 would suggest ordering the conjuncts to look for missiles first if there are fewer missiles than there are objects owned by Nono.

#### Conjunct ordering

#### Pattern matching

The connection between this **pattern matching** and constraint satisfaction is actually very close. We can view each conjunct as a constraint on the variables that it contains—for example, *Missile*(*x*) is a unary constraint on *x*. Extending this idea, we can express every finite-domain CSP as a single definite clause together with some associated ground facts. Consider the map-coloring problem from Figure 5.1, shown again in Figure 9.5(a). An equivalent formulation as a single definite clause is given in Figure 9.5(b). Clearly, the conclusion *Colorable*() can be inferred only if the CSP has a solution. Because CSPs in general include 3-SAT problems as special cases, we can conclude that *matching a definite clause against a set of facts is NP-hard*.

It might seem rather depressing that forward chaining has an NP-hard matching problem in its inner loop. There are three ways to cheer ourselves up:

- We can remind ourselves that most rules in real-world knowledge bases are small and simple (like the rules in our crime example) rather than large and complex (like the CSP formulation in Figure 9.5). It is common in the database world to assume that both the sizes of rules and the arities of predicates are bounded by a constant and to worry only about **data complexity**—that is, the complexity of inference as a function

#### Data complexity

of the number of ground facts in the knowledge base. It is easy to show that the data complexity of forward chaining is polynomial, not exponential.

- We can consider subclasses of rules for which matching is efficient. Essentially every Datalog clause can be viewed as defining a CSP, so matching will be tractable just when the corresponding CSP is tractable. Chapter 5 describes several tractable families of CSPs. For example, if the constraint graph (the graph whose nodes are variables and whose links are constraints) forms a tree, then the CSP can be solved in linear time. Exactly the same result holds for rule matching. For instance, if we remove South Australia from the map in Figure 9.5, the resulting clause is

$$\text{Diff}(wa, nt) \wedge \text{Diff}(nt, q) \wedge \text{Diff}(q, nsw) \wedge \text{Diff}(nsw, v) \Rightarrow \text{Colorable}()$$

which corresponds to the reduced CSP shown in Figure 5.12 on page 185. Algorithms for solving tree-structured CSPs can be applied directly to the problem of rule matching.

- We can try to eliminate redundant rule-matching attempts in the forward-chaining algorithm, as described next.

### Incremental forward chaining

When we showed how forward chaining works on the crime example, we cheated. In particular, we omitted some of the rule matching done by the algorithm shown in Figure 9.3. For example, on the second iteration, the rule

$$\text{Missile}(x) \Rightarrow \text{Weapon}(x)$$

matches against  $\text{Missile}(M_1)$  (again), and of course the conclusion  $\text{Weapon}(M_1)$  is already known so nothing happens. Such redundant rule matching can be avoided if we make the following observation: *Every new fact inferred on iteration  $t$  must be derived from at least one new fact inferred on iteration  $t - 1$ .* This is true because any inference that does not require a new fact from iteration  $t - 1$  could have been done at iteration  $t - 1$  already. 

This observation leads naturally to an incremental forward-chaining algorithm where, at iteration  $t$ , we check a rule only if its premise includes a conjunct  $p_i$  that unifies with a fact  $p'_i$  newly inferred at iteration  $t - 1$ . The rule-matching step then fixes  $p_i$  to match with  $p'_i$ , but allows the other conjuncts of the rule to match with facts from any previous iteration. This algorithm generates exactly the same facts at each iteration as the algorithm in Figure 9.3, but is much more efficient.

With suitable indexing, it is easy to identify all the rules that can be triggered by any given fact, and many real systems operate in an “update” mode wherein forward chaining occurs in response to every TELL. Inferences cascade through the set of rules until the fixed point is reached, and then the process begins again for the next new fact.

Typically, only a small fraction of the rules in the knowledge base are actually triggered by the addition of a given fact. This means that a great deal of redundant work is done in repeatedly constructing partial matches that have some unsatisfied premises. Our crime example is rather too small to show this effectively, but notice that a partial match is constructed on the first iteration between the rule

$$\text{American}(x) \wedge \text{Weapon}(y) \wedge \text{Sells}(x, y, z) \wedge \text{Hostile}(z) \Rightarrow \text{Criminal}(x)$$

and the fact  $\text{American}(West)$ . This partial match is then discarded and rebuilt on the second iteration (when the rule succeeds). It would be better to retain and gradually complete the partial matches as new facts arrive, rather than discarding them.

## Rete algorithm

The **Rete algorithm**<sup>3</sup> was the first to address this problem. The algorithm preprocesses the set of rules in the knowledge base to construct a dataflow network in which each node is a literal from a rule premise. Variable bindings flow through the network and are filtered out when they fail to match a literal. If two literals in a rule share a variable—for example,  $Sells(x, y, z) \wedge Hostile(z)$  in the crime example—then the bindings from each literal are filtered through an equality node. A variable binding reaching a node for an  $n$ -ary literal such as  $Sells(x, y, z)$  might have to wait for bindings for the other variables to be established before the process can continue. At any given point, the state of a Rete network captures all the partial matches of the rules, avoiding a great deal of recomputation.

## Production system

Rete networks, and various improvements thereon, have been a key component of so-called **production systems**, which were among the earliest forward-chaining systems in widespread use.<sup>4</sup> The XCON system (originally called R1; McDermott, 1982) was built with a production-system architecture. XCON contained several thousand rules for designing configurations of computer components for customers of the Digital Equipment Corporation. It was one of the first clear commercial successes in the emerging field of expert systems. Many other similar systems have been built with the same underlying technology, which has been implemented in the general-purpose language OPS-5.

## Cognitive architectures

Production systems are also popular in **cognitive architectures**—that is, models of human reasoning—such as ACT (Anderson, 1983) and SOAR (Laird *et al.*, 1987). In such systems, the “working memory” of the system models human short-term memory, and the productions are part of long-term memory. On each cycle of operation, productions are matched against the working memory of facts. A production whose conditions are satisfied can add or delete facts in working memory. In contrast to the typical situation in databases, production systems often have many rules and relatively few facts. With suitably optimized matching technology, systems can operate in real time with tens of millions of rules.

## Irrelevant facts

Another source of inefficiency is that forward chaining makes all allowable inferences based on the known facts, *even if they are irrelevant to the goal*. In our crime example, there were no rules capable of drawing irrelevant conclusions. But if there had been many rules describing the eating habits of Americans or the components and prices of missiles, then FOL-FC-ASK would have generated irrelevant conclusions.

## Deductive databases

One way to avoid drawing irrelevant conclusions is to use backward chaining, as described in Section 9.4. Another way is to restrict forward chaining to a selected subset of rules, as in PL-FC-ENTAILS? (page 249). A third approach has emerged in the field of **deductive databases**, which are large-scale databases, like relational databases, but which use forward chaining as the standard inference tool rather than SQL queries. The idea is to rewrite the rule set, using information from the goal, so that only relevant variable bindings—those belonging to a so-called **magic set**—are considered during forward inference. For example, if the goal is  $Criminal(West)$ , the rule that concludes  $Criminal(x)$  will be rewritten to include an extra conjunct that constrains the value of  $x$ :

$$Magic(x) \wedge American(x) \wedge Weapon(y) \wedge Sells(x, y, z) \wedge Hostile(z) \Rightarrow Criminal(x).$$

## Magic set

<sup>3</sup> Rete is Latin for *net*. It rhymes with *treaty*.

<sup>4</sup> The word **production** in **production systems** denotes a condition–action rule.

The fact  $Magic(West)$  is also added to the KB. In this way, even if the knowledge base contains facts about millions of Americans, only Colonel West will be considered during the forward inference process. The complete process for defining magic sets and rewriting the knowledge base is too complex to go into here, but the basic idea is to perform a sort of “generic” backward inference from the goal in order to work out which variable bindings need to be constrained. The magic sets approach can therefore be thought of as a kind of hybrid between forward inference and backward preprocessing.

## 9.4 Backward Chaining

---

The second major family of logical inference algorithms uses **backward chaining** over definite clauses. These algorithms work backward from the goal, chaining through rules to find known facts that support the proof.

### 9.4.1 A backward-chaining algorithm

Figure 9.6 shows a backward-chaining algorithm for definite clauses. FOL-BC-ASK( $KB, goal$ ) will be proved if the knowledge base contains a rule of the form  $lhs \Rightarrow goal$ , where  $lhs$  (left-hand side) is a list of conjuncts. An atomic fact like  $American(West)$  is considered as a clause whose  $lhs$  is the empty list. Now a query that contains variables might be proved in multiple ways. For example, the query  $Person(x)$  could be proved with the substitution  $\{x/John\}$  as well as with  $\{x/Richard\}$ . So we implement FOL-BC-ASK as a generator—a function that returns multiple times, each time giving one possible result (see Appendix B).

Backward chaining is a kind of AND/OR search—the OR part because the goal query can be proved by any rule in the knowledge base, and the AND part because all the conjuncts in the  $lhs$  of a clause must be proved. FOL-BC-OR works by fetching all clauses that might

---

```

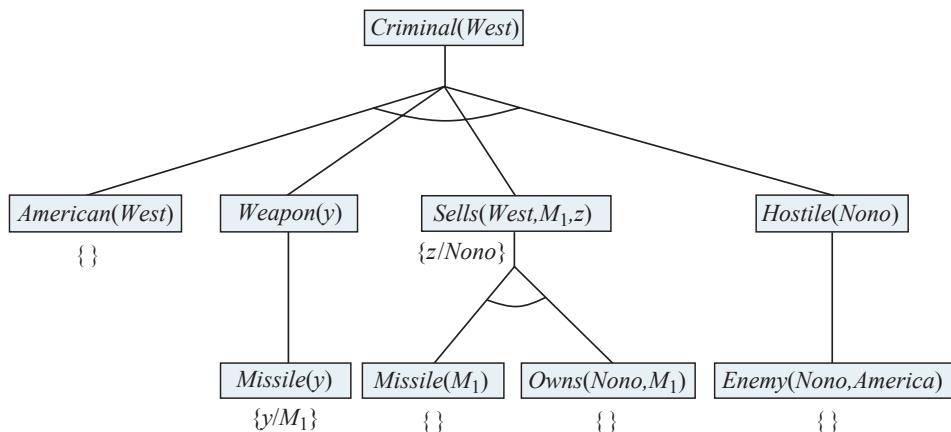

function FOL-BC-ASK( $KB, query$ ) returns a generator of substitutions
  return FOL-BC-OR( $KB, query, \{\}$ )

function FOL-BC-OR( $KB, goal, \theta$ ) returns a substitution
  for each  $rule$  in FETCH-RULES-FOR-GOAL( $KB, goal$ ) do
     $(lhs \Rightarrow rhs) \leftarrow$  STANDARDIZE-VARIABLES( $rule$ )
    for each  $\theta'$  in FOL-BC-AND( $KB, lhs, UNIFY(rhs, goal, \theta)$ ) do
      yield  $\theta'$ 

function FOL-BC-AND( $KB, goals, \theta$ ) returns a substitution
  if  $\theta = failure$  then return
  else if LENGTH( $goals$ ) = 0 then yield  $\theta$ 
  else
     $first, rest \leftarrow FIRST(goals), REST(goals)$ 
    for each  $\theta'$  in FOL-BC-OR( $KB, SUBST(\theta, first), \theta$ ) do
      for each  $\theta''$  in FOL-BC-AND( $KB, rest, \theta'$ ) do
        yield  $\theta''$ 
```

**Figure 9.6** A simple backward-chaining algorithm for first-order knowledge bases.

---

**Figure 9.7** Proof tree constructed by backward chaining to prove that West is a criminal. The tree should be read depth first, left to right. To prove  $\text{Criminal}(West)$ , we have to prove the four conjuncts below it. Some of these are in the knowledge base, and others require further backward chaining. Bindings for each successful unification are shown next to the corresponding subgoal. Note that once one subgoal in a conjunction succeeds, its substitution is applied to subsequent subgoals. Thus, by the time FOL-BC-ASK gets to the last conjunct, originally  $\text{Hostile}(z)$ ,  $z$  is already bound to  $Nono$ .

unify with the goal, standardizing the variables in the clause to be brand-new variables, and then, if the *rhs* of the clause does indeed unify with the goal, proving every conjunct in the *lhs*, using FOL-BC-AND. That function works by proving each of the conjuncts in turn, keeping track of the accumulated substitution as it goes. Figure 9.7 is the proof tree for deriving  $\text{Criminal}(West)$  from sentences (9.3) through (9.10).

Backward chaining, as we have written it, is clearly a depth-first search algorithm. This means that its space requirements are linear in the size of the proof. It also means that backward chaining (unlike forward chaining) suffers from problems with repeated states and incompleteness. Despite these limitations, backward chaining has proven to be popular and effective in logic programming languages.

### 9.4.2 Logic programming

Logic programming is a technology that comes close to embodying the declarative ideal described in Chapter 7: that systems should be constructed by expressing knowledge in a formal language and that problems should be solved by running inference processes on that knowledge. The ideal is summed up in Robert Kowalski's equation,

$$\text{Algorithm} = \text{Logic} + \text{Control}.$$

Prolog

**Prolog** is the most widely used logic programming language. It is used primarily as a rapid-prototyping language and for symbol-manipulation tasks such as writing compilers (Van Roy, 1990) and parsing natural language (Pereira and Warren, 1980). Many expert systems have been written in Prolog for legal, medical, financial, and other domains.

Prolog programs are sets of definite clauses written in a notation somewhat different from standard first-order logic. Prolog uses uppercase letters for variables and lowercase for constants—the opposite of our convention for logic. Commas separate conjuncts in a clause,

and the clause is written “backwards” from what we are used to; instead of  $A \wedge B \Rightarrow C$  in Prolog we have  $C :- A, B$ . Here is a typical example:

```
criminal(X) :- american(X), weapon(Y), sells(X,Y,Z), hostile(Z).
```

In Prolog the notation  $[E|L]$  denotes a list whose first element is  $E$  and whose rest is  $L$ . Here is a Prolog program for  $\text{append}(X, Y, Z)$ , which succeeds if list  $Z$  is the result of appending lists  $X$  and  $Y$ :

```
append([], Y, Y).
append([A|X], Y, [A|Z]) :- append(X, Y, Z).
```

In English, we can read these clauses as (1) appending the empty list and the list  $Y$  produces the same list  $Y$ , and (2)  $[A|Z]$  is the result of appending  $[A|X]$  and  $Y$ , provided that  $Z$  is the result of appending  $X$  and  $Y$ . In most high-level languages we can write a similar recursive function that describes how to append two lists. The Prolog definition is actually more powerful, however, because it describes a *relation* that holds among three arguments, rather than a *function* computed from two arguments. For example, we can ask the query  $\text{append}(X, Y, [1, 2, 3])$ : what two lists can be appended to give  $[1, 2, 3]$ ? Prolog gives us back the solutions

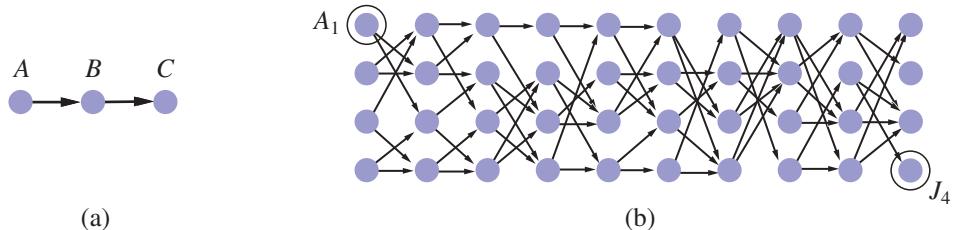

```
X=[]      Y=[1,2,3];
X=[1]      Y=[2,3];
X=[1,2]    Y=[3];
X=[1,2,3] Y=[]
```

The execution of Prolog programs is done through depth-first backward chaining, where clauses are tried in the order in which they are written in the knowledge base. Prolog’s design represents a compromise between declarativeness and execution efficiency. Some aspects of Prolog fall outside standard logical inference:

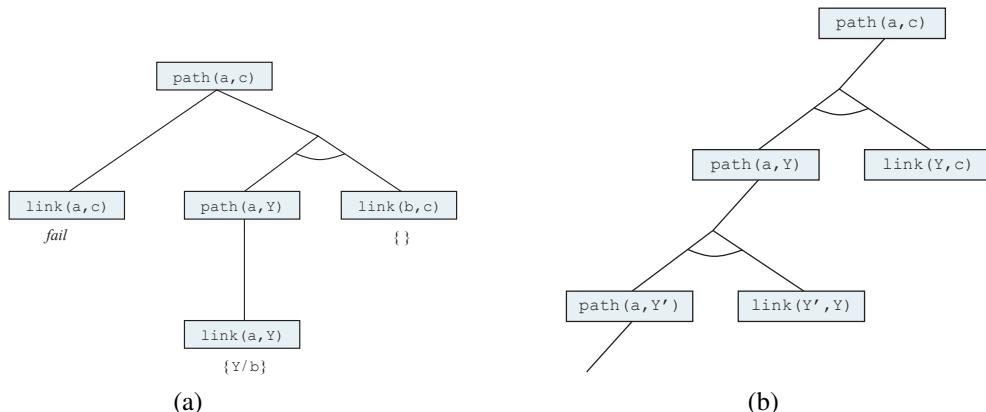

- Prolog uses the database semantics of Section 8.2.8 rather than first-order semantics, and this is apparent in its treatment of equality and negation (see Section 9.4.4).
- There is a set of built-in functions for arithmetic. Literals using these function symbols are “proved” by executing code rather than doing further inference. For example, the goal “ $X$  is  $4+3$ ” succeeds with  $X$  bound to 7. On the other hand, the goal “ $5$  is  $X+Y$ ” fails, because the built-in functions do not do arbitrary equation solving.
- There are built-in predicates that have side effects when executed. These include input–output predicates and the `assert/retract` predicates for modifying the knowledge base. Such predicates have no counterpart in logic and can produce confusing results—for example, if facts are asserted in a branch of the proof tree that eventually fails.
- The **occur check** is omitted from Prolog’s unification algorithm. This means that some unsound inferences can be made; these are almost never a problem in practice.
- Prolog uses depth-first backward-chaining search with no checks for infinite recursion. This makes for a usable programming language that is very fast when used properly, but it means that some programs that look like valid logic will fail to terminate.

### 9.4.3 Redundant inference and infinite loops

We now turn to the Achilles heel of Prolog: the mismatch between depth-first search and search trees that include repeated states and infinite paths. Consider the following logic program that decides if a path exists between two points on a directed graph:

**Figure 9.8** (a) Finding a path from A to C can lead Prolog into an infinite loop. (b) A graph in which each node is connected to two random successors in the next layer. Finding a path from  $A_1$  to  $J_4$  requires 877 inferences.

**Figure 9.9** (a) Proof that a path exists from  $A$  to  $C$ . (b) Infinite proof tree generated when the clauses are in the “wrong” order.

```
path(X,Z) :- link(X,Z).  
path(X,Z) :- path(X,Y), link(Y,Z).
```

A simple three-node graph, described by the facts `link(a,b)` and `link(b,c)`, is shown in Figure 9.8(a). With this program, the query `path(a,c)` generates the proof tree shown in Figure 9.9(a). On the other hand, if we put the two clauses in the order

```
path(X,Z) :- path(X,Y), link(Y,Z).  
path(X,Z) :- link(X,Z).
```

then Prolog follows the infinite path shown in Figure 9.9(b). Prolog is therefore **incomplete** as a theorem prover for definite clauses—even for Datalog programs, as this example shows—because, for some knowledge bases, it fails to prove sentences that are entailed. Notice that forward chaining does not suffer from this problem: once  $\text{path}(a,b)$ ,  $\text{path}(b,c)$ , and  $\text{path}(a,c)$  are inferred, forward chaining halts.

Depth-first backward chaining also has problems with redundant computations. For example, when finding a path from  $A_1$  to  $J_4$  in Figure 9.8(b), Prolog performs 877 inferences, most of which involve finding all possible paths to nodes from which the goal is unreachable. This is similar to the repeated-state problem discussed in Chapter 3. The total amount of

inference can be exponential in the number of ground facts that are generated. If we apply forward chaining instead, at most  $n^2$   $\text{path}(X, Y)$  facts can be generated linking  $n$  nodes. For the problem in Figure 9.8(b), only 62 inferences are needed.

Forward chaining on graph search problems is an example of **dynamic programming**, in which the solutions to subproblems are constructed incrementally from those of smaller subproblems and are cached to avoid recomputation. We can obtain a similar effect in a backward chaining system, except that here we are breaking down large goals into smaller ones, rather than building them up.

Either way, storing intermediate results to avoid duplication is key. This is the approach taken by **tabled logic programming** systems, which use efficient storage and retrieval mechanisms. Tabled logic programming combines the goal-directedness of backward chaining with the dynamic-programming efficiency of forward chaining. It is also complete for Data-log knowledge bases, which means that the programmer need worry less about infinite loops. (It is still possible to get an infinite loop with predicates like  $\text{father}(X, Y)$  that refer to a potentially unbounded number of objects.)

#### 9.4.4 Database semantics of Prolog

Prolog uses database semantics, as discussed in Section 8.2.8. The unique names assumption says that every Prolog constant and every ground term refers to a distinct object, and the closed world assumption says that the only sentences that are true are those that are entailed by the knowledge base. There is no way to assert that a sentence is false in Prolog. This makes Prolog less expressive than first-order logic, but it is part of what makes Prolog more efficient and more concise. Consider the following assertions about some course offerings:

$$\text{Course}(CS, 101), \text{Course}(CS, 102), \text{Course}(CS, 106), \text{Course}(EE, 101). \quad (9.11)$$

Under the unique names assumption, *CS* and *EE* are different (as are 101, 102, and 106), so this means that there are four distinct courses. Under the closed-world assumption there are no other courses, so there are exactly four courses. But if these were assertions in FOL rather than in database semantics, then all we could say is that there are somewhere between one and infinity courses. That's because the assertions (in FOL) do not deny the possibility that other unmentioned courses are also offered, nor do they say that the courses mentioned are different from each other. If we wanted to translate Equation (9.11) into FOL, we would get the following sentence:

$$\begin{aligned} \text{Course}(d, n) \Leftrightarrow & (d = CS \wedge n = 101) \vee (d = CS \wedge n = 102) \\ & \vee (d = CS \wedge n = 106) \vee (d = EE \wedge n = 101). \end{aligned} \quad (9.12)$$

This is called the **completion** of Equation (9.11). It expresses in FOL the idea that there are at most four courses. To express in FOL the idea that there are at least four courses, we need to write the completion of the equality predicate:

$$\begin{aligned} x = y \Leftrightarrow & (x = CS \wedge y = CS) \vee (x = EE \wedge y = EE) \vee (x = 101 \wedge y = 101) \\ & \vee (x = 102 \wedge y = 102) \vee (x = 106 \wedge y = 106). \end{aligned}$$

The completion is useful for understanding database semantics, but for practical purposes, if your problem can be described with database semantics, it is more efficient to reason with Prolog or some other database semantics system, rather than translating into FOL and reasoning with a full FOL theorem prover.

**Dynamic programming**

**Tabled logic programming**

**Completion**

### 9.4.5 Constraint logic programming

In our discussion of forward chaining (Section 9.3), we showed how constraint satisfaction problems (CSPs) can be encoded as definite clauses. Standard Prolog solves such problems in exactly the same way as the backtracking algorithm given in Figure 5.5.

Because backtracking enumerates the domains of the variables, it works only for **finite-domain** CSPs. In Prolog terms, there must be a finite number of solutions for any goal with unbound variables. (For example, a map coloring problem in which each variable can take on one of four different colors.) Infinite-domain CSPs—for example, with integer- or real-valued variables—require quite different algorithms, such as bounds propagation or linear programming.

Consider the following example. We define `triangle(X, Y, Z)` as a predicate that holds if the three arguments are numbers that satisfy the triangle inequality:

```
triangle(X, Y, Z) :-  
    X>0, Y>0, Z>0, X+Y>Z, Y+Z>X, X+Z>Y.
```

If we ask Prolog the query `triangle(3, 4, 5)`, it succeeds. On the other hand, if we ask `triangle(3, 4, Z)`, no solution will be found, because the subgoal `Z>0` cannot be handled by Prolog; we can't compare an unbound value to 0.

Constraint logic  
programming

**Constraint logic programming** (CLP) allows variables to be *constrained* rather than *bound*. A CLP solution is the most specific set of constraints on the query variables that can be derived from the knowledge base. For example, the solution to the `triangle(3, 4, Z)` query is the constraint  $7 > Z > 1$ . Standard logic programs are just a special case of CLP in which the solution constraints must be equality constraints—that is, bindings.

CLP systems incorporate various constraint-solving algorithms for the constraints allowed in the language. For example, a system that allows linear inequalities on real-valued variables might include a linear programming algorithm for solving those constraints. CLP systems also adopt a much more flexible approach to solving standard logic programming queries. For example, instead of depth-first, left-to-right backtracking, they might use any of the more efficient algorithms discussed in Chapter 5, including heuristic conjunct ordering, backjumping, cutset conditioning, and so on. CLP systems therefore combine elements of constraint satisfaction algorithms, logic programming, and deductive databases.

Metarule

Several systems that allow the programmer more control over the search order for inference have been defined. The MRS language (Genesereth and Smith, 1981; Russell, 1985) allows the programmer to write **metarules** to determine which conjuncts are tried first. The user could write a rule saying that the goal with the fewest variables should be tried first or could write domain-specific rules for particular predicates.

## 9.5 Resolution

The last of our three families of logical systems, and the only one that works for any knowledge base, not just definite clauses, is **resolution**. We saw on page 241 that propositional resolution is a complete inference procedure for propositional logic; in this section, we extend it to first-order logic.

### 9.5.1 Conjunctive normal form for first-order logic

The first step is to convert sentences to **conjunctive normal form** (CNF)—that is, a conjunction of clauses, where each clause is a disjunction of literals.<sup>5</sup> In CNF, literals can contain variables, which are assumed to be universally quantified. For example, the sentence

$$\forall x, y, z \text{ American}(x) \wedge \text{Weapon}(y) \wedge \text{Sells}(x, y, z) \wedge \text{Hostile}(z) \Rightarrow \text{Criminal}(x)$$

becomes, in CNF,

$$\neg \text{American}(x) \vee \neg \text{Weapon}(y) \vee \neg \text{Sells}(x, y, z) \vee \neg \text{Hostile}(z) \vee \text{Criminal}(x).$$

The key is that *Every sentence of first-order logic can be converted into an inferentially equivalent CNF sentence.* 

The procedure for conversion to CNF is similar to the propositional case, which we saw on page 244. The principal difference arises from the need to eliminate existential quantifiers. We illustrate the procedure by translating the sentence “Everyone who loves all animals is loved by someone,” or

$$\forall x [\forall y \text{ Animal}(y) \Rightarrow \text{Loves}(x, y)] \Rightarrow [\exists y \text{ Loves}(y, x)].$$

The steps are as follows:

- **Eliminate implications:** Replace  $P \Rightarrow Q$  with  $\neg P \vee Q$ . For our sample sentence, this needs to be done twice:

$$\begin{aligned} \forall x \neg [\forall y \text{ Animal}(y) \Rightarrow \text{Loves}(x, y)] \vee [\exists y \text{ Loves}(y, x)] \\ \forall x \neg [\forall y \neg \text{Animal}(y) \vee \text{Loves}(x, y)] \vee [\exists y \text{ Loves}(y, x)]. \end{aligned}$$

- **Move  $\neg$  inwards:** In addition to the usual rules for negated connectives, we need rules for negated quantifiers. Thus, we have

$$\begin{aligned} \neg \forall x p &\quad \text{becomes} & \exists x \neg p \\ \neg \exists x p &\quad \text{becomes} & \forall x \neg p. \end{aligned}$$

Our sentence goes through the following transformations:

$$\begin{aligned} \forall x [\exists y \neg (\neg \text{Animal}(y) \vee \text{Loves}(x, y))] \vee [\exists y \text{ Loves}(y, x)]. \\ \forall x [\exists y \neg \neg \text{Animal}(y) \wedge \neg \text{Loves}(x, y)] \vee [\exists y \text{ Loves}(y, x)]. \\ \forall x [\exists y \text{ Animal}(y) \wedge \neg \text{Loves}(x, y)] \vee [\exists y \text{ Loves}(y, x)]. \end{aligned}$$

Notice how a universal quantifier ( $\forall y$ ) in the premise of the implication has become an existential quantifier. The sentence now reads “Either there is some animal that  $x$  doesn’t love, or (if this is not the case) someone loves  $x$ .” Clearly, the meaning of the original sentence has been preserved.

- **Standardize variables:** For sentences like  $(\exists x P(x)) \vee (\exists x Q(x))$  that use the same variable name twice, change the name of one of the variables. This avoids confusion later when we drop the quantifiers. Thus, we have

$$\forall x [\exists y \text{ Animal}(y) \wedge \neg \text{Loves}(x, y)] \vee [\exists z \text{ Loves}(z, x)].$$

- **Skolemize:** **Skolemization** is the process of removing existential quantifiers by elimi-

[Skolemization](#)

<sup>5</sup> A clause can also be represented as an implication with a conjunction of atoms in the premise and a disjunction of atoms in the conclusion (Exercise 9.DISJ). This is called **implicative normal form** or **Kowalski form** (especially when written with a right-to-left implication symbol (Kowalski, 1979)) and is generally much easier to read than a disjunction with many negated literals.

nation. In the simple case, it is just like the Existential Instantiation rule of Section 9.1: translate  $\exists x P(x)$  into  $P(A)$ , where  $A$  is a new constant. However, we can't apply Existential Instantiation to our sentence above because it doesn't match the pattern  $\exists v \alpha$ ; only parts of the sentence match the pattern. If we blindly apply the rule to the two matching parts we get

$$\forall x [Animal(A) \wedge \neg Loves(x, A)] \vee Loves(B, x),$$

which has the wrong meaning entirely: it says that everyone either fails to love a particular animal  $A$  or is loved by some particular entity  $B$ . In fact, our original sentence allows each person to fail to love a different animal or to be loved by a different person. Thus, we want the Skolem entities to depend on  $x$ :

$$\forall x [Animal(F(x)) \wedge \neg Loves(x, F(x))] \vee Loves(G(x), x).$$

#### Skolem function

Here  $F$  and  $G$  are **Skolem functions**. The general rule is that the arguments of the Skolem function are all the universally quantified variables in whose scope the existential quantifier appears. As with Existential Instantiation, the Skolemized sentence is satisfiable exactly when the original sentence is satisfiable.

- **Drop universal quantifiers:** At this point, all remaining variables must be universally quantified. Therefore, we don't lose any information if we drop the quantifier:

$$[Animal(F(x)) \wedge \neg Loves(x, F(x))] \vee Loves(G(x), x).$$

- **Distribute  $\vee$  over  $\wedge$ :**

$$[Animal(F(x)) \vee Loves(G(x), x)] \wedge [\neg Loves(x, F(x)) \vee Loves(G(x), x)].$$

This step may also require flattening out nested conjunctions and disjunctions.

The sentence is now in CNF and consists of two clauses. It is much more difficult to read than the original sentence with implications. (It may help to explain that the Skolem function  $F(x)$  refers to the animal potentially unloved by  $x$ , whereas  $G(x)$  refers to someone who might love  $x$ .) Fortunately, humans seldom need to look at CNF sentences—the translation process is easily automated.

### 9.5.2 The resolution inference rule

The resolution rule for first-order clauses is simply a lifted version of the propositional resolution rule given on page 244. Two clauses, which are assumed to be standardized apart so that they share no variables, can be resolved if they contain complementary literals. Propositional literals are complementary if one is the negation of the other; first-order literals are complementary if one *unifies with* the negation of the other. Thus, we have

$$\frac{\ell_1 \vee \cdots \vee \ell_k, \quad m_1 \vee \cdots \vee m_n}{\text{SUBST}(\theta, \ell_1 \vee \cdots \vee \ell_{i-1} \vee \ell_{i+1} \vee \cdots \vee \ell_k \vee m_1 \vee \cdots \vee m_{j-1} \vee m_{j+1} \vee \cdots \vee m_n)}$$

where  $\text{UNIFY}(\ell_i, \neg m_j) = \theta$ . For example, we can resolve the two clauses

$$[Animal(F(x)) \vee Loves(G(x), x)] \quad \text{and} \quad [\neg Loves(u, v) \vee \neg Kills(u, v)]$$

by eliminating the complementary literals  $Loves(G(x), x)$  and  $\neg Loves(u, v)$ , with the unifier  $\theta = \{u/G(x), v/x\}$ , to produce the **resolvent** clause

$$[Animal(F(x)) \vee \neg Kills(G(x), x)].$$

#### Binary resolution

This rule is called the **binary resolution** rule because it resolves exactly two literals. The

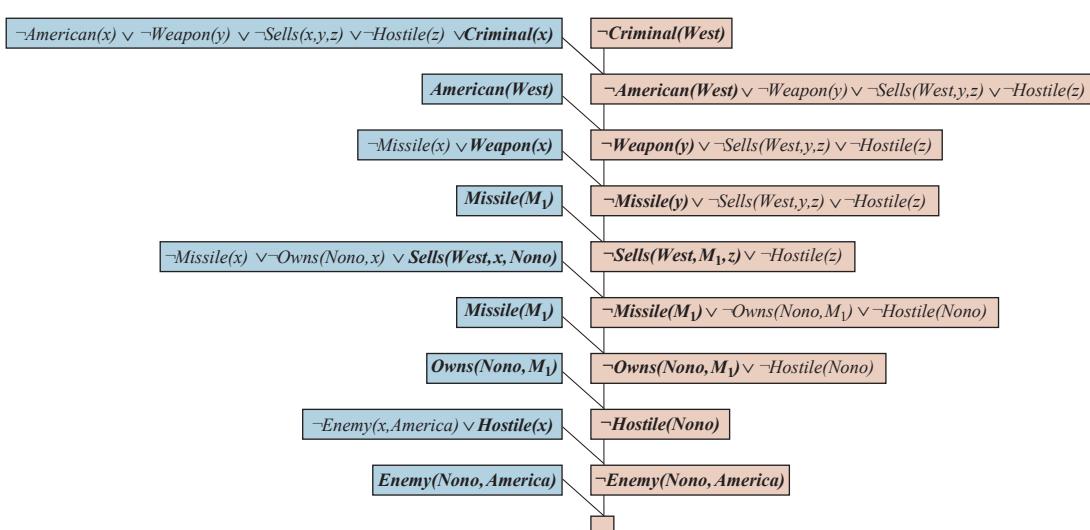

binary resolution rule by itself does not yield a complete inference procedure. The full resolution rule resolves subsets of literals in each clause that are unifiable. An alternative approach is to extend **factoring**—the removal of redundant literals—to the first-order case. Propositional factoring reduces two literals to one if they are *identical*; first-order factoring reduces two literals to one if they are *unifiable*. The unifier must be applied to the entire clause. The combination of binary resolution and factoring is complete.

### 9.5.3 Example proofs

Resolution proves that  $KB \models \alpha$  by proving that  $KB \wedge \neg\alpha$  unsatisfiable—that is, by deriving the empty clause. The algorithmic approach is identical to the propositional case, described in Figure 7.13, so we need not repeat it here. Instead, we give two example proofs. The first is the crime example from Section 9.3. The sentences in CNF are

$$\begin{array}{ll} \neg\text{American}(x) \vee \neg\text{Weapon}(y) \vee \neg\text{Sells}(x,y,z) \vee \neg\text{Hostile}(z) \vee \text{Criminal}(x) & \\ \neg\text{Missile}(x) \vee \neg\text{Owns}(\text{Nono},x) \vee \text{Sells}(\text{West},x,\text{Nono}) & \\ \neg\text{Enemy}(x,\text{America}) \vee \text{Hostile}(x) & \\ \neg\text{Missile}(x) \vee \text{Weapon}(x) & \\ \text{Owns}(\text{Nono},M_1) & \text{Missile}(M_1) \\ \text{American}(\text{West}) & \text{Enemy}(\text{Nono},\text{America}). \end{array}$$

We also include the negated goal  $\neg\text{Criminal}(\text{West})$ . The resolution proof is shown in Figure 9.10. Notice the structure: single “spine” beginning with the goal clause, resolving against clauses from the knowledge base until the empty clause is generated. This is characteristic of resolution on Horn clause knowledge bases. In fact, the clauses along the main spine correspond *exactly* to the consecutive values of the *goals* variable in the backward-chaining algorithm of Figure 9.6. This is because we always choose to resolve with a clause whose positive literal unifies with the leftmost literal of the “current” clause on the spine; this is

**Figure 9.10** A resolution proof that West is a criminal. At each resolution step, the literals that unify are in bold and the clause with the positive literal is shaded blue.

exactly what happens in backward chaining. Thus, backward chaining is just a special case of resolution with a particular control strategy to decide which resolution to perform next.

Our second example makes use of Skolemization and involves clauses that are not definite clauses. This results in a somewhat more complex proof structure. In English:

- Everyone who loves all animals is loved by someone.
- Anyone who kills an animal is loved by no one.
- Jack loves all animals.
- Either Jack or Curiosity killed the cat, who is named Tuna.
- Did Curiosity kill the cat?

First, we express the original sentences, some background knowledge, and the negated goal G in first-order logic:

- A.  $\forall x [\forall y \text{Animal}(y) \Rightarrow \text{Loves}(x,y)] \Rightarrow [\exists y \text{Loves}(y,x)]$
- B.  $\forall x [\exists z \text{Animal}(z) \wedge \text{Kills}(x,z)] \Rightarrow [\forall y \neg \text{Loves}(y,x)]$
- C.  $\forall x \text{Animal}(x) \Rightarrow \text{Loves}(\text{Jack},x)$
- D.  $\text{Kills}(\text{Jack},\text{Tuna}) \vee \text{Kills}(\text{Curiosity},\text{Tuna})$
- E.  $\text{Cat}(\text{Tuna})$
- F.  $\forall x \text{Cat}(x) \Rightarrow \text{Animal}(x)$
- $\neg G. \neg \text{Kills}(\text{Curiosity},\text{Tuna})$

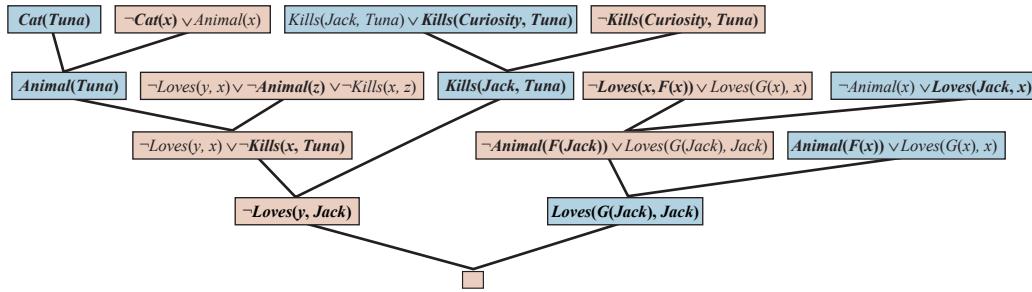

Now we apply the conversion procedure to convert each sentence to CNF:

- A1.  $\text{Animal}(F(x)) \vee \text{Loves}(G(x),x)$
- A2.  $\neg \text{Loves}(x,F(x)) \vee \text{Loves}(G(x),x)$
- B.  $\neg \text{Loves}(y,x) \vee \neg \text{Animal}(z) \vee \neg \text{Kills}(x,z)$
- C.  $\neg \text{Animal}(x) \vee \text{Loves}(\text{Jack},x)$
- D.  $\text{Kills}(\text{Jack},\text{Tuna}) \vee \text{Kills}(\text{Curiosity},\text{Tuna})$
- E.  $\text{Cat}(\text{Tuna})$
- F.  $\neg \text{Cat}(x) \vee \text{Animal}(x)$
- $\neg G. \neg \text{Kills}(\text{Curiosity},\text{Tuna})$

The resolution proof that Curiosity killed the cat is given in Figure 9.11. In English, the proof could be paraphrased as follows:

Suppose Curiosity did not kill Tuna. We know that either Jack or Curiosity did; thus Jack must have. Now, Tuna is a cat and cats are animals, so Tuna is an animal. Because anyone who kills an animal is loved by no one, we know that no one loves Jack. On the other hand, Jack loves all animals, so someone loves him; so we have a contradiction. Therefore, Curiosity killed the cat.

The proof answers the question “Did Curiosity kill the cat?” but often we want to pose more general questions, such as “Who killed the cat?” Resolution can do this, but it takes a little more work to obtain the answer. The goal is  $\exists w \text{Kills}(w,\text{Tuna})$ , which, when negated, becomes  $\neg \text{Kills}(w,\text{Tuna})$  in CNF. Repeating the proof in Figure 9.11 with the new negated goal, we obtain a similar proof tree, but with the substitution  $\{w/\text{Curiosity}\}$  in one of the steps. So, in this case, finding out who killed the cat is just a matter of keeping track of the bindings for the query variables in the proof. Unfortunately, resolution can sometimes produce **nonconstructive proofs** for existential goals, where we know a query is true, but there isn’t a unique binding for the variable.

**Figure 9.11** A resolution proof that Curiosity killed the cat. Notice the use of factoring in the derivation of the clause  $\text{Loves}(\text{G}(\text{Jack}), \text{Jack})$ . Notice also in the upper right, the unification of  $\text{Loves}(x, F(x))$  and  $\text{Loves}(\text{Jack}, x)$  can only succeed after the variables have been standardized apart.

#### 9.5.4 Completeness of resolution

This section gives a completeness proof of resolution. It can be safely skipped by those who are willing to take it on faith.

We show that resolution is **refutation-complete**, which means that if a set of sentences is unsatisfiable, then resolution will always be able to derive a contradiction. Resolution cannot be used to generate all logical consequences of a set of sentences, but it can be used to establish that a given sentence is entailed by the set of sentences. Hence, it can be used to find all answers to a given question,  $Q(x)$ , by proving that  $KB \wedge \neg Q(x)$  is unsatisfiable.

We take it as given that any sentence in first-order logic (without equality) can be rewritten as a set of clauses in CNF. This can be proved by induction on the form of the sentence, using atomic sentences as the base case (Davis and Putnam, 1960). Our goal therefore is to prove the following: *if  $S$  is an unsatisfiable set of clauses, then the application of a finite number of resolution steps to  $S$  will yield a contradiction.* ◀

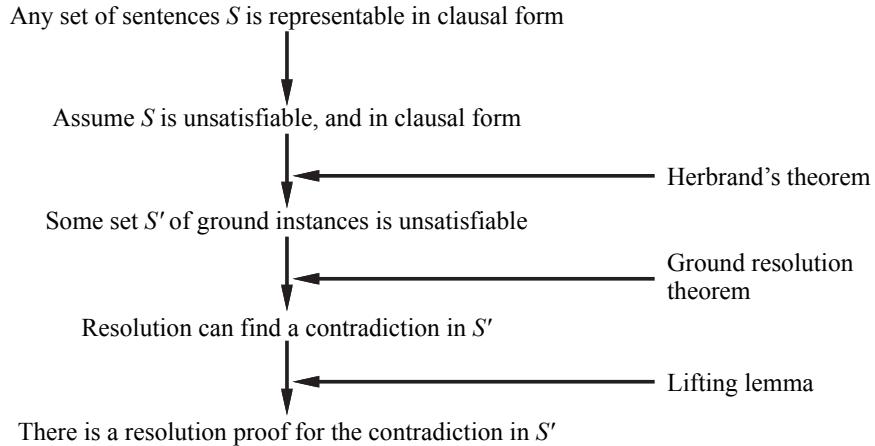

Our proof sketch follows Robinson's original proof with some simplifications from Genesereth and Nilsson (1987). The basic structure of the proof (Figure 9.12) is as follows:

1. First, we observe that if  $S$  is unsatisfiable, then there exists a particular set of *ground instances* of the clauses of  $S$  such that this set is also unsatisfiable (Herbrand's theorem).
2. We then appeal to the **ground resolution theorem** given in Chapter 7, which states that propositional resolution is complete for ground sentences.
3. We then use a **lifting lemma** to show that, for any propositional resolution proof using the set of ground sentences, there is a corresponding first-order resolution proof using the first-order sentences from which the ground sentences were obtained.

To carry out the first step, we need three new concepts:

- **Herbrand universe:** If  $S$  is a set of clauses, then  $H_S$ , the Herbrand universe of  $S$ , is the set of all ground terms constructible from the following:
  - a. The function symbols in  $S$ , if any.
  - b. The constant symbols in  $S$ , if any; if none, then a default constant symbol,  $S$ .

Refutation completeness

**Figure 9.12** Structure of a completeness proof for resolution.

For example, if  $S$  contains just the clause  $\neg P(x, F(x, A)) \vee \neg Q(x, A) \vee R(x, B)$ , then  $H_S$  is the following infinite set of ground terms:

$$\{A, B, F(A, A), F(A, B), F(B, A), F(B, B), F(A, F(A, A)), \dots\}.$$

Saturation

- **Saturation:** If  $S$  is a set of clauses and  $P$  is a set of ground terms, then  $P(S)$ , the saturation of  $S$  with respect to  $P$ , is the set of all ground clauses obtained by applying all possible consistent substitutions of ground terms in  $P$  for variables in  $S$ .
- **Herbrand base:** The saturation of a set  $S$  of clauses with respect to its Herbrand universe is called the Herbrand base of  $S$ , written as  $H_S(S)$ . For example, if  $S$  contains solely the clause given above, then  $H_S(S)$  is the infinite set of clauses

$$\begin{aligned} &\{\neg P(A, F(A, A)) \vee \neg Q(A, A) \vee R(A, B), \\ &\quad \neg P(B, F(B, A)) \vee \neg Q(B, A) \vee R(B, B), \\ &\quad \neg P(F(A, A), F(F(A, A), A)) \vee \neg Q(F(A, A), A) \vee R(F(A, A), B), \\ &\quad \neg P(F(A, B), F(F(A, B), A)) \vee \neg Q(F(A, B), A) \vee R(F(A, B), B), \dots\} \end{aligned}$$

Herbrand's theorem

These definitions allow us to state a form of **Herbrand's theorem** (Herbrand, 1930):

If a set  $S$  of clauses is unsatisfiable, then there exists a finite subset of  $H_S(S)$  that is also unsatisfiable.

Let  $S'$  be this finite subset of ground sentences. Now, we can appeal to the ground resolution theorem (page 246) to show that the **resolution closure**  $RC(S')$  contains the empty clause. That is, running propositional resolution to completion on  $S'$  will derive a contradiction.

Now that we have established that there is always a resolution proof involving some finite subset of the Herbrand base of  $S$ , the next step is to show that there is a resolution proof using the clauses of  $S$  itself, which are not necessarily ground clauses. We start by considering a single application of the resolution rule. Robinson stated this lemma:

Let  $C_1$  and  $C_2$  be two clauses with no shared variables, and let  $C'_1$  and  $C'_2$  be ground instances of  $C_1$  and  $C_2$ . If  $C'$  is a resolvent of  $C'_1$  and  $C'_2$ , then there exists a clause  $C$  such that (1)  $C$  is a resolvent of  $C_1$  and  $C_2$  and (2)  $C'$  is a ground instance of  $C$ .

## Gödel's Incompleteness Theorem

By slightly extending the language of first-order logic to allow for the **mathematical induction schema** in arithmetic, Kurt Gödel was able to show, in his **incompleteness theorem**, that there are true arithmetic sentences that cannot be proved.

The proof of the incompleteness theorem is somewhat beyond the scope of this book, occupying, as it does, at least 30 pages, but we can give a hint here. We begin with the logical theory of numbers. In this theory, there is a single constant, 0, and a single function,  $S$  (the successor function). In the intended model,  $S(0)$  denotes 1,  $S(S(0))$  denotes 2, and so on; the language therefore has names for all the natural numbers. The vocabulary also includes the function symbols  $+$ ,  $\times$ , and  $Expt$  (exponentiation) and the usual set of logical connectives and quantifiers.

The first step is to notice that the set of sentences that we can write in this language can be enumerated. (Imagine defining an alphabetical order on the symbols and then arranging, in alphabetical order, each of the sets of sentences of length 1, 2, and so on.) We can then number each sentence  $\alpha$  with a unique natural number  $\#\alpha$  (the **Gödel number**). This is crucial: number theory contains a name for each of its own sentences. Similarly, we can number each possible proof  $P$  with a Gödel number  $G(P)$ , because a proof is simply a finite sequence of sentences.

Now suppose we have a recursively enumerable set  $A$  of sentences that are true statements about the natural numbers. Recalling that  $A$  can be named by a given set of integers, we can imagine writing in our language a sentence  $\alpha(j, A)$  of the following sort:

$$\forall i \ i \text{ is not the Gödel number of a proof of the sentence whose Gödel number is } j, \text{ where the proof uses only premises in } A.$$

Then let  $\sigma$  be the sentence  $\alpha(\#\sigma, A)$ , that is, a sentence that states its own unprovability from  $A$ . (That this sentence always exists is true but not entirely obvious.)

Now we make the following ingenious argument: Suppose that  $\sigma$  is provable from  $A$ ; then  $\sigma$  is false (because  $\sigma$  says it cannot be proved). But then we have a false sentence that is provable from  $A$ , so  $A$  cannot consist of only true sentences—a violation of our premise. Therefore,  $\sigma$  is not provable from  $A$ . But this is exactly what  $\sigma$  itself claims; hence  $\sigma$  is a true sentence.

So, we have shown (barring  $29\frac{1}{2}$  pages) that for any set of true sentences of number theory, and in particular any set of basic axioms, there are other true sentences that *cannot* be proved from those axioms. This establishes, among other things, that we can never prove all the theorems of mathematics *within any given system of axioms*. Clearly, this was an important discovery for mathematics. Its significance for AI has been widely debated, beginning with speculations by Gödel himself. We take up the debate in Chapter 28.

## Lifting lemma

This is called a **lifting lemma**, because it lifts a proof step from ground clauses up to general first-order clauses. In order to prove his basic lifting lemma, Robinson had to invent unification and derive all of the properties of most general unifiers. Rather than repeat the proof here, we simply illustrate the lemma:

$$\begin{aligned} C_1 &= \neg P(x, F(x, A)) \vee \neg Q(x, A) \vee R(x, B) \\ C_2 &= \neg N(G(y), z) \vee P(H(y), z) \\ C'_1 &= \neg P(H(B), F(H(B), A)) \vee \neg Q(H(B), A) \vee R(H(B), B) \\ C'_2 &= \neg N(G(B), F(H(B), A)) \vee P(H(B), F(H(B), A)) \\ C' &= \neg N(G(B), F(H(B), A)) \vee \neg Q(H(B), A) \vee R(H(B), B) \\ C &= \neg N(G(y), F(H(y), A)) \vee \neg Q(H(y), A) \vee R(H(y), B). \end{aligned}$$

We see that indeed  $C'$  is a ground instance of  $C$ . In general, for  $C'_1$  and  $C'_2$  to have any resolvents, they must be constructed by first applying to  $C_1$  and  $C_2$  the most general unifier of a pair of complementary literals in  $C_1$  and  $C_2$ . From the lifting lemma, it is easy to derive a similar statement about any sequence of applications of the resolution rule:

For any clause  $C'$  in the resolution closure of  $S'$  there is a clause  $C$  in the resolution closure of  $S$  such that  $C'$  is a ground instance of  $C$  and the derivation of  $C$  is the same length as the derivation of  $C'$ .

From this fact, it follows that if the empty clause appears in the resolution closure of  $S'$ , it must also appear in the resolution closure of  $S$ . This is because the empty clause cannot be a ground instance of any other clause. To recap: we have shown that if  $S$  is unsatisfiable, then there is a finite derivation of the empty clause using the resolution rule.

The lifting of theorem proving from ground clauses to first-order clauses provides a vast increase in power. This increase comes from the fact that the first-order proof need instantiate variables only as far as necessary for the proof, whereas the ground-clause methods were required to examine a huge number of arbitrary instantiations.

### 9.5.5 Equality

None of the inference methods described so far in this chapter can handle an assertion of the form  $x = y$  without some additional work. Three distinct approaches can be taken. The first is to axiomatize equality—to write down sentences about the equality relation in the knowledge base. We need to say that equality is reflexive, symmetric, and transitive, and we also have to say that we can substitute equals for equals in any predicate or function. So we need three basic axioms, and then one for each predicate and function:

$$\begin{aligned} &\forall x \ x=x \\ &\forall x, y \ x=y \Rightarrow y=x \\ &\forall x, y, z \ x=y \wedge y=z \Rightarrow x=z \\ &\forall x, y \ x=y \Rightarrow (P_1(x) \Leftrightarrow P_1(y)) \\ &\forall x, y \ x=y \Rightarrow (P_2(x) \Leftrightarrow P_2(y)) \\ &\vdots \\ &\forall w, x, y, z \ w=y \wedge x=z \Rightarrow (F_1(w, x)=F_1(y, z)) \\ &\forall w, x, y, z \ w=y \wedge x=z \Rightarrow (F_2(w, x)=F_2(y, z)) \\ &\vdots \end{aligned}$$

Given these sentences, a standard inference procedure such as resolution can perform tasks requiring equality reasoning, such as solving mathematical equations. However, these axioms will generate a lot of conclusions, most of them not helpful to a proof. So the second approach is to add inference rules rather than axioms. The simplest rule, **demodulation**, takes a unit clause  $x=y$  and some clause  $\alpha$  that contains the term  $x$ , and yields a new clause formed by substituting  $y$  for  $x$  within  $\alpha$ . It works if the term within  $\alpha$  unifies with  $x$ ; it need not be exactly equal to  $x$ . Note that demodulation is directional; given  $x=y$ , the  $x$  always gets replaced with  $y$ , never vice versa. That means that demodulation can be used for simplifying expressions using demodulators such as  $z+0=z$  or  $z^1=z$ . As another example, given

$$\text{Father}(\text{Father}(x)) = \text{PaternalGrandfather}(x)$$

$$\text{Birthdate}(\text{Father}(\text{Father}(\text{Bella})), 1926)$$

we can conclude by demodulation

$$\text{Birthdate}(\text{PaternalGrandfather}(\text{Bella}), 1926).$$

More formally, we have

- **Demodulation:** For any terms  $x$ ,  $y$ , and  $z$ , where  $z$  appears somewhere in literal  $m_i$  and where  $\text{UNIFY}(x, z) = \theta \neq \text{failure}$ ,

$$\frac{x=y, \quad m_1 \vee \cdots \vee m_n}{\text{SUB}(\text{SUBST}(\theta, x), \text{SUBST}(\theta, y), m_1 \vee \cdots \vee m_n)}.$$

where  $\text{SUBST}$  is the usual substitution of a binding list, and  $\text{SUB}(x, y, m)$  means to replace  $x$  with  $y$  somewhere within  $m$ .

The rule can also be extended to handle non-unit clauses in which an equal sign appears:

- **Paramodulation:** For any terms  $x$ ,  $y$ , and  $z$ , where  $z$  appears somewhere in literal  $m_i$ , and where  $\text{UNIFY}(x, z) = \theta$ ,

$$\frac{\ell_1 \vee \cdots \vee \ell_k \vee x=y, \quad m_1 \vee \cdots \vee m_n}{\text{SUB}(\text{SUBST}(\theta, x), \text{SUBST}(\theta, y), \text{SUBST}(\theta, \ell_1 \vee \cdots \vee \ell_k \vee m_1 \vee \cdots \vee m_n))}.$$

For example, from

$$P(F(x, B), x) \vee Q(x) \quad \text{and} \quad F(A, y) = y \vee R(y)$$

we have  $\theta = \text{UNIFY}(F(A, y), F(x, B)) = \{x/A, y/B\}$ , and we can conclude by paramodulation the sentence

$$P(B, A) \vee Q(A) \vee R(B).$$

Paramodulation yields a complete inference procedure for first-order logic with equality.

A third approach handles equality reasoning entirely within an extended unification algorithm. That is, terms are unifiable if they are *provably* equal under some substitution, where “provably” allows for equality reasoning. For example, the terms  $1+2$  and  $2+1$  normally are not unifiable, but a unification algorithm that knows that  $x+y=y+x$  could unify them with the empty substitution. **Equational unification** of this kind can be done with efficient algorithms designed for the particular axioms used (commutativity, associativity, and so on) rather than through explicit inference with those axioms. Theorem provers using this technique are closely related to the CLP systems described in Section 9.4.

### 9.5.6 Resolution strategies

We know that repeated applications of the resolution inference rule will eventually find a proof if one exists. In this subsection, we examine strategies that help find proofs *efficiently*.

#### Unit preference

**Unit preference:** This strategy prefers to do resolutions where one of the sentences is a single literal (also known as a **unit clause**). The idea behind the strategy is that we are trying to produce an empty clause, so it might be a good idea to prefer inferences that produce shorter clauses. Resolving a unit sentence (such as  $P$ ) with any other sentence (such as  $\neg P \vee \neg Q \vee R$ ) always yields a clause (in this case,  $\neg Q \vee R$ ) that is shorter than the other clause. When the unit preference strategy was first tried for propositional inference in 1964, it led to a dramatic speedup, making it feasible to prove theorems that could not be handled without the preference. **Unit resolution** is a restricted form of resolution in which every resolution step must involve a unit clause. Unit resolution is incomplete in general, but complete for Horn clauses. Unit resolution proofs on Horn clauses resemble forward chaining.

The OTTER theorem prover (McCune, 1990), uses a form of best-first search. Its heuristic function measures the “weight” of each clause, where lighter clauses are preferred. The exact choice of heuristic is up to the user, but generally, the weight of a clause should be correlated with its size or difficulty. Unit clauses are treated as light; the search can thus be seen as a generalization of the unit preference strategy.

#### Set of support

**Set of support:** Preferences that try certain resolutions first are helpful, but in general it is more effective to try to eliminate some potential resolutions altogether. For example, we can insist that every resolution step involve at least one element of a special set of clauses—the *set of support*. The resolvent is then added into the set of support. If the set of support is small relative to the whole knowledge base, the search space will be reduced dramatically.

To ensure completeness of this strategy, we can choose the set of support  $S$  so that the remainder of the sentences are jointly satisfiable. For example, one can use the negated query as the set of support, on the assumption that the original knowledge base is consistent. (After all, if it is not consistent, then the fact that the query follows from it is vacuous.) The set-of-support strategy has the additional advantage of generating goal-directed proof trees that are often easy for humans to understand.

#### Input resolution

**Input resolution:** In this strategy, every resolution combines one of the input sentences (from the KB or the query) with some other sentence. The proof in Figure 9.10 on page 319 uses only input resolutions and has the characteristic shape of a single “spine” with single sentences combining onto the spine. Clearly, the space of proof trees of this shape is smaller than the space of all proof graphs. In Horn knowledge bases, Modus Ponens is a kind of input resolution strategy, because it combines an implication from the original KB with some other sentences. Thus, it is no surprise that input resolution is complete for knowledge bases that are in Horn form, but incomplete in the general case. The **linear resolution** strategy is a slight generalization that allows  $P$  and  $Q$  to be resolved together either if  $P$  is in the original KB or if  $P$  is an ancestor of  $Q$  in the proof tree. Linear resolution is complete.

#### Linear resolution

**Subsumption:** The subsumption method eliminates all sentences that are subsumed by (that is, more specific than) an existing sentence in the KB. For example, if  $P(x)$  is in the KB, then there is no sense in adding  $P(A)$  and even less sense in adding  $P(A) \vee Q(B)$ . Subsumption helps keep the KB small and thus helps keep the search space small.

#### Subsumption

**Learning:** We can improve a theorem prover by learning from experience. Given a collection of previously-proved theorems, train a machine learning system to answer the question: given a set of premises and a goal to prove, what proof steps are similar to steps that were successful in the past? The DEEP HOL system (Bansal *et al.*, 2019) does exactly that, using deep neural networks (see Chapter 22) to build models (called *embeddings*) of goals and premises, and using them to make selections. Training can use both human- and computer-generated proofs as examples, starting from a collection of 10,000 proofs.

Learning

### Practical uses of resolution theorem provers

We have shown how first-order logic can represent a simple real-world scenario involving concepts like selling, weapons, and citizenship. But complex real-world scenarios have too much uncertainty and too many unknowns. Logic has proven to be more successful for scenarios involving formal, strictly defined concepts, such as the **synthesis** and **verification** of both hardware and software. Theorem-proving research is carried out in the fields of hardware design, programming languages, and software engineering—not just in AI.

Synthesis  
Verification

In the case of hardware, the axioms describe the interactions between signals and circuit elements. (See Section 8.4.2 on page 291 for an example.) Logical reasoners designed specially for verification have been able to verify entire CPUs, including their timing properties (Sivas and Bickford, 1990). The AURA theorem prover has been applied to design circuits that are more compact than any previous design (Wojciechowski and Wojcik, 1983).

In the case of software, reasoning about programs is quite similar to reasoning about actions, as in Chapter 7: axioms describe the preconditions and effects of each statement. The formal synthesis of algorithms was one of the first uses of theorem provers, as outlined by Cordell Green (1969a), who built on earlier ideas by Herbert Simon (1963). The idea is to constructively prove a theorem to the effect that “there exists a program  $p$  satisfying a certain specification.” Although fully automated **deductive synthesis**, as it is called, has not yet become feasible for general-purpose programming, hand-guided deductive synthesis has been successful in designing several novel and sophisticated algorithms. Synthesis of special-purpose programs, such as scientific computing code, is also an active area of research.

Similar techniques are now being applied to software verification by systems such as the SPIN model checker (Holzmann, 1997). For example, the Remote Agent spacecraft control program was verified before and after flight (Havelund *et al.*, 2000). The RSA public key encryption algorithm and the Boyer–Moore string-matching algorithm have been verified this way (Boyer and Moore, 1984).

## Summary

---

We have presented an analysis of logical inference in first-order logic and a number of algorithms for doing it.

- A first approach uses inference rules (**universal instantiation** and **existential instantiation**) to **propositionalize** the inference problem. Typically, this approach is slow, unless the domain is small.
- The use of **unification** to identify appropriate substitutions for variables eliminates the instantiation step in first-order proofs, making the process more efficient in many cases.

- A lifted version of **Modus Ponens** uses unification to provide a natural and powerful inference rule, **generalized Modus Ponens**. The **forward-chaining** and **backward-chaining** algorithms apply this rule to sets of definite clauses.
- Generalized Modus Ponens is complete for definite clauses, although the entailment problem is **semidecidable**. For **Datalog** knowledge bases consisting of function-free definite clauses, entailment is decidable.
- Forward chaining is used in **deductive databases**, where it can be combined with relational database operations. It is also used in **production systems**, which perform efficient updates with very large rule sets. Forward chaining is complete for Datalog and runs in polynomial time.
- Backward chaining is used in **logic programming systems**, which employ sophisticated compiler technology to provide very fast inference. Backward chaining suffers from redundant inferences and infinite loops; these can be alleviated by **memoization**.
- **Prolog**, unlike first-order logic, uses a closed world with the unique names assumption and negation as failure. These make Prolog a more practical programming language, but bring it further from pure logic.
- The generalized **resolution** inference rule provides a complete proof system for first-order logic, using knowledge bases in conjunctive normal form.
- Several strategies exist for reducing the search space of a resolution system without compromising completeness. One of the most important issues is dealing with equality; we showed how **demodulation** and **paramodulation** can be used.
- Efficient resolution-based theorem provers have been used to prove interesting mathematical theorems and to verify and synthesize software and hardware.

## Bibliographical and Historical Notes

---

Gottlob Frege, who developed full first-order logic in 1879, based his system of inference on a collection of valid schemas plus a single inference rule, Modus Ponens. Whitehead and Russell (1910) expounded the so-called *rules of passage* (the actual term is from Herbrand (1930)) that are used to move quantifiers to the front of formulas. Skolem constants and Skolem functions were introduced, appropriately enough, by Thoralf Skolem (1920). Oddly enough, it was Skolem who introduced the Herbrand universe (Skolem, 1928).

Herbrand's theorem (Herbrand, 1930) has played a vital role in the development of automated reasoning. Herbrand is also the inventor of **unification**. Gödel (1930) built on the ideas of Skolem and Herbrand to show that first-order logic has a complete proof procedure. Alan Turing (1936) and Alonzo Church (1936) simultaneously showed, using very different proofs, that validity in first-order logic was not decidable. The excellent text by Enderton (1972) explains all of these results in a rigorous yet understandable fashion.

Abraham Robinson proposed that an automated reasoner could be built using propositionalization and Herbrand's theorem, and Paul Gilmore (1960) wrote the first program. Davis and Putnam (1960) introduced the propositionalization method of Section 9.1. Prawitz (1960) developed the key idea of letting the quest for propositional inconsistency drive the search, and generating terms from the Herbrand universe only when they were necessary to estab-

lish propositional inconsistency. This idea led John Alan Robinson (no relation) to develop resolution (Robinson, 1965).

Resolution was adopted for question-answering systems by Cordell Green and Bertram Raphael (1968). Early AI implementations put a good deal of effort into data structures that would allow efficient retrieval of facts; this work is covered in AI programming texts (Charniak *et al.*, 1987; Norvig, 1992; Forbus and de Kleer, 1993). By the early 1970s, **forward chaining** was well established in AI as an easily understandable alternative to resolution. AI applications typically involved large numbers of rules, so it was important to develop efficient rule-matching technology, particularly for incremental updates.

The technology for **production systems** was developed to support such applications. The production system language OPS-5 (Forgy, 1981; Brownston *et al.*, 1985), incorporating the efficient Rete match process (Forgy, 1982), was used for applications such as the R1 expert system for minicomputer configuration (McDermott, 1982). Kraska *et al.* (2017) describe how neural nets can learn an efficient indexing scheme for specific data sets.

The SOAR cognitive architecture (Laird *et al.*, 1987; Laird, 2008) was designed to handle very large rule sets—up to a million rules (Doorenbos, 1994). Example applications of SOAR include controlling simulated fighter aircraft (Jones *et al.*, 1998), airspace management (Taylor *et al.*, 2007), AI characters for computer games (Winternmute *et al.*, 2007), and training tools for soldiers (Wray and Jones, 2005).

The field of **deductive databases** began with a workshop in Toulouse in 1977 attended by experts in logical inference and databases (Gallaire and Minker, 1978). Influential work by Chandra and Harel (1980) and Ullman (1985) led to the adoption of **Datalog** as a standard language for deductive databases. The development of the **magic sets** technique for rule rewriting by Bancilhon *et al.* (1986) allowed forward chaining to borrow the advantage of goal-directedness from backward chaining.

The rise of the Internet led to increased availability of massive online databases. This drove increased interest in integrating multiple databases into a consistent dataspace (Halevy, 2007). Kraska *et al.* (2017) showed speedups of up to 70% by using machine learning to create **learned index structures** for efficient data lookup.

**Backward chaining** for logical inference originated in the **PLANNER** language (Hewitt, 1969). Meanwhile, in 1972, Alain Colmerauer had developed and implemented **Prolog** for the purpose of parsing natural language—Prolog’s clauses were intended initially as context-free grammar rules (Roussel, 1975; Colmerauer *et al.*, 1973).

Much of the theoretical background for logic programming was developed by Robert Kowalski at Imperial College London, working with Colmerauer; see Kowalski (1988) and Colmerauer and Roussel (1993) for a historical overview. Efficient Prolog compilers are generally based on the Warren Abstract Machine (WAM) model of computation developed by David H. D. Warren (1983). Van Roy (1990) showed that Prolog programs can be competitive with C programs in terms of speed.

Methods for avoiding unnecessary looping in recursive logic programs were developed independently by Smith *et al.* (1986) and Tamaki and Sato (1986). The latter paper also included memoization for logic programs, a method developed extensively as **tailed logic programming** by David S. Warren. Swift and Warren (1994) show how to extend the WAM to handle tabling, enabling Datalog programs to execute an order of magnitude faster than forward-chaining deductive database systems.

Early work on constraint logic programming was done by Jaffar and Lassez (1987). Jaffar *et al.* (1992) developed the CLP(R) system for handling real-valued constraints. There are now commercial products for solving large-scale configuration and optimization problems with constraint programming; one of the best known is ILOG (Junker, 2003). Answer set programming (Gelfond, 2008) extends Prolog, allowing disjunction and negation.

Texts on logic programming and Prolog include Shoham (1994), Bratko (2009), Clocksin (2003), and Clocksin and Mellish (2003). Prior to 2000, the *Journal of Logic Programming* was the journal of record; it has been replaced by *Theory and Practice of Logic Programming*. Logic programming conferences include the International Conference on Logic Programming (ICLP) and the International Logic Programming Symposium (ILPS).

Research into **mathematical theorem proving** began even before the first complete first-order systems were developed. Herbert Gelernter's Geometry Theorem Prover (Gelernter, 1959) used heuristic search methods combined with diagrams for pruning false subgoals and was able to prove some quite intricate results in Euclidean geometry. The **demodulation** and **paramodulation** rules for equality reasoning were introduced by Wos *et al.* (1967) and Wos and Robinson (1968), respectively. These rules were also developed independently in the context of term-rewriting systems (Knuth and Bendix, 1970). The incorporation of equality reasoning into the unification algorithm is due to Gordon Plotkin (1972). Jouannaud and Kirchner (1991) survey equational unification from a term-rewriting perspective. An overview of unification is given by Baader and Snyder (2001).

A number of control strategies have been proposed for resolution, beginning with the unit preference strategy (Wos *et al.*, 1964). The set-of-support strategy was proposed by Wos *et al.* (1965) to provide a degree of goal-directedness in resolution. Linear resolution first appeared in Loveland (1970). Genesereth and Nilsson (1987, Chapter 5) provide an analysis of a wide variety of control strategies. Alemi *et al.* (2017) show how the DEEPMATH system uses deep neural nets to select the axioms that are most likely to lead to a proof when handed to a traditional theorem prover. In a sense, the neural net plays the role of the mathematician's intuition, and the theorem prover plays the role of the mathematician's technical expertise. (Loos *et al.*, 2017) show that this approach can be extended to help guide the search, allowing more theorems to be proved.

*A Computational Logic* (Boyer and Moore, 1979) is the basic reference on the Boyer-Moore theorem prover. Stickel (1992) describes the Prolog Technology Theorem Prover (PTTP), which combines Prolog compilation and model elimination. SETHEO (Letz *et al.*, 1992) is another widely used theorem prover based on this approach. LEANTAP (Beckert and Posegga, 1995) is an efficient theorem prover implemented in only 25 lines of Prolog. Weidenbach (2001) describes SPASS, one of the strongest current theorem provers. The most successful theorem prover in recent annual competitions has been VAMPIRE (Riazanov and Voronkov, 2002). The COQ system (Bertot *et al.*, 2004) and the E equational solver (Schulz, 2004) have also proven to be valuable tools for proving correctness.

Theorem provers have been used to automatically synthesize and verify software. Examples include the control software for NASA's Orion capsule (Lowry, 2008) and other space-craft (Denney *et al.*, 2006). The design of the FM9001 32-bit microprocessor was proved correct by the NQTHM theorem proving system (Hunt and Brock, 1992).

The Conference on Automated Deduction (CADE) runs an annual contest for automated theorem provers. Sutcliffe (2016) describes the 2016 competition; top-scoring systems in-

clude VAMPIRE (Riazanov and Voronkov, 2002), PROVER9 (Sabri, 2015), and an updated version of E (Schulz, 2013). Wiedijk (2003) compares the strength of 15 mathematical provers. TPTP (Thousands of Problems for Theorem Provers) is a library of theorem-proving problems, useful for comparing the performance of systems (Sutcliffe and Suttner, 1998; Sutcliffe *et al.*, 2006).

Theorem provers have come up with novel mathematical results that eluded human mathematicians for decades, as detailed in the book *Automated Reasoning and the Discovery of Missing Elegant Proofs* (Wos and Pieper, 2003). The SAM (Semi-Automated Mathematics) program was the first, proving a lemma in lattice theory (Guard *et al.*, 1969). The AURA program has also answered open questions in several areas of mathematics (Wos and Winker, 1983). The Boyer–Moore theorem prover (Boyer and Moore, 1979) was used by Natarajan Shankar to construct a formal proof of Gödel’s Incompleteness Theorem (Shankar, 1986). The NUPRL system proved Girard’s paradox (Howe, 1987) and Higman’s Lemma (Murthy and Russell, 1990).

In 1933, Herbert Robbins proposed a simple set of axioms—the **Robbins algebra**—that appeared to define Boolean algebra, but no proof could be found (despite serious work by Alfred Tarski and others) until EQP (a version of OTTER) computed a proof (McCune, 1997). Benzmüller and Paleo (2013) used a higher-order theorem prover to verify Gödel’s proof of the existence of “God.” The Kepler sphere-packing theorem was proved by Thomas Hales (2005) with the help of some complicated computer calculations, but the proof was not completely accepted until a formal proof was generated with the help of the HOL Light and Isabelle proof assistants (Hales *et al.*, 2017).

Many early papers in mathematical logic are collected in *From Frege to Gödel: A Source Book in Mathematical Logic* (van Heijenoort, 1967). Textbooks geared toward automated deduction include the classic *Symbolic Logic and Mechanical Theorem Proving* (Chang and Lee, 1973), as well as more recent works by Duffy (1991), Wos *et al.* (1992), Bibel (1993), and Kaufmann *et al.* (2000). The principal journal for theorem proving is the *Journal of Automated Reasoning*; the main conferences are the annual Conference on Automated Deduction (CADE) and the International Joint Conference on Automated Reasoning (IJCAR). The *Handbook of Automated Reasoning* (Robinson and Voronkov, 2001) collects papers in the field. MacKenzie’s *Mechanizing Proof* (2004) covers the history and technology of theorem proving for the popular audience.

Robbins algebra

# CHAPTER 10

## KNOWLEDGE REPRESENTATION

*In which we show how to represent diverse facts about the real world in a form that can be used to reason and solve problems.*

The previous chapters showed how an agent with a knowledge base can make inferences that enable it to act appropriately. In this chapter we address the question of what *content* to put into such an agent’s knowledge base—how to represent facts about the world. We will use first-order logic as the representation language, but later chapters will introduce different representation formalisms such as hierarchical task networks for reasoning about plans (Chapter 11), Bayesian networks for reasoning with uncertainty (Chapter 13), Markov models for reasoning over time (Chapter 16), and deep neural networks for reasoning about images, sounds, and other data (Chapter 22). But no matter what representation you use, the facts about the world still need to be handled, and this chapter gives you a feeling for the issues.

Section 10.1 introduces the idea of a general ontology, which organizes everything in the world into a hierarchy of categories. Section 10.2 covers the basic categories of objects, substances, and measures; Section 10.3 covers events; and Section 10.4 discusses knowledge about beliefs. We then return to consider the technology for reasoning with this content: Section 10.5 discusses reasoning systems designed for efficient inference with categories, and Section 10.6 discusses reasoning with default information.

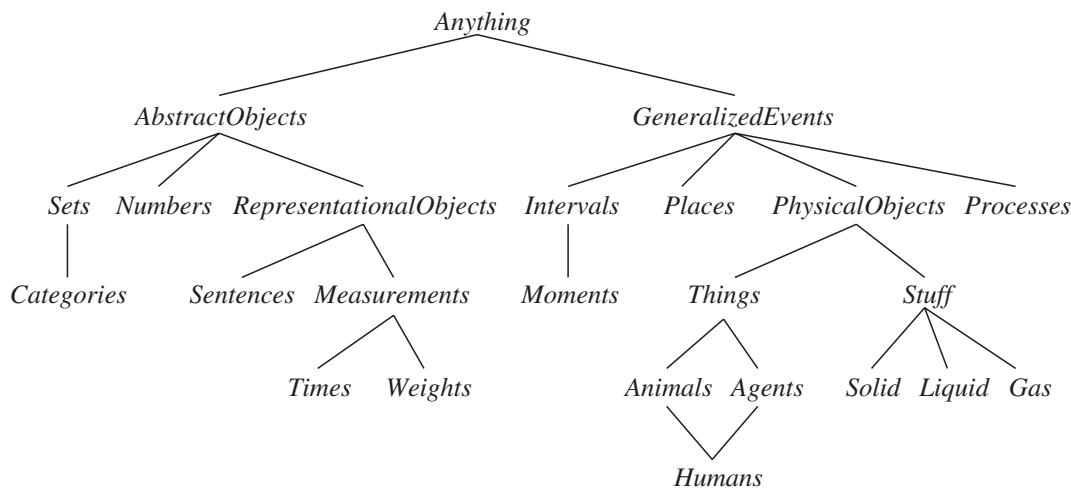

### 10.1 Ontological Engineering

Ontological engineering

In “toy” domains, the choice of representation is not that important; many choices will work. Complex domains such as shopping on the Internet or driving a car in traffic require more general and flexible representations. This chapter shows how to create these representations, concentrating on general concepts—such as *Events*, *Time*, *Physical Objects*, and *Beliefs*—that occur in many different domains. Representing these abstract concepts is sometimes called **ontological engineering**.

Upper ontology

We cannot hope to represent *everything* in the world, even a 1000-page textbook, but we will leave placeholders where new knowledge for any domain can fit in. For example, we will define what it means to be a physical object, and the details of different types of objects—robots, televisions, books, or whatever—can be filled in later. This is analogous to the way that designers of an object-oriented programming framework (such as the Java Swing graphical framework) define general concepts like *Window*, expecting users to use these to define more specific concepts like *SpreadsheetWindow*. The general framework of concepts is called an **upper ontology** because of the convention of drawing graphs with the general concepts at the top and the more specific concepts below them, as in Figure 10.1.

**Figure 10.1** The upper ontology of the world, showing the topics to be covered later in the chapter. Each link indicates that the lower concept is a specialization of the upper one. Specializations are not necessarily disjoint—a human is both an animal and an agent. We will see in Section 10.3.2 why physical objects come under generalized events.

Before considering the ontology further, we should state one important caveat. We have elected to use first-order logic to discuss the content and organization of knowledge, although certain aspects of the real world are hard to capture in FOL. The principal difficulty is that most generalizations have exceptions or hold only to a degree. For example, although “tomatoes are red” is a useful rule, some tomatoes are green, yellow, or orange. Similar exceptions can be found to almost all the rules in this chapter. The ability to handle exceptions and uncertainty is extremely important, but is orthogonal to the task of understanding the general ontology. For this reason, we delay the discussion of exceptions until Section 10.5 of this chapter, and the more general topic of reasoning with uncertainty until Chapter 12.

Of what use is an upper ontology? Consider the ontology for circuits in Section 8.4.2. It makes many simplifying assumptions: time is omitted completely; signals are fixed and do not propagate; the structure of the circuit remains constant. A more general ontology would consider signals at particular times, and would include the wire lengths and propagation delays. This would allow us to simulate the timing properties of the circuit, and indeed such simulations are often carried out by circuit designers.

We could also introduce more interesting classes of gates, for example, by describing the technology (TTL, CMOS, and so on) as well as the input–output specification. If we wanted to discuss reliability or diagnosis, we would include the possibility that the structure of the circuit or the properties of the gates might change spontaneously. To account for stray capacitances, we would need to represent where the wires are on the board.

If we look at the wumpus world, similar considerations apply. Although we do represent time, it has a simple structure: Nothing happens except when the agent acts, and all changes are instantaneous. A more general ontology, better suited for the real world, would allow for simultaneous changes extended over time. We also used a *Pit* predicate to say which squares have pits. We could have allowed for different kinds of pits by having several individuals

belonging to the class of pits, each having different properties. Similarly, we might want to allow for other animals besides wumpuses. It might not be possible to pin down the exact species from the available percepts, so we would need to build up a biological taxonomy to help the agent predict the behavior of cave dwellers from scanty clues.

For any special-purpose ontology, it is possible to make changes like these to move toward greater generality. An obvious question then arises: do all these ontologies converge on a general-purpose ontology? After centuries of philosophical and computational investigation, the answer is “Maybe.” In this section, we present one general-purpose ontology that synthesizes ideas from those centuries. Two major characteristics of general-purpose ontologies distinguish them from collections of special-purpose ontologies:

- A general-purpose ontology should be applicable in more or less any special-purpose domain (with the addition of domain-specific axioms). This means that no representational issue can be finessed or swept under the carpet.
- In any sufficiently demanding domain, different areas of knowledge must be *unified*, because reasoning and problem solving could involve several areas simultaneously. A robot circuit-repair system, for instance, needs to reason about circuits in terms of electrical connectivity and physical layout, and about time, both for circuit timing analysis and estimating labor costs. The sentences describing time therefore must be capable of being combined with those describing spatial layout and must work equally well for nanoseconds and minutes and for angstroms and meters.

We should say up front that the enterprise of general ontological engineering has so far had only limited success. None of the top AI applications (as listed in Chapter 1) make use of a general ontology—they all use special-purpose knowledge engineering and machine learning. Social/political considerations can make it difficult for competing parties to agree on an ontology. As Tom Gruber (2004) says, “Every ontology is a treaty—a social agreement—among people with some common motive in sharing.” When competing concerns outweigh the motivation for sharing, there can be no common ontology. The smaller the number of stakeholders, the easier it is to create an ontology, and thus it is harder to create a general-purpose ontology than a limited-purpose one, such as the Open Biomedical Ontology (Smith *et al.*, 2007). Those ontologies that do exist have been created along four routes:

1. By a team of trained ontologists or logicians, who architect the ontology and write axioms. The CYC system was mostly built this way (Lenat and Guha, 1990).
2. By importing categories, attributes, and values from an existing database or databases. DBPEDIA was built by importing structured facts from Wikipedia (Bizer *et al.*, 2007).
3. By parsing text documents and extracting information from them. TEXTRUNNER was built by reading a large corpus of Web pages (Banko and Etzioni, 2008).
4. By enticing unskilled amateurs to enter commonsense knowledge. The OPENMIND system was built by volunteers who proposed facts in English (Singh *et al.*, 2002; Chklovski and Gil, 2005).

As an example, the Google Knowledge Graph uses semistructured content from Wikipedia, combining it with other content gathered from across the web under human curation. It contains over 70 billion facts and provides answers for about a third of Google searches (Dong *et al.*, 2014).

## 10.2 Categories and Objects

The organization of objects into **categories** is a vital part of knowledge representation. Although interaction with the world takes place at the level of individual objects, *much reasoning takes place at the level of categories*. For example, a shopper would normally have the goal of buying a basketball, rather than a *particular* basketball such as  $BB_9$ . Categories also serve to make predictions about objects once they are classified. One infers the presence of certain objects from perceptual input, infers category membership from the perceived properties of the objects, and then uses category information to make predictions about the objects. For example, from its green and yellow mottled skin, one-foot diameter, ovoid shape, red flesh, black seeds, and presence in the fruit aisle, one can infer that an object is a watermelon; from this, one infers that it would be useful for fruit salad.

There are two choices for representing categories in first-order logic: predicates and objects. That is, we can use the predicate  $Basketball(b)$ , or we can **reify**<sup>1</sup> the category as an object,  $Basketballs$ . We could then say  $Member(b, Basketballs)$ , which we will abbreviate as  $b \in Basketballs$ , to say that  $b$  is a member of the category of basketballs. We say  $Subset(Basketballs, Balls)$ , abbreviated as  $Basketballs \subset Balls$ , to say that  $Basketballs$  is a **subcategory** of  $Balls$ . We will use subcategory, subclass, and subset interchangeably.

Categories organize knowledge through **inheritance**. If we say that all instances of the category  $Food$  are edible, and if we assert that  $Fruit$  is a subclass of  $Food$  and  $Apples$  is a subclass of  $Fruit$ , then we can infer that every apple is edible. We say that the individual apples **inherit** the property of edibility, in this case from their membership in the  $Food$  category.

Subclass relations organize categories into a **taxonomic hierarchy** or **taxonomy**. Taxonomies have been used explicitly for centuries in technical fields. The largest such taxonomy organizes about 10 million living and extinct species, many of them beetles,<sup>2</sup> into a single hierarchy; library science has developed a taxonomy of all fields of knowledge, encoded as the Dewey Decimal system; and tax authorities and other government departments have developed extensive taxonomies of occupations and commercial products.

First-order logic makes it easy to state facts about categories, either by relating objects to categories or by quantifying over their members. Here are some example facts:

- An object is a member of a category.  
 $BB_9 \in Basketballs$
- A category is a subclass of another category.  
 $Basketballs \subset Balls$
- All members of a category have some properties.  
 $(x \in Basketballs) \Rightarrow Spherical(x)$
- Members of a category can be recognized by some properties.  
 $Orange(x) \wedge Round(x) \wedge Diameter(x) = 9.5'' \wedge x \in Balls \Rightarrow x \in Basketballs$
- A category as a whole has some properties.  
 $Dogs \in DomesticatedSpecies$

<sup>1</sup> Turning a proposition into an object is called **reification**, from the Latin word *res*, or thing. John McCarthy proposed the term “thingification,” but it never caught on.

<sup>2</sup> When asked what one could deduce about the Creator from the study of nature, biologist J. B. S. Haldane said “An inordinate fondness for beetles.”

Category

Reification

Subcategory

Inheritance

Taxonomic hierarchy

Disjoint

Exhaustive decomposition  
Partition

Composite object

Notice that because *Dogs* is a category and is a member of *DomesticatedSpecies*, the latter must be a category of categories. Of course there are exceptions to many of the above rules (punctured basketballs are not spherical); we deal with these exceptions later.

Although subclass and member relations are the most important ones for categories, we also want to be able to state relations between categories that are not subclasses of each other. For example, if we just say that *Undergraduates* and *GraduateStudents* are subclasses of *Students*, then we have not said that an undergraduate cannot also be a graduate student. We say that two or more categories are **disjoint** if they have no members in common. We may also want to say that the classes undergrad and graduate student form an **exhaustive decomposition** of university students. A exhaustive decomposition of disjoint sets is known as a **partition**. Here are some more examples of these three concepts:

$$\begin{aligned} & \text{Disjoint}(\{\text{Animals}, \text{Vegetables}\}) \\ & \text{ExhaustiveDecomposition}(\{\text{Americans}, \text{Canadians}, \text{Mexicans}\}, \\ & \quad \text{NorthAmericans}) \\ & \text{Partition}(\{\text{Animals}, \text{Plants}, \text{Fungi}, \text{Protista}, \text{Monera}\}, \\ & \quad \text{LivingThings}). \end{aligned}$$

(Note that the *ExhaustiveDecomposition* of *NorthAmericans* is not a *Partition*, because some people have dual citizenship.) The three predicates are defined as follows:

$$\begin{aligned} \text{Disjoint}(s) &\Leftrightarrow (\forall c_1, c_2 \ c_1 \in s \wedge c_2 \in s \wedge c_1 \neq c_2 \Rightarrow \text{Intersection}(c_1, c_2) = \{\}) \\ \text{ExhaustiveDecomposition}(s, c) &\Leftrightarrow (\forall i \ i \in c \Leftrightarrow \exists c_2 \ c_2 \in s \wedge i \in c_2) \\ \text{Partition}(s, c) &\Leftrightarrow \text{Disjoint}(s) \wedge \text{ExhaustiveDecomposition}(s, c). \end{aligned}$$

Categories can also be *defined* by providing necessary and sufficient conditions for membership. For example, a bachelor is an unmarried adult male:

$$x \in \text{Bachelors} \Leftrightarrow \text{Unmarried}(x) \wedge x \in \text{Adults} \wedge x \in \text{Males}.$$

As we discuss in the sidebar on natural kinds on page 338, strict logical definitions for categories are usually possible only for artificial formal terms, not for ordinary objects. But definitions are not always necessary.

### 10.2.1 Physical composition

The idea that one object can be part of another is a familiar one. One's nose is part of one's head, Romania is part of Europe, and this chapter is part of this book. We use the general *PartOf* relation to say that one thing is part of another. Objects can be grouped into *PartOf* hierarchies, reminiscent of the *Subset* hierarchy:

$$\begin{aligned} & \text{PartOf}(\text{Bucharest}, \text{Romania}) \\ & \text{PartOf}(\text{Romania}, \text{EasternEurope}) \\ & \text{PartOf}(\text{EasternEurope}, \text{Europe}) \\ & \text{PartOf}(\text{Europe}, \text{Earth}). \end{aligned}$$

The *PartOf* relation is transitive and reflexive; that is,

$$\begin{aligned} \text{PartOf}(x, y) \wedge \text{PartOf}(y, z) &\Rightarrow \text{PartOf}(x, z) \\ \text{PartOf}(x, x). \end{aligned}$$

Therefore, we can conclude *PartOf(Bucharest, Earth)*. Categories of **composite objects** are often characterized by structural relations among parts. For example, a biped is an object

with exactly two legs attached to a body:

$$\begin{aligned} \text{Biped}(a) \Rightarrow & \exists l_1, l_2, b \text{ Leg}(l_1) \wedge \text{Leg}(l_2) \wedge \text{Body}(b) \wedge \\ & \text{PartOf}(l_1, a) \wedge \text{PartOf}(l_2, a) \wedge \text{PartOf}(b, a) \wedge \\ & \text{Attached}(l_1, b) \wedge \text{Attached}(l_2, b) \wedge \\ & l_1 \neq l_2 \wedge [\forall l_3 \text{ Leg}(l_3) \wedge \text{PartOf}(l_3, a) \Rightarrow (l_3 = l_1 \vee l_3 = l_2)]. \end{aligned}$$

The notation for “exactly two” is a little awkward; we are forced to say that there are two legs, that they are not the same, and that if anyone proposes a third leg, it must be the same as one of the other two. In Section 10.5.2, we describe a formalism called description logic that makes it easier to represent constraints like “exactly two.”

We can define a *PartPartition* relation analogous to the *Partition* relation for categories. (See Exercise 10.DECM.) An object is composed of the parts in its *PartPartition* and can be viewed as deriving some properties from those parts. For example, the mass of a composite object is the sum of the masses of the parts. Notice that this is not the case with categories, which have no mass, even though their elements might.

It is also useful to define composite objects with definite parts but no particular structure. For example, we might want to say “The apples in this bag weigh two pounds.” The temptation would be to ascribe this weight to the *set* of apples in the bag, but this would be a mistake because the set is an abstract mathematical concept that has elements but does not have weight. Instead, we need a new concept, which we will call a **bunch**. For example, if the apples are *Apple*<sub>1</sub>, *Apple*<sub>2</sub>, and *Apple*<sub>3</sub>, then

$$\text{BunchOf}(\{\text{Apple}_1, \text{Apple}_2, \text{Apple}_3\})$$

denotes the composite object with the three apples as parts (not elements). We can then use the bunch as a normal, albeit unstructured, object. Notice that  $\text{BunchOf}(\{x\}) = x$ . Furthermore,  $\text{BunchOf}(\text{Apples})$  is the composite object consisting of all apples—not to be confused with *Apples*, the category or set of all apples.

We can define *BunchOf* in terms of the *PartOf* relation. Obviously, each element of *s* is part of *BunchOf(s)*:

$$\forall x \ x \in s \Rightarrow \text{PartOf}(x, \text{BunchOf}(s)).$$

Furthermore, *BunchOf(s)* is the smallest object satisfying this condition. In other words, *BunchOf(s)* must be part of any object that has all the elements of *s* as parts:

$$\forall y \ [\forall x \ x \in s \Rightarrow \text{PartOf}(x, y)] \Rightarrow \text{PartOf}(\text{BunchOf}(s), y).$$

These axioms are an example of a general technique called **logical minimization**, which means defining an object as the smallest one satisfying certain conditions.

### 10.2.2 Measurements

In both scientific and commonsense theories of the world, objects have height, mass, cost, and so on. The values that we assign for these properties are called **measures**. Ordinary quantitative measures are quite easy to represent. We imagine that the universe includes abstract “measure objects,” such as the *length* that is the length of this line segment:  . We can call this length 1.5 inches or 3.81 centimeters. Thus, the same length has different names in our language. We represent the length with a **units function** that takes a number as argument. (An alternative is explored in Exercise 10.ALTM.)

Logical minimization

Measure

Units function

## Natural Kinds

Some categories have strict definitions: an object is a triangle if and only if it is a polygon with three sides. On the other hand, most categories in the real world have no clear-cut definition; these are called **natural kind** categories. For example, tomatoes tend to be a dull scarlet; roughly spherical; with an indentation at the top where the stem was; about two to four inches in diameter; with a thin but tough skin; and with flesh, seeds, and juice inside. However, there is variation: some tomatoes are yellow or orange, unripe tomatoes are green, some are smaller or larger than average, and cherry tomatoes are uniformly small. Rather than having a complete definition of tomatoes, we have a set of features that serves to identify objects that are clearly typical tomatoes, but might not definitively identify other objects. (Could there be a tomato that is fuzzy like a peach?)

This poses a problem for a logical agent. The agent cannot be sure that an object it has perceived is a tomato, and even if it were sure, it could not be certain which of the properties of typical tomatoes this one has. This problem is an inevitable consequence of operating in partially observable environments.

One useful approach is to separate what is true of all instances of a category from what is true only of typical instances. So in addition to the category *Tomatoes*, we will also have the category *Typical(Tomatoes)*. Here, the *Typical* function maps a category to the subclass that contains only typical instances:

$$\text{Typical}(c) \subseteq c.$$

Most knowledge about natural kinds will actually be about their typical instances:

$$x \in \text{Typical}(\text{Tomatoes}) \Rightarrow \text{Red}(x) \wedge \text{Round}(x).$$

Thus, we can write down useful facts about categories without exact definitions. The difficulty of providing exact definitions for most natural categories was explained in depth by Wittgenstein (1953). He used the example of *games* to show that members of a category shared “family resemblances” rather than necessary and sufficient characteristics: what strict definition encompasses chess, tag, solitaire, and dodgeball?

The utility of the notion of strict definition was also challenged by Quine (1953). He pointed out that even the definition of “bachelor” as an unmarried adult male is suspect; one might, for example, question a statement such as “the Pope is a bachelor.” While not strictly *false*, this usage is certainly *infelicitous* because it induces unintended inferences on the part of the listener. The tension could perhaps be resolved by distinguishing between logical definitions suitable for internal knowledge representation and the more nuanced criteria for felicitous linguistic usage. The latter may be achieved by “filtering” the assertions derived from the former. It is also possible that failures of linguistic usage serve as feedback for modifying internal definitions, so that filtering becomes unnecessary.

If the line segment is called  $L_1$ , we can write

$$\text{Length}(L_1) = \text{Inches}(1.5) = \text{Centimeters}(3.81).$$

Conversion between units is done by equating multiples of one unit to another:

$$\text{Centimeters}(2.54 \times d) = \text{Inches}(d).$$

Similar axioms can be written for pounds and kilograms, seconds and days, and dollars and cents. Measures can be used to describe objects as follows:

$$\text{Diameter}(\text{Basketball}_{12}) = \text{Inches}(9.5)$$

$$\text{ListPrice}(\text{Basketball}_{12}) = \$\{19\}$$

$$\text{Weight}(\text{BunchOf}(\{\text{Apple}_1, \text{Apple}_2, \text{Apple}_3\})) = \text{Pounds}(2)$$

$$d \in \text{Days} \Rightarrow \text{Duration}(d) = \text{Hours}(24).$$

Note that  $\$\{1\}$  is *not* a dollar bill—it is a price. One can have two dollar bills, but there is only one object named  $\$\{1\}$ . Note also that, while  $\text{Inches}(0)$  and  $\text{Centimeters}(0)$  refer to the same zero length, they are not identical to other zero measures, such as  $\text{Seconds}(0)$ .

Simple, quantitative measures are easy to represent. Other measures present more of a problem, because they have no agreed scale of values. Exercises have difficulty, desserts have deliciousness, and poems have beauty, yet numbers cannot be assigned to these qualities. One might, in a moment of pure accountancy, dismiss such properties as useless for the purpose of logical reasoning; or, still worse, attempt to impose a numerical scale on beauty. This would be a grave mistake, because it is unnecessary. The most important aspect of measures is not the particular numerical values, but the fact that measures can be *ordered*.

Although measures are not numbers, we can still compare them, using an ordering symbol such as  $>$ . For example, we might well believe that Norvig’s exercises are tougher than Russell’s, and that one scores less on tougher exercises:

$$e_1 \in \text{Exercises} \wedge e_2 \in \text{Exercises} \wedge \text{Wrote}(\text{Norvig}, e_1) \wedge \text{Wrote}(\text{Russell}, e_2) \Rightarrow \\ \text{Difficulty}(e_1) > \text{Difficulty}(e_2).$$

$$e_1 \in \text{Exercises} \wedge e_2 \in \text{Exercises} \wedge \text{Difficulty}(e_1) > \text{Difficulty}(e_2) \Rightarrow \\ \text{ExpectedScore}(e_1) < \text{ExpectedScore}(e_2).$$

This is enough to allow one to decide which exercises to do, even though no numerical values for difficulty were ever used. (One does, however, have to discover who wrote which exercises.) These sorts of monotonic relationships among measures form the basis for the field of **qualitative physics**, a subfield of AI that investigates how to reason about physical systems without plunging into detailed equations and numerical simulations. Qualitative physics is discussed in the historical notes section.

### 10.2.3 Objects: Things and stuff

The real world can be seen as consisting of primitive objects (e.g., atomic particles) and composite objects built from them. By reasoning at the level of large objects such as apples and cars, we can overcome the complexity involved in dealing with vast numbers of primitive objects individually. There is, however, a significant portion of reality that seems to defy any obvious **individuation**—division into distinct objects. We give this portion the generic name **stuff**. For example, suppose I have some butter and an aardvark in front of me. I can say there is one aardvark, but there is no obvious number of “butter-objects,” because any part of a butter-object is also a butter-object, at least until we get to very small parts indeed. This is

Count nouns  
Mass noun

the major distinction between *stuff* and *things*. If we cut an aardvark in half, we do not get two aardvarks (unfortunately).

The English language distinguishes clearly between *stuff* and *things*. We say “an aardvark,” but, except in pretentious California restaurants, one cannot say “a butter.” Linguists distinguish between **count nouns**, such as aardvarks, holes, and theorems, and **mass nouns**, such as butter, water, and energy. Several competing ontologies claim to handle this distinction. Here we describe just one; the others are covered in the historical notes section.

To represent *stuff* properly, we begin with the obvious. We need to have as objects in our ontology at least the gross “lumps” of *stuff* we interact with. For example, we might recognize a lump of butter as the one left on the table the night before; we might pick it up, weigh it, sell it, or whatever. In these senses, it is an object just like the aardvark. Let us call it *Butter*<sub>3</sub>. We also define the category *Butter*. Informally, its elements will be all those things of which one might say “It’s butter,” including *Butter*<sub>3</sub>. With some caveats about very small parts that we will omit for now, any part of a butter-object is also a butter-object:

$$b \in \text{Butter} \wedge \text{PartOf}(p, b) \Rightarrow p \in \text{Butter}.$$

We can now say that butter melts at around 30 degrees centigrade:

$$b \in \text{Butter} \Rightarrow \text{MeltingPoint}(b, \text{Centigrade}(30)).$$

We could go on to say that butter is yellow, is less dense than water, is soft at room temperature, has a high fat content, and so on. On the other hand, butter has no particular size, shape, or weight. We can define more specialized categories of butter such as *UnsaltedButter*, which is also a kind of *stuff*. Note that the category *PoundOfButter*, which includes as members all butter-objects weighing one pound, is not a kind of *stuff*. If we cut a pound of butter in half, we do not, alas, get two pounds of butter.

Intrinsic

What is actually going on is this: some properties are **intrinsic**: they belong to the very substance of the object, rather than to the object as a whole. When you cut an instance of *stuff* in half, the two pieces retain the intrinsic properties—things like density, boiling point, flavor, color, ownership, and so on. On the other hand, their **extrinsic** properties—weight, length, shape, and so on—are not retained under subdivision. A category of objects that includes in its definition only *intrinsic* properties is then a substance, or mass noun; a class that includes *any* extrinsic properties in its definition is a count noun. *Stuff* and *Thing* are the most general substance and object categories, respectively.

Extrinsic

## 10.3 Events

---

In Section 7.7.1 we discussed actions: things that happen, such as *Shoot*<sub>t</sub>; and fluents: aspects of the world that change, such as *HaveArrow*<sub>t</sub>. Both were represented as propositions, and we used successor-state axioms to say that a fluent will be true at time  $t + 1$  if the action at time  $t$  caused it to be true, or if it was already true at time  $t$  and the action did not cause it to be false. That was for a world in which actions are discrete, instantaneous, happen one at a time, and have no variation in how they are performed (that is, there is only one kind of *Shoot* action, there is no distinction between shooting quickly, slowly, nervously, etc.).

But as we move from simplistic domains to the real world, there is a much richer range of actions or events<sup>3</sup> to deal with. Consider a continuous action, such as filling a bathtub. A

<sup>3</sup> The terms “event” and “action” may be used interchangeably—they both mean “something that can happen.”

successor-state axiom can say that the tub is empty before the action and full when the action is done, but it can't talk about what happens *during* the action. It also can't easily describe two actions happening at the same time—such as brushing one's teeth while waiting for the tub to fill. To handle such cases we introduce an approach known as **event calculus**.

The objects of event calculus are events, fluents, and time points.  $At(Shankar, Berkeley)$  is a fluent: an object that refers to the fact of Shankar being in Berkeley. The event  $E_1$  of Shankar flying from San Francisco to Washington, D.C., is described as

$$E_1 \in Flyings \wedge Flyer(E_1, Shankar) \wedge Origin(E_1, SF) \wedge Destination(E_1, DC).$$

where *Flyings* is the category of all flying events. By reifying events we make it possible to add any amount of arbitrary information about them. For example, we can say that Shankar's flight was bumpy with  $Bumpy(E_1)$ . In an ontology where events are  $n$ -ary predicates, there would be no way to add extra information like this; moving to an  $n + 1$ -ary predicate isn't a scalable solution.

To assert that a fluent is actually true starting at some point in time  $t_1$  and continuing to time  $t_2$ , we use the predicate  $T$ , as in  $T(At(Shankar, Berkeley), t_1, t_2)$ . Similarly, we use  $Happens(E_1, t_1, t_2)$  to say that the event  $E_1$  actually happened, starting at time  $t_1$  and ending at time  $t_2$ . The complete set of predicates for one version of the event calculus<sup>4</sup> is:

$T(f, t_1, t_2)$	Fluent $f$ is true for all times between $t_1$ and $t_2$
$Happens(e, t_1, t_2)$	Event $e$ starts at time $t_1$ and ends at $t_2$
$Initiates(e, f, t)$	Event $e$ causes fluent $f$ to become true at time $t$
$Terminates(e, f, t)$	Event $e$ causes fluent $f$ to cease to be true at time $t$
$Initiated(f, t_1, t_2)$	Fluent $f$ become true at some point between $t_1$ and $t_2$
$Terminated(f, t_1, t_2)$	Fluent $f$ cease to be true at some point between $t_1$ and $t_2$
$t_1 < t_2$	Time point $t_1$ occurs before time $t_2$

We can describe the effects of a flying event:

$$\begin{aligned} E = Flyings(a, here, there) \wedge Happens(E, t_1, t_2) \Rightarrow \\ Terminates(E, At(a, here), t_1) \wedge Initiates(E, At(a, there), t_2) \end{aligned}$$

We assume a distinguished event, *Start*, that describes the initial state by saying which fluents are true (using *Initiates*) or false (using *Terminated*) at the start time. We can then describe what fluents are true at what points in time with a pair of axioms for  $T$  and  $\neg T$  that follow the same general format as the successor-state axioms: Assume an event happens between time  $t_1$  and  $t_3$ , and at  $t_2$  somewhere in that time interval the event changes the value of fluent  $f$ , either initiating it (making it true) or terminating it (making it false). Then at time  $t_4$  in the future, if no other intervening event has changed the fluent (either terminated or initiated it, respectively), then the fluent will have maintained its value. Formally, the axioms are:

$$\begin{aligned} &Happens(e, t_1, t_3) \wedge Initiates(e, f, t_2) \wedge \neg Terminated(f, t_2, t_4) \wedge t_1 \leq t_2 \leq t_3 \leq t_4 \Rightarrow \\ &\quad T(f, t_2, t_4) \\ &Happens(e, t_1, t_3) \wedge Terminates(e, f, t_2) \wedge \neg Initiated(f, t_2, t_4) \wedge t_1 \leq t_2 \leq t_3 \leq t_4 \Rightarrow \\ &\quad \neg T(f, t_2, t_4) \end{aligned}$$

<sup>4</sup> Our version is based on Shanahan (1999), but with some alterations.

where *Terminated* and *Initiated* are defined by:

$$\begin{aligned} \text{Terminated}(f, t_1, t_5) &\Leftrightarrow \\ &\exists e, t_2, t_3, t_4 \text{ Happens}(e, t_2, t_4) \wedge \text{Terminates}(e, f, t_3) \wedge t_1 \leq t_2 \leq t_3 \leq t_4 \leq t_5 \\ \text{Initiated}(f, t_1, t_5) &\Leftrightarrow \\ &\exists e, t_2, t_3, t_4 \text{ Happens}(e, t_2, t_4) \wedge \text{Initiates}(e, f, t_3) \wedge t_1 \leq t_2 \leq t_3 \leq t_4 \leq t_5 \end{aligned}$$

We can extend event calculus to represent simultaneous events (such as two people being necessary to ride a seesaw), exogenous events (such as the wind moving an object), continuous events (such as the rising of the tide), nondeterministic events (such as flipping a coin and having it come up heads or tails), and other complications.

### 10.3.1 Time

Event calculus opens us up to the possibility of talking about time points and time intervals. We will consider two kinds of time intervals: moments and extended intervals. The distinction is that only moments have zero duration:

$$\begin{aligned} \text{Partition}(\{\text{Moments}, \text{ExtendedIntervals}\}, \text{Intervals}) \\ i \in \text{Moments} \Leftrightarrow \text{Duration}(i) = \text{Seconds}(0). \end{aligned}$$

Next we invent a time scale and associate points on that scale with moments, giving us absolute times. The time scale is arbitrary; we will measure it in seconds and say that the moment at midnight (GMT) on January 1, 1900, has time 0. The functions *Begin* and *End* pick out the earliest and latest moments in an interval, and the function *Time* delivers the point on the time scale for a moment. The function *Duration* gives the difference between the end time and the start time.

$$\begin{aligned} \text{Interval}(i) &\Rightarrow \text{Duration}(i) = (\text{Time}(\text{End}(i)) - \text{Time}(\text{Begin}(i))). \\ \text{Time}(\text{Begin}(\text{AD1900})) &= \text{Seconds}(0). \\ \text{Time}(\text{Begin}(\text{AD2001})) &= \text{Seconds}(3187324800). \\ \text{Time}(\text{End}(\text{AD2001})) &= \text{Seconds}(3218860800). \\ \text{Duration}(\text{AD2001}) &= \text{Seconds}(31536000). \end{aligned}$$

To make these numbers easier to read, we also introduce a function *Date*, which takes six arguments (hours, minutes, seconds, day, month, and year) and returns a time point:

$$\begin{aligned} \text{Time}(\text{Begin}(\text{AD2001})) &= \text{Date}(0, 0, 0, 1, \text{Jan}, 2001) \\ \text{Date}(0, 20, 21, 24, 1, 1995) &= \text{Seconds}(3000000000). \end{aligned}$$

Two intervals *Meet* if the end time of the first equals the start time of the second. The complete set of interval relations (Allen, 1983) is shown below and in Figure 10.2:

$$\begin{aligned} \text{Meet}(i, j) &\Leftrightarrow \text{End}(i) = \text{Begin}(j) \\ \text{Before}(i, j) &\Leftrightarrow \text{End}(i) < \text{Begin}(j) \\ \text{After}(j, i) &\Leftrightarrow \text{Before}(i, j) \\ \text{During}(i, j) &\Leftrightarrow \text{Begin}(j) < \text{Begin}(i) < \text{End}(i) < \text{End}(j) \\ \text{Overlap}(i, j) &\Leftrightarrow \text{Begin}(i) < \text{Begin}(j) < \text{End}(i) < \text{End}(j) \\ \text{Starts}(i, j) &\Leftrightarrow \text{Begin}(i) = \text{Begin}(j) \\ \text{Finishes}(i, j) &\Leftrightarrow \text{End}(i) = \text{End}(j) \\ \text{Equals}(i, j) &\Leftrightarrow \text{Begin}(i) = \text{Begin}(j) \wedge \text{End}(i) = \text{End}(j) \end{aligned}$$

These all have their intuitive meaning, with the exception of *Overlap*: we tend to think of overlap as symmetric (if *i* overlaps *j* then *j* overlaps *i*), but in this definition, *Overlap*(*i, j*) only is true if *i* begins before *j*. Experience has shown that this definition is more useful for

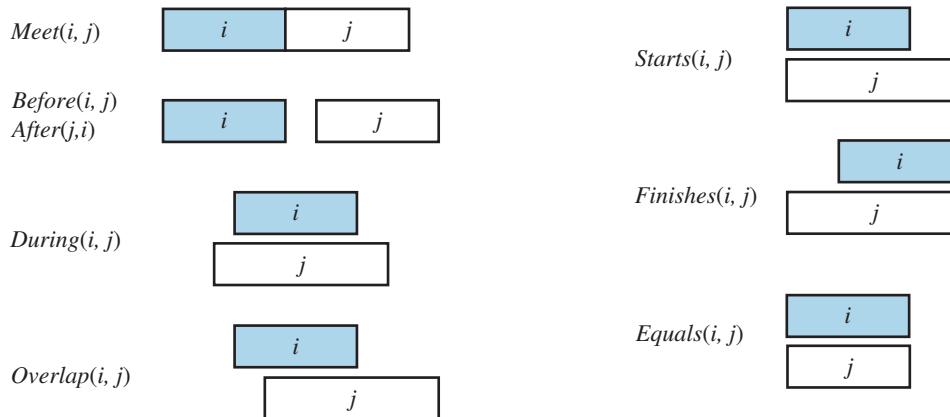

Figure 10.2 Predicates on time intervals.

writing axioms. To say that the reign of Elizabeth II immediately followed that of George VI, and the reign of Elvis overlapped with the 1950s, we can write the following:

$\text{Meets}(\text{ReignOf}(\text{GeorgeVI}), \text{ReignOf}(\text{ElizabethII}))$ .

$\text{Overlap}(\text{Fifties}, \text{ReignOf}(\text{Elvis}))$ .

$\text{Begin}(\text{Fifties}) = \text{Begin}(\text{AD1950})$ .

$\text{End}(\text{Fifties}) = \text{End}(\text{AD1959})$ .

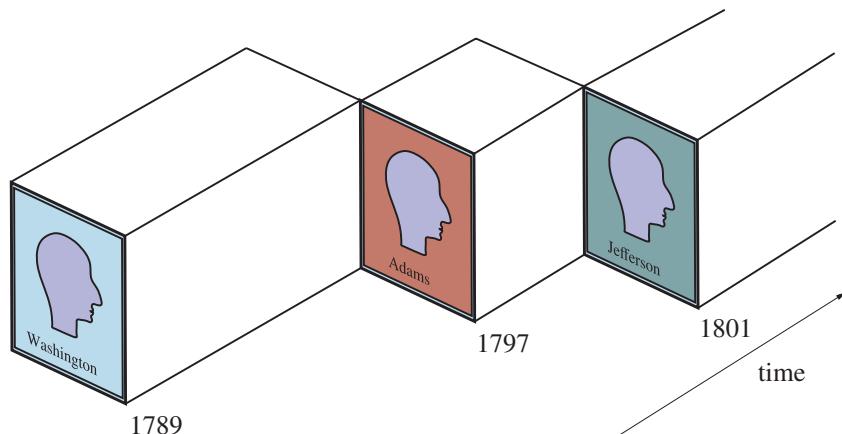

### 10.3.2 Fluents and objects

Physical objects can be viewed as generalized events, in the sense that a physical object is a chunk of space–time. For example, *USA* can be thought of as an event that began in 1776 as a union of 13 states and is still in progress today as a union of 50. We can describe the changing properties of *USA* using state fluents, such as *Population(USA)*. A property of *USA* that changes every four or eight years, barring mishaps, is its president. One might propose that *President(USA)* is a logical term that denotes a different object at different times.

Unfortunately, this is not possible, because a term denotes exactly one object in a given model structure. (The term *President(USA, t)* can denote different objects, depending on the value of  $t$ , but our ontology keeps time indices separate from fluents.) The only possibility is that *President(USA)* denotes a single object that consists of different people at different times. It is the object that is George Washington from 1789 to 1797, John Adams from 1797 to 1801, and so on, as in Figure 10.3. To say that George Washington was president throughout 1790, we can write

$T(\text{Equals}(\text{President}(\text{USA}), \text{GeorgeWashington}), \text{Begin}(\text{AD1790}), \text{End}(\text{AD1790}))$ .

We use the function symbol *Equals* rather than the standard logical predicate  $=$ , because we cannot have a predicate as an argument to  $T$ , and because the interpretation is *not* that *GeorgeWashington* and *President(USA)* are logically identical in 1790; logical identity is not something that can change over time. The identity is between the subevents of the objects *President(USA)* and *GeorgeWashington* that are defined by the period 1790.

**Figure 10.3** A schematic view of the object *President(USA)* for the early years.

## 10.4 Mental Objects and Modal Logic

The agents we have constructed so far have beliefs and can deduce new beliefs. Yet none of them has any knowledge *about* beliefs or *about* deduction. Knowledge about one's own knowledge and reasoning processes is useful for controlling inference. For example, suppose Alice asks "what is the square root of 1764" and Bob replies "I don't know." If Alice insists "think harder," Bob should realize that with some more thought, this question can in fact be answered. On the other hand, if the question were "Is the president sitting down right now?" then Bob should realize that thinking harder is unlikely to help. Knowledge about the knowledge of other agents is also important; Bob should realize that the president does know.

What we need is a model of the mental objects that are in someone's head (or something's knowledge base) and of the mental processes that manipulate those mental objects. The model does not have to be detailed. We do not have to be able to predict how many milliseconds it will take for a particular agent to make a deduction. We will be happy just to be able to conclude that mother knows whether or not she is sitting.

Propositional attitude

We begin with the **propositional attitudes** that an agent can have toward mental objects: attitudes such as *Believes*, *Knows*, *Wants*, and *Informs*. The difficulty is that these attitudes do not behave like "normal" predicates. For example, suppose we try to assert that Lois knows that Superman can fly:

$$\text{Knows}(\text{Lois}, \text{CanFly}(\text{Superman})).$$

One minor issue with this is that we normally think of *CanFly(Superman)* as a sentence, but here it appears as a term. That issue can be patched up by reifying *CanFly(Superman)*; making it a fluent. A more serious problem is that, if it is true that Superman is Clark Kent, then we must conclude that Lois knows that Clark can fly, which is wrong because (in most versions of the story) Lois does *not* know that Clark is Superman.

$$\begin{aligned} (\text{Superman} = \text{Clark}) \wedge \text{Knows}(\text{Lois}, \text{CanFly}(\text{Superman})) \\ \models \text{Knows}(\text{Lois}, \text{CanFly}(\text{Clark})) \end{aligned}$$

This is a consequence of the fact that equality reasoning is built into logic. Normally that is

a good thing; if our agent knows that  $2 + 2 = 4$  and  $4 < 5$ , then we want our agent to know that  $2 + 2 < 5$ . This property is called **referential transparency**—it doesn’t matter what term a logic uses to refer to an object, what matters is the object that the term names. But for propositional attitudes like *believes* and *knows*, we would like to have referential opacity—the terms used *do* matter, because not all agents know which terms are co-referential.

We could patch this up with even more reification: we could have one object to represent Clark/Superman, another object to represent the person that Lois knows as Clark, and yet another for the person Lois knows as Superman. However, this proliferation of objects means that the sentences we want to write quickly become verbose and clumsy.

**Modal logic** is designed to address this problem. Regular logic is concerned with a single modality, the modality of truth, allowing us to express “ $P$  is true” or “ $P$  is false.” Modal logic includes special **modal operators** that take sentences (rather than terms) as arguments. For example, “ $A$  knows  $P$ ” is represented with the notation  $\mathbf{K}_A P$ , where  $\mathbf{K}$  is the modal operator for knowledge. It takes two arguments, an agent (written as the subscript) and a sentence. The syntax of modal logic is the same as first-order logic, except that sentences can also be formed with modal operators.

The semantics of modal logic is more complicated. In first-order logic a **model** contains a set of objects and an interpretation that maps each name to the appropriate object, relation, or function. In modal logic we want to be able to consider both the possibility that Superman’s secret identity is Clark and the possibility that it isn’t.

Therefore, we will need a more complicated model, one that consists of a collection of **possible worlds** rather than just one true world. The worlds are connected in a graph by **accessibility relations**, one relation for each modal operator. We say that world  $w_1$  is accessible from world  $w_0$  with respect to the modal operator  $\mathbf{K}_A$  if everything in  $w_1$  is consistent with what  $A$  knows in  $w_0$ . As an example, in the real world, Bucharest is the capital of Romania, but for an agent that did not know that, a world where the capital of Romania is, say, Sofia is accessible. Hopefully a world where  $2 + 2 = 5$  would not be accessible to any agent.

In general, a knowledge atom  $\mathbf{K}_A P$  is true in world  $w$  if and only if  $P$  is true in every world accessible from  $w$ . The truth of more complex sentences is derived by recursive application of this rule and the normal rules of first-order logic. That means that modal logic can be used to reason about nested knowledge sentences: what one agent knows about another agent’s knowledge. For example, we can say that even though Lois doesn’t know whether Superman’s secret identity is Clark Kent, she does know that Clark knows:

$$\mathbf{K}_{\text{Lois}}[\mathbf{K}_{\text{Clark}} \text{Identity}(\text{Superman}, \text{Clark}) \vee \mathbf{K}_{\text{Clark}} \neg \text{Identity}(\text{Superman}, \text{Clark})]$$

Modal logic solves some tricky issues with the interplay of quantifiers and knowledge. The English sentence “Bond knows that someone is a spy” is ambiguous. The first reading is that there is a particular someone who Bond knows is a spy; we can write this as

$$\exists x \mathbf{K}_{\text{Bond}} \text{Spy}(x),$$

which in modal logic means that there is an  $x$  that, in all accessible worlds, Bond knows to be a spy. The second reading is that Bond just knows that there is at least one spy:

$$\mathbf{K}_{\text{Bond}} \exists x \text{ Spy}(x).$$

The modal logic interpretation is that in each accessible world there is an  $x$  that is a spy, but it need not be the same  $x$  in each world.

Referential transparency

Modal logic

Modal operators

Possible world

Accessibility relation

Now that we have a modal operator for knowledge, we can write axioms for it. First, we can say that agents are able to draw conclusions; if an agent knows  $P$  and knows that  $P$  implies  $Q$ , then the agent knows  $Q$ :

$$(\mathbf{K}_a P \wedge \mathbf{K}_a(P \Rightarrow Q)) \Rightarrow \mathbf{K}_a Q.$$

From this (and a few other rules about logical identities) we can establish that  $\mathbf{K}_A(P \vee \neg P)$  is a tautology; every agent knows every proposition  $P$  is either true or false. On the other hand,  $(\mathbf{K}_A P) \vee (\mathbf{K}_A \neg P)$  is not a tautology; in general, there will be lots of propositions that an agent does not know to be true and does not know to be false.

It is said (going back to Plato) that knowledge is justified true belief. That is, if it is true, if you believe it, and if you have an unassailably good reason, then you know it. That means that if you know something, it must be true, and we have the axiom:

$$\mathbf{K}_a P \Rightarrow P.$$

Furthermore, logical agents (but not all people) are able to introspect on their own knowledge. If they know something, then they know that they know it:

$$\mathbf{K}_a P \Rightarrow \mathbf{K}_a(\mathbf{K}_a P).$$

#### Logical omniscience

We can define similar axioms for belief (often denoted by **B**) and other modalities. However, one problem with the modal logic approach is that it assumes **logical omniscience** on the part of agents. That is, if an agent knows a set of axioms, then it knows all consequences of those axioms. This is on shaky ground even for the somewhat abstract notion of knowledge, but it seems even worse for belief, because belief has more connotation of referring to things that are physically represented in the agent, not just potentially derivable.

There have been attempts to define a form of limited rationality for agents—to say that agents believe only those assertions that can be derived with the application of no more than  $k$  reasoning steps, or no more than  $s$  seconds of computation. These attempts have been generally unsatisfactory.

### 10.4.1 Other modal logics

#### Linear temporal logic

Many modal logics have been proposed, for different modalities besides knowledge. One proposal is to add modal operators for *possibility* and *necessity*: it is possibly true that one of the authors of this book is sitting down right now, and it is necessarily true that  $2 + 2 = 4$ .

As mentioned in Section 8.1.2, some logicians favor modalities related to time. In **linear temporal logic**, we add the following modal operators:

- **X**  $P$ : “ $P$  will be true in the next time step”
- **F**  $P$ : “ $P$  will eventually (Finally) be true in some future time step”
- **G**  $P$ : “ $P$  is always (Globally) true”
- **P** **U**  $Q$ : “ $P$  remains true until  $Q$  occurs”

Sometimes there are additional operators that can be derived from these. Adding these modal operators makes the logic itself more complex (and thus makes it harder for a logical inference algorithm to find a proof). But the operators also allow us to state certain facts in a more succinct form (which makes logical inference faster). The choice of which logic to use is similar to the choice of which programming language to use: pick one that is appropriate to your task, that is familiar to you and the others who will share your work, and that is efficient enough for your purposes.

## 10.5 Reasoning Systems for Categories

Categories are the primary building blocks of large-scale knowledge representation schemes. This section describes systems specially designed for organizing and reasoning with categories. There are two closely related families of systems: **semantic networks** provide graphical aids for visualizing a knowledge base and efficient algorithms for inferring properties of an object on the basis of its category membership; and **description logics** provide a formal language for constructing and combining category definitions and efficient algorithms for deciding subset and superset relationships between categories.

Semantic networks

Description logics

### 10.5.1 Semantic networks

In 1909, Charles S. Peirce proposed a graphical notation of nodes and edges called **existential graphs** that he called “the logic of the future.” Thus began a long-running debate between advocates of “logic” and advocates of “semantic networks.” Unfortunately, the debate obscured the fact that semantic networks *are* a form of logic. The notation that semantic networks provide for certain kinds of sentences is often more convenient, but if we strip away the “human interface” issues, the underlying concepts—objects, relations, quantification, and so on—are the same.

Existential graphs

There are many variants of semantic networks, but all are capable of representing individual objects, categories of objects, and relations among objects. A typical graphical notation displays object or category names in ovals or boxes, and connects them with labeled links. For example, Figure 10.4 has a *MemberOf* link between *Mary* and *FemalePersons*, corresponding to the logical assertion  $Mary \in FemalePersons$ ; similarly, the *SisterOf* link between *Mary* and *John* corresponds to the assertion  $SisterOf(Mary, John)$ . We can connect categories using *SubsetOf* links, and so on. It is such fun drawing bubbles and arrows that one can get carried away. For example, we know that persons have female persons as mothers, so can we draw a *HasMother* link from *Persons* to *FemalePersons*? The answer is no, because *HasMother* is a relation between a person and his or her mother, and categories do not have mothers.<sup>5</sup>

For this reason, we have used a special notation—the double-boxed link—in Figure 10.4. This link asserts that

$$\forall x \ x \in Persons \Rightarrow [\forall y \ HasMother(x, y) \Rightarrow y \in FemalePersons].$$

We might also want to assert that persons have two legs—that is,

$$\forall x \ x \in Persons \Rightarrow Legs(x, 2).$$

As before, we need to be careful not to assert that a category has legs; the single-boxed link in Figure 10.4 is used to assert properties of every member of a category.

The semantic network notation makes it convenient to perform **inheritance** reasoning of the kind introduced in Section 10.2. For example, by virtue of being a person, Mary inherits the property of having two legs. Thus, to find out how many legs Mary has, the inheritance algorithm follows the *MemberOf* link from *Mary* to the category she belongs to, and then

<sup>5</sup> Several early systems failed to distinguish between properties of members of a category and properties of the category as a whole. This can lead directly to inconsistencies, as pointed out by Drew McDermott (1976) in his article “Artificial Intelligence Meets Natural Stupidity.” Another common problem was the use of *IsA* links for both subset and membership relations, in correspondence with English usage: “a cat is a mammal” and “Fifi is a cat.” See Exercise 10.NATS for more on these issues.

**Figure 10.4** A semantic network with four objects (John, Mary, 1, and 2) and four categories. Relations are denoted by labeled links.

**Figure 10.5** A fragment of a semantic network showing the representation of the logical assertion  $\text{Fly}(\text{Shankar}, \text{NewYork}, \text{NewDelhi}, \text{Yesterday})$ .

follows *SubsetOf* links up the hierarchy until it finds a category for which there is a boxed *Legs* link—in this case, the *Persons* category. The simplicity and efficiency of this inference mechanism, compared with semidecidable logical theorem proving, has been one of the main attractions of semantic networks.

Inheritance becomes complicated when an object can belong to more than one category or when a category can be a subset of more than one other category; this is called **multiple inheritance**. In such cases, the inheritance algorithm might find two or more conflicting values answering the query. For this reason, multiple inheritance is banned in some **object-oriented programming** (OOP) languages, such as Java, that use inheritance in a class hierarchy. It is usually allowed in semantic networks, but we defer discussion of that until Section 10.6.

The reader might have noticed an obvious drawback of semantic network notation, compared to first-order logic: the fact that links between bubbles represent only *binary* relations. For example, the sentence  $\text{Fly}(\text{Shankar}, \text{NewYork}, \text{NewDelhi}, \text{Yesterday})$  cannot be asserted directly in a semantic network. Nonetheless, we *can* obtain the effect of *n*-ary assertions by reifying the proposition itself as an event belonging to an appropriate event category. Figure 10.5 shows the semantic network structure for this particular event. Notice that the restriction to binary relations forces the creation of a rich ontology of reified concepts.

Reification of propositions makes it possible to represent every ground, function-free atomic sentence of first-order logic in the semantic network notation. Certain kinds of universally quantified sentences can be asserted using inverse links and the singly boxed and doubly boxed arrows applied to categories, but that still leaves us a long way short of full first-order logic. Negation, disjunction, nested function symbols, and existential quantification are all missing. Now it is *possible* to extend the notation to make it equivalent to first-order logic—as in Peirce’s existential graphs—but doing so negates one of the main advantages of semantic networks, which is the simplicity and transparency of the inference processes. Designers can build a large network and still have a good idea about what queries will be efficient, because (a) it is easy to visualize the steps that the inference procedure will go through and (b) in some cases the query language is so simple that difficult queries cannot be posed.

In cases where the expressive power proves to be too limiting, many semantic network systems provide for **procedural attachment** to fill in the gaps. Procedural attachment is a technique whereby a query about (or sometimes an assertion of) a certain relation results in a call to a special procedure designed for that relation rather than a general inference algorithm.

Procedural attachment

One of the most important aspects of semantic networks is their ability to represent **default values** for categories. Examining Figure 10.4 carefully, one notices that John has one leg, despite the fact that he is a person and all persons have two legs. In a strictly logical KB, this would be a contradiction, but in a semantic network, the assertion that all persons have two legs has only default status; that is, a person is assumed to have two legs unless this is contradicted by more specific information. The default semantics is enforced naturally by the inheritance algorithm, because it follows links upwards from the object itself (John in this case) and stops as soon as it finds a value. We say that the default is **overridden** by the more specific value. Notice that we could also override the default number of legs by creating a category of *OneLeggedPersons*, a subset of *Persons* of which *John* is a member.

Default value

Overriding

We can retain a strictly logical semantics for the network if we say that the *Legs* assertion for *Persons* includes an exception for John:

$$\forall x \ x \in \text{Persons} \wedge x \neq \text{John} \Rightarrow \text{Legs}(x, 2).$$

For a *fixed* network, this is semantically adequate but will be much less concise than the network notation itself if there are lots of exceptions. For a network that will be updated with more assertions, however, such an approach fails—we really want to say that any persons as yet unknown with one leg are exceptions too. Section 10.6 goes into more depth on this issue and on default reasoning in general.

### 10.5.2 Description logics

The syntax of first-order logic is designed to make it easy to say things about objects. **Description logics** are notations that are designed to make it easier to describe definitions and properties of categories. Description logic systems evolved from semantic networks in response to pressure to formalize what the networks mean while retaining the emphasis on taxonomic structure as an organizing principle.

Description logic

The principal inference tasks for description logics are **subsumption** (checking if one category is a subset of another by comparing their definitions) and **classification** (checking whether an object belongs to a category). Some systems also include **consistency** of a category definition—whether the membership criteria are logically satisfiable.

Subsumption

Classification

Consistency

---

$$\begin{aligned}
 \text{Concept} &\rightarrow \text{Thing} \mid \text{ConceptName} \\
 &\mid \text{And}(\text{Concept}, \dots) \\
 &\mid \text{All}(\text{RoleName}, \text{Concept}) \\
 &\mid \text{AtLeast}(\text{Integer}, \text{RoleName}) \\
 &\mid \text{AtMost}(\text{Integer}, \text{RoleName}) \\
 &\mid \text{Fills}(\text{RoleName}, \text{IndividualName}, \dots) \\
 &\mid \text{SameAs}(\text{Path}, \text{Path}) \\
 &\mid \text{OneOf}(\text{IndividualName}, \dots) \\
 \text{Path} &\rightarrow [\text{RoleName}, \dots] \\
 \text{ConceptName} &\rightarrow \text{Adult} \mid \text{Female} \mid \text{Male} \mid \dots \\
 \text{RoleName} &\rightarrow \text{Spouse} \mid \text{Daughter} \mid \text{Son} \mid \dots
 \end{aligned}$$

**Figure 10.6** The syntax of descriptions in a subset of the CLASSIC language.

---

The CLASSIC language (Borgida *et al.*, 1989) is a typical description logic. The syntax of CLASSIC descriptions is shown in Figure 10.6.<sup>6</sup> For example, to say that bachelors are unmarried adult males we would write

$$\text{Bachelor} = \text{And}(\text{Unmarried}, \text{Adult}, \text{Male}).$$

The equivalent in first-order logic would be

$$\text{Bachelor}(x) \Leftrightarrow \text{Unmarried}(x) \wedge \text{Adult}(x) \wedge \text{Male}(x).$$

Notice that the description logic has an algebra of operations on predicates, which of course we can't do in first-order logic. Any description in CLASSIC can be translated into an equivalent first-order sentence, but some descriptions are more straightforward in CLASSIC. For example, to describe the set of men with at least three sons who are all unemployed and married to doctors, and at most two daughters who are all professors in physics or math departments, we would use

$$\begin{aligned}
 &\text{And}(\text{Man}, \text{AtLeast}(3, \text{Son}), \text{AtMost}(2, \text{Daughter}), \\
 &\quad \text{All}(\text{Son}, \text{And}(\text{Unemployed}, \text{Married}, \text{All}(\text{Spouse}, \text{Doctor}))), \\
 &\quad \text{All}(\text{Daughter}, \text{And}(\text{Professor}, \text{Fills}(\text{Department}, \text{Physics}, \text{Math}))))).
 \end{aligned}$$

We leave it as an exercise to translate this into first-order logic.

Perhaps the most important aspect of description logics is their emphasis on tractability of inference. A problem instance is solved by describing it and then asking if it is subsumed by one of several possible solution categories. In standard first-order logic systems, predicting the solution time is often impossible. It is frequently left to the user to engineer the representation to detour around sets of sentences that seem to be causing the system to take several

---

<sup>6</sup> Notice that the language does *not* allow one to simply state that one concept, or category, is a subset of another. This is a deliberate policy: subsumption between categories must be derivable from some aspects of the descriptions of the categories. If not, then something is missing from the descriptions.

weeks to solve a problem. The thrust in description logics, on the other hand, is to ensure that subsumption-testing can be solved in time polynomial in the size of the descriptions.<sup>7</sup>

This sounds wonderful in principle, until one realizes that it can only have one of two consequences: either hard problems cannot be stated at all, or they require exponentially large descriptions! However, the tractability results do shed light on what sorts of constructs cause problems and thus help the user to understand how different representations behave. For example, description logics usually lack *negation* and *disjunction*. Each forces first-order logical systems to go through a potentially exponential case analysis in order to ensure completeness. CLASSIC allows only a limited form of disjunction in the *Fills* and *OneOf* constructs, which permit disjunction over explicitly enumerated individuals but not over descriptions. With disjunctive descriptions, nested definitions can lead easily to an exponential number of alternative routes by which one category can subsume another.

## 10.6 Reasoning with Default Information

In the preceding section, we saw a simple example of an assertion with default status: people have two legs. This default can be overridden by more specific information, such as that Long John Silver has one leg. We saw that the inheritance mechanism in semantic networks implements the overriding of defaults in a simple and natural way. In this section, we study defaults more generally, with a view toward understanding the *semantics* of defaults rather than just providing a procedural mechanism.

### 10.6.1 Circumscription and default logic

We have seen two examples of reasoning processes that violate the **monotonicity** property of logic that was proved in Chapter 7.<sup>8</sup> In this chapter we saw that a property inherited by all members of a category in a semantic network could be overridden by more specific information for a subcategory. In Section 9.4.4, we saw that under the closed-world assumption, if a proposition  $\alpha$  is not mentioned in  $KB$  then  $KB \models \neg\alpha$ , but  $KB \wedge \alpha \models \alpha$ .

Monotonicity

Simple introspection suggests that these failures of monotonicity are widespread in commonsense reasoning. It seems that humans often “jump to conclusions.” For example, when one sees a car parked on the street, one is normally willing to believe that it has four wheels even though only three are visible. Now, probability theory can certainly provide a conclusion that the fourth wheel exists with high probability; yet, for most people, the possibility that the car does not have four wheels *will not arise unless some new evidence presents itself*. Thus, it seems that the four-wheel conclusion is reached *by default*, in the absence of any reason to doubt it. If new evidence arrives—for example, if one sees the owner carrying a wheel and notices that the car is jacked up—then the conclusion can be retracted. This kind of reasoning is said to exhibit **nonmonotonicity**, because the set of beliefs does not grow monotonically over time as new evidence arrives. **Nonmonotonic logics** have been devised with modified notions of truth and entailment in order to capture such behavior. We will look at two such logics that have been studied extensively: circumscription and default logic.

Nonmonotonicity  
Nonmonotonic logic

**Circumscription** can be seen as a more powerful and precise version of the closed-world

Circumscription

<sup>7</sup> CLASSIC provides efficient subsumption testing in practice, but the worst-case run time is exponential.

<sup>8</sup> Recall that monotonicity requires all entailed sentences to remain entailed after new sentences are added to the KB. That is, if  $KB \models \alpha$  then  $KB \wedge \beta \models \alpha$ .

assumption. The idea is to specify particular predicates that are assumed to be “as false as possible”—that is, false for every object except those for which they are known to be true. For example, suppose we want to assert the default rule that birds fly. We would introduce a predicate, say  $Abnormal_1(x)$ , and write

$$Bird(x) \wedge \neg Abnormal_1(x) \Rightarrow Flies(x).$$

If we say that  $Abnormal_1$  is to be **circumscribed**, a circumscriptive reasoner is entitled to assume  $\neg Abnormal_1(x)$  unless  $Abnormal_1(x)$  is known to be true. This allows the conclusion  $Flies(Tweety)$  to be drawn from the premise  $Bird(Tweety)$ , but the conclusion no longer holds if  $Abnormal_1(Tweety)$  is asserted.

#### Model preference

Circumscription can be viewed as an example of a **model preference** logic. In such logics, a sentence is entailed (with default status) if it is true in all *preferred* models of the KB, as opposed to the requirement of truth in *all* models in classical logic. For circumscription, one model is preferred to another if it has fewer abnormal objects.<sup>9</sup> Let us see how this idea works in the context of multiple inheritance in semantic networks. The standard example for which multiple inheritance is problematic is called the “Nixon diamond.” It arises from the observation that Richard Nixon was both a Quaker (and hence by default a pacifist) and a Republican (and hence by default not a pacifist). We can write this as follows:

$$Republican(Nixon) \wedge Quaker(Nixon).$$

$$Republican(x) \wedge \neg Abnormal_2(x) \Rightarrow \neg Pacifist(x).$$

$$Quaker(x) \wedge \neg Abnormal_3(x) \Rightarrow Pacifist(x).$$

#### Prioritized circumscription

If we circumscribe  $Abnormal_2$  and  $Abnormal_3$ , there are two preferred models: one in which  $Abnormal_2(Nixon)$  and  $Pacifist(Nixon)$  are true and one in which  $Abnormal_3(Nixon)$  and  $\neg Pacifist(Nixon)$  are true. Thus, the circumscriptive reasoner remains properly agnostic as to whether Nixon was a pacifist. If we wish, in addition, to assert that religious beliefs take precedence over political beliefs, we can use a formalism called **prioritized circumscription** to give preference to models where  $Abnormal_3$  is minimized.

#### Default logic

#### Default rules

**Default logic** is a formalism in which **default rules** can be written to generate contingent, nonmonotonic conclusions. A default rule looks like this:

$$Bird(x) : Flies(x) / Flies(x).$$

This rule means that if  $Bird(x)$  is true, and if  $Flies(x)$  is consistent with the knowledge base, then  $Flies(x)$  may be concluded by default. In general, a default rule has the form

$$P : J_1, \dots, J_n / C$$

where  $P$  is called the prerequisite,  $C$  is the conclusion, and  $J_i$  are the justifications—if any one of them can be proven false, then the conclusion cannot be drawn. Any variable that appears in  $J_i$  or  $C$  must also appear in  $P$ . The Nixon-diamond example can be represented in default logic with one fact and two default rules:

$$Republican(Nixon) \wedge Quaker(Nixon).$$

$$Republican(x) : \neg Pacifist(x) / \neg Pacifist(x).$$

$$Quaker(x) : Pacifist(x) / Pacifist(x).$$

---

<sup>9</sup> For the closed-world assumption, one model is preferred to another if it has fewer true atoms—that is, preferred models are **minimal** models. There is a natural connection between the closed-world assumption and definite-clause KBs, because the fixed point reached by forward chaining on definite-clause KBs is the unique minimal model. See page 249 for more on this point.

To interpret what the default rules mean, we define the notion of an **extension** of a default theory to be a maximal set of consequences of the theory. That is, an extension  $S$  consists of the original known facts and a set of conclusions from the default rules, such that no additional conclusions can be drawn from  $S$ , and the justifications of every default conclusion in  $S$  are consistent with  $S$ . As in the case of the preferred models in circumscription, we have two possible extensions for the Nixon diamond: one wherein he is a pacifist and one wherein he is not. Prioritized schemes exist in which some default rules can be given precedence over others, allowing some ambiguities to be resolved.

Since 1980, when nonmonotonic logics were first proposed, a great deal of progress has been made in understanding their mathematical properties. There are still unresolved questions, however. For example, if “Cars have four wheels” is false, what does it mean to have it in one’s knowledge base? What is a good set of default rules to have? If we cannot decide, for each rule separately, whether it belongs in our knowledge base, then we have a serious problem of nonmodularity. Finally, how can beliefs that have default status be used to make decisions? This is probably the hardest issue for default reasoning.

Decisions often involve tradeoffs, and one therefore needs to compare the *strengths* of belief in the outcomes of different actions, and the *costs* of making a wrong decision. In cases where the same kinds of decisions are being made repeatedly, it is possible to interpret default rules as “threshold probability” statements. For example, the default rule “My brakes are always OK” really means “The probability that my brakes are OK, given no other information, is sufficiently high that the optimal decision is for me to drive without checking them.” When the decision context changes—for example, when one is driving a heavily laden truck down a steep mountain road—the default rule suddenly becomes inappropriate, even though there is no new evidence of faulty brakes. These considerations have led researchers to consider how to embed default reasoning within probability theory or utility theory.

### 10.6.2 Truth maintenance systems

We have seen that many of the inferences drawn by a knowledge representation system will have only default status, rather than being absolutely certain. Inevitably, some of these inferred facts will turn out to be wrong and will have to be retracted in the face of new information. This process is called **belief revision**.<sup>10</sup> Suppose that a knowledge base  $KB$  contains a sentence  $P$ —perhaps a default conclusion recorded by a forward-chaining algorithm, or perhaps just an incorrect assertion—and we want to execute  $\text{TELL}(KB, \neg P)$ . To avoid creating a contradiction, we must first execute  $\text{RETRACT}(KB, P)$ . This sounds easy enough. Problems arise, however, if any *additional* sentences were inferred from  $P$  and asserted in the KB. For example, the implication  $P \Rightarrow Q$  might have been used to add  $Q$ . The obvious “solution”—retracting all sentences inferred from  $P$ —fails because such sentences may have other justifications besides  $P$ . For example, if  $R$  and  $R \Rightarrow Q$  are also in the KB, then  $Q$  does not have to be removed after all. **Truth maintenance systems**, or TMSs, are designed to handle exactly these kinds of complications.

One simple approach to truth maintenance is to keep track of the order in which sentences are told to the knowledge base by numbering them from  $P_1$  to  $P_n$ . When the call

<sup>10</sup> Belief revision is often contrasted with **belief update**, which occurs when a knowledge base is revised to reflect a change in the world rather than new information about a fixed world. Belief update combines belief revision with reasoning about time and change; it is also related to the process of **filtering** described in Chapter 14.

Extension

Belief revision

Truth maintenance system

$\text{RETRACT}(KB, P_i)$  is made, the system reverts to the state just before  $P_i$  was added, thereby removing both  $P_i$  and any inferences that were derived from  $P_i$ . The sentences  $P_{i+1}$  through  $P_n$  can then be added again. This is simple, and it guarantees that the knowledge base will be consistent, but retracting  $P_i$  requires retracting and reasserting  $n - i$  sentences as well as undoing and redoing all the inferences drawn from those sentences. For systems to which many facts are being added—such as large commercial databases—this is impractical.

#### JTMS Justification

A more efficient approach is the justification-based truth maintenance system, or **JTMS**. In a JTMS, each sentence in the knowledge base is annotated with a **justification** consisting of the set of sentences from which it was inferred. For example, if the knowledge base already contains  $P \Rightarrow Q$ , then  $\text{TELL}(P)$  will cause  $Q$  to be added with the justification  $\{P, P \Rightarrow Q\}$ . In general, a sentence can have any number of justifications. Justifications make retraction efficient. Given the call  $\text{RETRACT}(P)$ , the JTMS will delete exactly those sentences for which  $P$  is a member of every justification. So, if a sentence  $Q$  had the single justification  $\{P, P \Rightarrow Q\}$ , it would be removed; if it had the additional justification  $\{P, P \vee R \Rightarrow Q\}$ , it would still be removed; but if it also had the justification  $\{R, P \vee R \Rightarrow Q\}$ , then it would be spared. In this way, the time required for retraction of  $P$  depends only on the number of sentences derived from  $P$  rather than on the number of sentences added after  $P$ .

The JTMS assumes that sentences that are considered once will probably be considered again, so rather than deleting a sentence from the knowledge base entirely when it loses all justifications, we merely mark the sentence as being *out* of the knowledge base. If a subsequent assertion restores one of the justifications, then we mark the sentence as being back *in*. In this way, the JTMS retains all the inference chains that it uses and need not rederive sentences when a justification becomes valid again.

In addition to handling the retraction of incorrect information, TMSs can be used to speed up the analysis of multiple hypothetical situations. Suppose, for example, that the Romanian Olympic Committee is choosing sites for the swimming, athletics, and equestrian events at the 2048 Games to be held in Romania. For example, let the first hypothesis be  $\text{Site}(\text{Swimming}, \text{Pitesti})$ ,  $\text{Site}(\text{Athletics}, \text{Bucharest})$ , and  $\text{Site}(\text{Equestrian}, \text{Arad})$ .

A great deal of reasoning must then be done to work out the logistical consequences and hence the desirability of this selection. If we want to consider  $\text{Site}(\text{Athletics}, \text{Sibiu})$  instead, the TMS avoids the need to start again from scratch. Instead, we simply retract  $\text{Site}(\text{Athletics}, \text{Bucharest})$  and assert  $\text{Site}(\text{Athletics}, \text{Sibiu})$  and the TMS takes care of the necessary revisions. Inference chains generated from the choice of Bucharest can be reused with Sibiu, provided that the conclusions are the same.

## ATMS

An assumption-based truth maintenance system, or **ATMS**, makes this type of context-switching between hypothetical worlds particularly efficient. In a JTMS, the maintenance of justifications allows you to move quickly from one state to another by making a few retractions and assertions, but at any time only one state is represented. An ATMS represents *all* the states that have ever been considered at the same time. Whereas a JTMS simply labels each sentence as being *in* or *out*, an ATMS keeps track, for each sentence, of which assumptions would cause the sentence to be true. In other words, each sentence has a label that consists of a set of assumption sets. The sentence is true just in those cases in which all the assumptions in one of the assumption sets are true.

## Explanation

Truth maintenance systems also provide a mechanism for generating **explanations**. Technically, an explanation of a sentence  $P$  is a set of sentences  $E$  such that  $E$  entails  $P$ . If the

sentences in  $E$  are already known to be true, then  $E$  simply provides a sufficient basis for proving that  $P$  must be the case. But explanations can also include **assumptions**—sentences that are not known to be true, but would suffice to prove  $P$  if they were true. For example, if your car won't start, you probably don't have enough information to definitively prove the reason for the problem. But a reasonable explanation might include the assumption that the battery is dead. This, combined with knowledge of how cars operate, explains the observed nonbehavior. In most cases, we will prefer an explanation  $E$  that is minimal, meaning that there is no proper subset of  $E$  that is also an explanation. An ATMS can generate explanations for the “car won't start” problem by making assumptions (such as “no gas in car” or “battery dead”) in any order we like, even if some assumptions are contradictory. Then we look at the label for the sentence “car won't start” to read off the sets of assumptions that would justify the sentence.

The exact algorithms used to implement truth maintenance systems are a little complicated, and we do not cover them here. The computational complexity of the truth maintenance problem is at least as great as that of propositional inference—that is, NP-hard. Therefore, you should not expect truth maintenance to be a panacea. When used carefully, however, a TMS can provide a substantial increase in the ability of a logical system to handle complex environments and hypotheses.

## Summary

---

By delving into the details of how one represents a variety of knowledge, we hope we have given the reader a sense of how real knowledge bases are constructed and a feeling for the interesting philosophical issues that arise. The major points are as follows:

- Large-scale knowledge representation requires a general-purpose ontology to organize and tie together the various specific domains of knowledge.
- A general-purpose ontology needs to cover a wide variety of knowledge and should be capable, in principle, of handling any domain.
- Building a large, general-purpose ontology is a significant challenge that has yet to be fully realized, although current frameworks seem to be quite robust.
- We presented an **upper ontology** based on categories and the event calculus. We covered categories, subcategories, parts, structured objects, measurements, substances, events, time and space, change, and beliefs.
- Natural kinds cannot be defined completely in logic, but properties of natural kinds can be represented.
- Actions, events, and time can be represented with the event calculus. Such representations enable an agent to construct sequences of actions and make logical inferences about what will be true when these actions happen.
- Special-purpose representation systems, such as **semantic networks** and **description logics**, have been devised to help in organizing a hierarchy of categories. **Inheritance** is an important form of inference, allowing the properties of objects to be deduced from their membership in categories.

- The **closed-world assumption**, as implemented in logic programs, provides a simple way to avoid having to specify lots of negative information. It is best interpreted as a **default** that can be overridden by additional information.
- **Nonmonotonic logics**, such as **circumscription** and **default logic**, are intended to capture default reasoning in general.
- **Truth maintenance systems** handle knowledge updates and revisions efficiently.
- It is difficult to construct large ontologies by hand; extracting knowledge from text makes the job easier.

## Bibliographical and Historical Notes

---

Briggs (1985) claims that knowledge representation research began with first millennium BCE Indian theorizing about the grammar of Shastric Sanskrit. Western philosophers trace their work on the subject back to c. 300 BCE in Aristotle's *Metaphysics* (literally, what comes after the book on physics). The development of technical terminology in any field can be regarded as a form of knowledge representation.

Early discussions of representation in AI tended to focus on “*problem* representation” rather than “*knowledge* representation.” (See, for example, Amarel's (1968) discussion of the “Missionaries and Cannibals” problem.) In the 1970s, AI emphasized the development of “expert systems” (also called “knowledge-based systems”) that could, if given the appropriate domain knowledge, match or exceed the performance of human experts on narrowly defined tasks. For example, the first expert system, DENDRAL (Feigenbaum *et al.*, 1971; Lindsay *et al.*, 1980), interpreted the output of a mass spectrometer (a type of instrument used to analyze the structure of organic chemical compounds) as accurately as expert chemists. Although the success of DENDRAL was instrumental in convincing the AI research community of the importance of knowledge representation, the representational formalisms used in DENDRAL are highly specific to the domain of chemistry.

Over time, researchers became interested in standardized knowledge representation formalisms and ontologies that could assist in the creation of new expert systems. This brought them into territory previously explored by philosophers of science and of language. The discipline imposed in AI by the need for one's theories to “work” has led to more rapid and deeper progress than when these problems were the exclusive domain of philosophy (although it has at times also led to the repeated reinvention of the wheel).

But to what extent can we trust expert knowledge? As far back as 1955, Paul Meehl (see also Grove and Meehl, 1996) studied the decision-making processes of trained experts at subjective tasks such as predicting the success of a student in a training program or the recidivism of a criminal. In 19 out of the 20 studies he looked at, Meehl found that simple statistical learning algorithms (such as linear regression or naive Bayes) predict better than the experts. Tetlock (2017) also studies expert knowledge and finds it lacking in difficult cases. The Educational Testing Service has used an automated program to grade millions of essay questions on the GMAT exam since 1999. The program agrees with human graders 97% of the time, about the same level that two human graders agree (Burstein *et al.*, 2001). (This does not mean the program understands essays, just that it can distinguish good ones from bad ones about as well as human graders can.)

The creation of comprehensive taxonomies or classifications dates back to ancient times. Aristotle (384–322 BCE) strongly emphasized classification and categorization schemes. His *Organon*, a collection of works on logic assembled by his students after his death, included a treatise called *Categories* in which he attempted to construct what we would now call an upper ontology. He also introduced the notions of **genus** and **species** for lower-level classification. Our present system of biological classification, including the use of “binomial nomenclature” (classification via genus and species in the technical sense), was invented by the Swedish biologist Carolus Linnaeus, or Carl von Linne (1707–1778). The problems associated with natural kinds and inexact category boundaries have been addressed by Wittgenstein (1953), Quine (1953), Lakoff (1987), and Schwartz (1977), among others.

See Chapter 25 for a discussion of deep neural network representations of words and concepts that escape some of the problems of a strict ontology, but also sacrifice some of the precision. We still don’t know the best way to combine the advantages of neural networks and logical semantics for representation.

Interest in larger-scale ontologies is increasing, as documented by the *Handbook on Ontologies* (Staab, 2004). The OPENCYC project (Lenat and Guha, 1990; Matuszek *et al.*, 2006) has released a 150,000-concept ontology, with an upper ontology similar to the one in Figure 10.1 as well as specific concepts like “OLED Display” and “iPhone,” which is a type of “cellular phone,” which in turn is a type of “consumer electronics,” “phone,” “wireless communication device,” and other concepts. The NEXTKB project extends CYC and other resources including FrameNet and WordNet into a knowledge base with almost 3 million facts, and provides a reasoning engine, FIRE to go with it (Forbus *et al.*, 2010).

The DBPEDIA project extracts structured data from Wikipedia, specifically from Infoboxes: the attribute/value pairs that accompany many Wikipedia articles (Wu and Weld, 2008; Bizer *et al.*, 2007). As of 2015, DBPEDIA contained 400 million facts about 4 million objects in the English version alone; counting all 110 languages yields 1.5 billion facts (Lehmann *et al.*, 2015).

The IEEE working group P1600.1 created SUMO, the Suggested Upper Merged Ontology (Niles and Pease, 2001; Pease and Niles, 2002), with about 1000 terms in the upper ontology and links to over 20,000 domain-specific terms. Stoffel *et al.* (1997) describe algorithms for efficiently managing a very large ontology. A survey of techniques for extracting knowledge from Web pages is given by Etzioni *et al.* (2008).

On the Web, representation languages are emerging. RDF (Brickley and Guha, 2004) allows for assertions to be made in the form of relational triples and provides some means for evolving the meaning of names over time. OWL (Smith *et al.*, 2004) is a description logic that supports inferences over these triples. So far, usage seems to be inversely proportional to representational complexity: the traditional HTML and CSS formats account for over 99% of Web content, followed by the simplest representation schemes, such as RDFa (Adida and Birbeck, 2008), and microformats (Khare, 2006; Patel-Schneider, 2014) which use HTML and XHTML markup to add attributes to text on web pages. Usage of sophisticated RDF and OWL ontologies is not yet widespread, and the full vision of the Semantic Web (Berners-Lee *et al.*, 2001) has not been realized. The conferences on *Formal Ontology in Information Systems* (FOIS) covers both general and domain-specific ontologies.

The taxonomy used in this chapter was developed by the authors and is based in part on their experience in the CYC project and in part on work by Hwang and Schubert (1993)

and Davis (1990, 2005). An inspirational discussion of the general project of commonsense knowledge representation appears in Hayes's (1978, 1985b) "Naive Physics Manifesto."

Successful deep ontologies within a specific field include the Gene Ontology project (Gene Ontology Consortium, 2008) and the Chemical Markup Language (Murray-Rust *et al.*, 2003). Doubts about the feasibility of a single ontology for *all* knowledge are expressed by Doctorow (2001), Gruber (2004), Halevy *et al.* (2009), and Smith (2004).

The event calculus was introduced by Kowalski and Sergot (1986) to handle continuous time, and there have been several variations (Sadri and Kowalski, 1995; Shanahan, 1997) and overviews (Shanahan, 1999; Mueller, 2006). James Allen introduced time intervals for the same reason (Allen, 1984), arguing that intervals were much more natural than situations for reasoning about extended and concurrent events. In van Lambalgen and Hamm (2005) we see how the logic of events maps onto the language we use to talk about events. An alternative to the event and situation calculi is the fluent calculus (Thielscher, 1999), which reifies the facts out of which states are composed.

Peter Ladkin (1986a, 1986b) introduced "concave" time intervals (intervals with gaps—essentially, unions of ordinary "convex" time intervals) and applied the techniques of mathematical abstract algebra to time representation. Allen (1991) systematically investigates the wide variety of techniques available for time representation; van Beek and Manchak (1996) analyze algorithms for temporal reasoning. There are significant commonalities between the event-based ontology given in this chapter and an analysis of events due to the philosopher Donald Davidson (1980). The **histories** in Pat Hayes's (1985a) ontology of liquids and the **chronicles** in McDermott's (1985) theory of plans were also important influences on the field and on this chapter.

The question of the ontological status of substances has a long history. Plato proposed that substances were abstract entities entirely distinct from physical objects; he would say *MadeOf(Butter<sub>3</sub>, Butter)* rather than *Butter<sub>3</sub> ∈ Butter*. This leads to a substance hierarchy in which, for example, *UnsaltedButter* is a more specific substance than *Butter*. The position adopted in this chapter, in which substances are categories of objects, was championed by Richard Montague (1973). It has also been adopted in the CYC project. Copeland (1993) mounts a serious, but not invincible, attack.

The alternative approach mentioned in the chapter, in which butter is one object consisting of all buttery objects in the universe, was proposed originally by the Polish logician Leśniewski (1916). His **mereology** (the name is derived from the Greek word for "part") used the part–whole relation as a substitute for mathematical set theory, with the aim of eliminating abstract entities such as sets. A more readable exposition of these ideas is given by Leonard and Goodman (1940), and Goodman's *The Structure of Appearance* (1977) applies the ideas to various problems in knowledge representation.

While some aspects of the mereological approach are awkward—for example, the need for a separate inheritance mechanism based on part–whole relations—the approach gained the support of Quine (1960). Harry Bunt (1985) has provided an extensive analysis of its use in knowledge representation. Casati and Varzi (1999) cover parts, wholes, and a general theory of spatial locations.

There are three main approaches to the study of mental objects. The one taken in this chapter, based on modal logic and possible worlds, is the classical approach from philosophy (Hintikka, 1962; Kripke, 1963; Hughes and Cresswell, 1996). The book *Reasoning about*

*Knowledge* (Fagin *et al.*, 1995) provides a thorough introduction, and Gordon and Hobbs (2017) provide *A Formal Theory of Commonsense Psychology*.

The second approach is a first-order theory in which mental objects are fluents. Davis (2005) and Davis and Morgenstern (2005) describe this approach. It relies on the possible-worlds formalism, and builds on work by Robert Moore (1980, 1985).

The third approach is a **syntactic theory**, in which mental objects are represented by character strings. A string is just a complex term denoting a list of symbols, so *CanFly(Clark)* can be represented by the list of symbols  $[C, a, n, F, l, y, (, C, l, a, r, k, )]$ . The syntactic theory of mental objects was first studied in depth by Kaplan and Montague (1960), who showed that it led to paradoxes if not handled carefully. Ernie Davis (1990) provides an excellent comparison of the syntactic and modal theories of knowledge. Pnueli (1977) describes a temporal logic used to reason about programs, work that won him the Turing Award and which was expanded upon by Vardi (1996). Littman *et al.* (2017) show that a temporal logic can be a good language for specifying goals to a reinforcement learning robot in a way that is easy for a human to specify, and generalizes well to different environments.

The Greek philosopher Porphyry (c. 234–305 CE), commenting on Aristotle’s *Categories*, drew what might qualify as the first semantic network. Charles S. Peirce (1909) developed existential graphs as the first semantic network formalism using modern logic. Ross Quillian (1961), driven by an interest in human memory and language processing, initiated work on semantic networks within AI. An influential paper by Marvin Minsky (1975) presented a version of semantic networks called **frames**; a frame was a representation of an object or category, with attributes and relations to other objects or categories.

The question of semantics arose quite acutely with respect to Quillian’s semantic networks (and those of others who followed his approach), with their ubiquitous and very vague “IS-A links.” Bill Woods’s (1975) famous article “What’s In a Link?” drew the attention of AI researchers to the need for precise semantics in knowledge representation formalisms. Ron Brachman (1979) elaborated on this point and proposed solutions. Patrick Hayes’s (1979) “The Logic of Frames” cut even deeper, claiming that “Most of ‘frames’ is just a new syntax for parts of first-order logic.” Drew McDermott’s (1978b) “Tarskian Semantics, or, No Notation without Denotation!” argued that the model-theoretic approach to semantics used in first-order logic should be applied to all knowledge representation formalisms. This remains a controversial idea; notably, McDermott himself has reversed his position in “A Critique of Pure Reason” (McDermott, 1987). Selman and Levesque (1993) discuss the complexity of inheritance with exceptions, showing that in most formulations it is NP-complete.

Description logics were developed as a useful subset of first-order logic for which inference is computationally tractable. Hector Levesque and Ron Brachman (1987) showed that certain uses of disjunction and negation were primarily responsible for the intractability of logical inference. This led to a better understanding of the interaction between complexity and expressiveness in reasoning systems. Calvanese *et al.* (1999) summarize the state of the art, and Baader *et al.* (2007) present a comprehensive handbook of description logic.

The three main formalisms for dealing with nonmonotonic inference—circumscription (McCarthy, 1980), default logic (Reiter, 1980), and modal nonmonotonic logic (McDermott and Doyle, 1980)—were all introduced in one special issue of the AI Journal. Delgrande and Schaub (2003) discuss the merits of the variants, given 25 years of hindsight. Answer set programming can be seen as an extension of negation as failure or as a refinement of

circumscription; the underlying theory of stable model semantics was introduced by Gelfond and Lifschitz (1988), and the leading answer set programming systems are DLV (Eiter *et al.*, 1998) and SMODELS (Niemelä *et al.*, 2000). Brewka *et al.* (1997) give a good overview of the various approaches to nonmonotonic logic. Clark (1978) covers the negation-as-failure approach to logic programming and Clark completion. Lifschitz (2001) discusses the application of answer set programming to planning. A variety of nonmonotonic reasoning systems based on logic programming are documented in the proceedings of the conferences on *Logic Programming and Nonmonotonic Reasoning* (LPNMR).

The study of truth maintenance systems began with the TMS (Doyle, 1979) and RUP (McAllester, 1980) systems, both of which were essentially JTMSs. Forbus and de Kleer (1993) explain in depth how TMSs can be used in AI applications. Nayak and Williams (1997) show how an efficient incremental TMS called an ITMS makes it feasible to plan the operations of a NASA spacecraft in real time.

This chapter could not cover *every* area of knowledge representation in depth. The three principal topics omitted are the following:

#### [Qualitative physics](#)

**Qualitative physics:** Qualitative physics is a subfield of knowledge representation concerned specifically with constructing a logical, nonnumeric theory of physical objects and processes. The term was coined by Johan de Kleer (1975), although the enterprise could be said to have started in Fahlman's (1974) BUILD, a sophisticated planner for constructing complex towers of blocks. Fahlman discovered in the process of designing it that most of the effort (80%, by his estimate) went into modeling the physics of the blocks world to calculate the stability of various subassemblies of blocks, rather than into planning per se. He sketches a hypothetical naive-physics-like process to explain why young children can solve BUILD-like problems without access to the high-speed floating-point arithmetic used in BUILD's physical modeling. Hayes (1985a) uses "histories"—four-dimensional slices of space-time similar to Davidson's events—to construct a fairly complex naive physics of liquids. Davis (2008) gives an update to the ontology of liquids that describes the pouring of liquids into containers.

De Kleer and Brown (1985), Ken Forbus (1985), and Benjamin Kuipers (1985) independently and almost simultaneously developed systems that can reason about a physical system based on qualitative abstractions of the underlying equations. Qualitative physics soon developed to the point where it became possible to analyze an impressive variety of complex physical systems (Yip, 1991). Qualitative techniques have been used to construct novel designs for clocks, windshield wipers, and six-legged walkers (Subramanian and Wang, 1994). The collection *Readings in Qualitative Reasoning about Physical Systems* (Weld and de Kleer, 1990), an encyclopedia article by Kuipers (2001), and a handbook article by Davis (2007) provide good introductions to the field.

#### [Spatial reasoning](#)

**Spatial reasoning:** The reasoning necessary to navigate in the wumpus world is trivial in comparison to the rich spatial structure of the real world. The earliest serious attempt to capture commonsense reasoning about space appears in the work of Ernest Davis (1986, 1990). The region connection calculus of Cohn *et al.* (1997) supports a form of qualitative spatial reasoning and has led to new kinds of geographical information systems; see also (Davis, 2006). As with qualitative physics, an agent can go a long way, so to speak, without resorting to a full metric representation.

**Psychological reasoning:** Psychological reasoning involves the development of a working *psychology* for artificial agents to use in reasoning about themselves and other agents. This is often based on so-called folk psychology, the theory that humans in general are believed to use in reasoning about themselves and other humans. When AI researchers provide their artificial agents with psychological theories for reasoning about other agents, the theories are frequently based on the researchers' description of the logical agents' own design. Psychological reasoning is currently most useful within the context of natural language understanding, where divining the speaker's intentions is of paramount importance.

Minker (2001) collects papers by leading researchers in knowledge representation, summarizing 40 years of work in the field. The proceedings of the international conferences on *Principles of Knowledge Representation and Reasoning* provide the most up-to-date sources for work in this area. *Readings in Knowledge Representation* (Brachman and Levesque, 1985) and *Formal Theories of the Commonsense World* (Hobbs and Moore, 1985) are excellent anthologies on knowledge representation; the former focuses more on historically important papers in representation languages and formalisms, the latter on the accumulation of the knowledge itself. Davis (1990), Stefik (1995), and Sowa (1999) provide textbook introductions to knowledge representation, van Harmelen *et al.* (2007) contributes a handbook, and Davis and Morgenstern (2004) edited a special issue of the AI Journal on the topic. Davis (2017) gives a survey of logic for commonsense reasoning. The biennial conference on *Theoretical Aspects of Reasoning About Knowledge* (TARK) covers applications of the theory of knowledge in AI, economics, and distributed systems.

Psychological  
reasoning

# CHAPTER 11

## AUTOMATED PLANNING

*In which we see how an agent can take advantage of the structure of a problem to efficiently construct complex plans of action.*

Planning a course of action is a key requirement for an intelligent agent. The right representation for actions and states and the right algorithms can make this easier. In Section 11.1 we introduce a general **factored** representation language for planning problems that can naturally and succinctly represent a wide variety of domains, can efficiently scale up to large problems, and does not require ad hoc heuristics for a new domain. Section 11.4 extends the representation language to allow for hierarchical actions, allowing us to tackle more complex problems. We cover efficient algorithms for planning in Section 11.2, and heuristics for them in Section 11.3. In Section 11.5 we account for partially observable and nondeterministic domains, and in Section 11.6 we extend the language once again to cover scheduling problems with resource constraints. This gets us closer to planners that are used in the real world for planning and scheduling the operations of spacecraft, factories, and military campaigns. Section 11.7 analyzes the effectiveness of these techniques.

### 11.1 Definition of Classical Planning

[Classical planning](#)

**Classical planning** is defined as the task of finding a sequence of actions to accomplish a goal in a discrete, deterministic, static, fully observable environment. We have seen two approaches to this task: the problem-solving agent of Chapter 3 and the hybrid propositional logical agent of Chapter 7. Both share two limitations. First, they both require ad hoc heuristics for each new domain: a heuristic evaluation function for search, and hand-written code for the hybrid wumpus agent. Second, they both need to explicitly represent an exponentially large state space. For example, in the propositional logic model of the wumpus world, the axiom for moving a step forward had to be repeated for all four agent orientations,  $T$  time steps, and  $n^2$  current locations.

[PDDL](#)

In response to these limitations, planning researchers have invested in a **factored representation** using a family of languages called **PDDL**, the Planning Domain Definition Language (Ghallab *et al.*, 1998), which allows us to express all  $4Tn^2$  actions with a single action schema, and does not need domain-specific knowledge. Basic PDDL can handle classical planning domains, and extensions can handle non-classical domains that are continuous, partially observable, concurrent, and multi-agent. The syntax of PDDL is based on Lisp, but we will translate it into a form that matches the notation used in this book.

[State](#)

In PDDL, a **state** is represented as a conjunction of ground atomic fluents. Recall that “ground” means no variables, “fluent” means an aspect of the world that changes over time,

and “ground atomic” means there is a single predicate, and if there are any arguments, they must be constants. For example,  $Poor \wedge Unknown$  might represent the state of a hapless agent, and  $At(Truck_1, Melbourne) \wedge At(Truck_2, Sydney)$  could represent a state in a package delivery problem. PDDL uses **database semantics**: the closed-world assumption means that any fluents that are not mentioned are false, and the unique names assumption means that  $Truck_1$  and  $Truck_2$  are distinct.

The following fluents are *not* allowed in a state:  $At(x, y)$  (because it has variables),  $\neg Poor$  (because it is a negation), and  $At(Spouse(Ali), Sydney)$  (because it uses a function symbol,  $Spouse$ ). When convenient, we can think of the conjunction of fluents as a *set* of fluents.

An **action schema** represents a family of ground actions. For example, here is an action schema for flying a plane from one location to another:

Action( $Fly(p, from, to)$ ,  
 PRECOND: $At(p, from) \wedge Plane(p) \wedge Airport(from) \wedge Airport(to)$   
 EFFECT: $\neg At(p, from) \wedge At(p, to)$ )

The schema consists of the action name, a list of all the variables used in the schema, a **precondition** and an **effect**. The precondition and the effect are each conjunctions of literals (positive or negated atomic sentences). We can choose constants to instantiate the variables, yielding a ground (variable-free) action:

Action( $Fly(P_1, SFO, JFK)$ ,  
 PRECOND: $At(P_1, SFO) \wedge Plane(P_1) \wedge Airport(SFO) \wedge Airport(JFK)$   
 EFFECT: $\neg At(P_1, SFO) \wedge At(P_1, JFK)$ )

A ground action  $a$  is **applicable** in state  $s$  if  $s$  entails the precondition of  $a$ ; that is, if every positive literal in the precondition is in  $s$  and every negated literal is not.

The **result** of executing applicable action  $a$  in state  $s$  is defined as a state  $s'$  which is represented by the set of fluents formed by starting with  $s$ , removing the fluents that appear as negative literals in the action’s effects (what we call the **delete list** or  $DEL(a)$ ), and adding the fluents that are positive literals in the action’s effects (what we call the **add list** or  $ADD(a)$ ):

$$\text{RESULT}(s, a) = (s - \text{DEL}(a)) \cup \text{ADD}(a). \quad (11.1)$$

For example, with the action  $Fly(P_1, SFO, JFK)$ , we would remove the fluent  $At(P_1, SFO)$  and add the fluent  $At(P_1, JFK)$ .

A set of action schemas serves as a definition of a planning *domain*. A specific *problem* within the domain is defined with the addition of an initial state and a goal. The **initial state** is a conjunction of ground fluents (introduced with the keyword *Init* in Figure 11.1). As with all states, the closed-world assumption is used, which means that any atoms that are not mentioned are false. The **goal** (introduced with *Goal*) is just like a precondition: a conjunction of literals (positive or negative) that may contain variables. For example, the goal  $At(C_1, SFO) \wedge \neg At(C_2, SFO) \wedge At(p, SFO)$ , refers to any state in which cargo  $C_1$  is at  $SFO$  but  $C_2$  is not, and in which there is a plane at  $SFO$ .

### 11.1.1 Example domain: Air cargo transport

Figure 11.1 shows an air cargo transport problem involving loading and unloading cargo and flying it from place to place. The problem can be defined with three actions: *Load*, *Unload*, and *Fly*. The actions affect two predicates:  $In(c, p)$  means that cargo  $c$  is inside plane  $p$ , and  $At(x, a)$  means that object  $x$  (either plane or cargo) is at airport  $a$ . Note that some care

---

```

Init(At(C1, SFO) ∧ At(C2, JFK) ∧ At(P1, SFO) ∧ At(P2, JFK)
     ∧ Cargo(C1) ∧ Cargo(C2) ∧ Plane(P1) ∧ Plane(P2)
     ∧ Airport(JFK) ∧ Airport(SFO))
Goal(At(C1, JFK) ∧ At(C2, SFO))
Action(Load(c, p, a),
       PRECOND: At(c, a) ∧ At(p, a) ∧ Cargo(c) ∧ Plane(p) ∧ Airport(a)
       EFFECT: ¬At(c, a) ∧ In(c, p))
Action(Unload(c, p, a),
       PRECOND: In(c, p) ∧ At(p, a) ∧ Cargo(c) ∧ Plane(p) ∧ Airport(a)
       EFFECT: At(c, a) ∧ ¬In(c, p))
Action(Fly(p, from, to),
       PRECOND: At(p, from) ∧ Plane(p) ∧ Airport(from) ∧ Airport(to)
       EFFECT: ¬At(p, from) ∧ At(p, to))

```

**Figure 11.1** A PDDL description of an air cargo transportation planning problem.

---

must be taken to make sure the *At* predicates are maintained properly. When a plane flies from one airport to another, all the cargo inside the plane goes with it. In first-order logic it would be easy to quantify over all objects that are inside the plane. But PDDL does not have a universal quantifier, so we need a different solution. The approach we use is to say that a piece of cargo ceases to be *At* anywhere when it is *In* a plane; the cargo only becomes *At* the new airport when it is unloaded. So *At* really means “available for use *at* a given location.” The following plan is a solution to the problem:

[Load(C<sub>1</sub>, P<sub>1</sub>, SFO), Fly(P<sub>1</sub>, SFO, JFK), Unload(C<sub>1</sub>, P<sub>1</sub>, JFK),
 Load(C<sub>2</sub>, P<sub>2</sub>, JFK), Fly(P<sub>2</sub>, JFK, SFO), Unload(C<sub>2</sub>, P<sub>2</sub>, SFO)].

### 11.1.2 Example domain: The spare tire problem

Consider the problem of changing a flat tire (Figure 11.2). The goal is to have a good spare tire properly mounted onto the car’s axle, where the initial state has a flat tire on the axle and a good spare tire in the trunk. To keep it simple, our version of the problem is an abstract one, with no sticky lug nuts or other complications. There are just four actions: removing the spare from the trunk, removing the flat tire from the axle, putting the spare on the axle, and leaving the car unattended overnight. We assume that the car is parked in a particularly bad neighborhood, so that the effect of leaving it overnight is that the tires disappear. [Remove(Flat, Axle), Remove(Spare, Trunk), PutOn(Spare, Axle)] is a solution to the problem.

### 11.1.3 Example domain: The blocks world

One of the most famous planning domains is the **blocks world**. This domain consists of a set of cube-shaped blocks sitting on an arbitrarily-large table.<sup>1</sup> The blocks can be stacked, but only one block can fit directly on top of another. A robot arm can pick up a block and move it to another position, either on the table or on top of another block. The arm can pick up only one block at a time, so it cannot pick up a block that has another one on top of it. A typical goal to get block *A* on *B* and block *B* on *C* (see Figure 11.3).

---

<sup>1</sup> The blocks world commonly used in planning research is much simpler than SHRDLU’s version (page 38).

---

```

Init(Tire(Flat) ∧ Tire(Spare) ∧ At(Flat,Axle) ∧ At(Spare,Trunk))
Goal(At(Spare,Axle))
Action(Remove(obj,loc),
  PRECOND: At(obj,loc)
  EFFECT: ¬At(obj,loc) ∧ At(obj,Ground))
Action(PutOn(t, Axle),
  PRECOND: Tire(t) ∧ At(t,Ground) ∧ ¬At(Flat,Axle) ∧ ¬At(Spare,Axle)
  EFFECT: ¬At(t,Ground) ∧ At(t,Axle))
Action(LeaveOvernight,
  PRECOND:
  EFFECT: ¬At(Spare,Ground) ∧ ¬At(Spare,Axle) ∧ ¬At(Spare,Trunk)
        ∧ ¬At(Flat,Ground) ∧ ¬At(Flat,Axle) ∧ ¬At(Flat, Trunk))

```

**Figure 11.2** The simple spare tire problem.

---

---

---

---

```

Init(On(A,Table) ∧ On(B,Table) ∧ On(C,A)
     ∧ Block(A) ∧ Block(B) ∧ Block(C) ∧ Clear(B) ∧ Clear(C) ∧ Clear(Table))
Goal(On(A,B) ∧ On(B,C))
Action(Move(b,x,y),
  PRECOND: On(b,x) ∧ Clear(b) ∧ Clear(y) ∧ Block(b) ∧ Block(y) ∧
            (b≠x) ∧ (b≠y) ∧ (x≠y),
  EFFECT: On(b,y) ∧ Clear(x) ∧ ¬On(b,x) ∧ ¬Clear(y))
Action(MoveToTable(b,x),
  PRECOND: On(b,x) ∧ Clear(b) ∧ Block(b) ∧ Block(x),
  EFFECT: On(b,Table) ∧ Clear(x) ∧ ¬On(b,x))

```

**Figure 11.4** A planning problem in the blocks world: building a three-block tower. One solution is the sequence [MoveToTable(C,A), Move(B,Table,C), Move(A,Table,B)].

---

We use  $On(b,x)$  to indicate that block  $b$  is on  $x$ , where  $x$  is either another block or the table. The action for moving block  $b$  from the top of  $x$  to the top of  $y$  will be  $Move(b,x,y)$ . Now, one of the preconditions on moving  $b$  is that no other block be on it. In first-order logic, this would be  $\neg\exists x On(x,b)$  or, alternatively,  $\forall x \neg On(x,b)$ . Basic PDDL does not allow quantifiers, so instead we introduce a predicate  $Clear(x)$  that is true when nothing is on  $x$ . (The complete problem description is in Figure 11.4.)

The action  $Move$  moves a block  $b$  from  $x$  to  $y$  if both  $b$  and  $y$  are clear. After the move is made,  $b$  is still clear but  $y$  is not. A first attempt at the  $Move$  schema is

```
Action( $Move(b,x,y)$ ),
  PRECOND: $On(b,x) \wedge Clear(b) \wedge Clear(y)$ ,
  EFFECT: $On(b,y) \wedge Clear(x) \wedge \neg On(b,x) \wedge \neg Clear(y)$ .
```

Unfortunately, this does not maintain  $Clear$  properly when  $x$  or  $y$  is the table. When  $x$  is the *Table*, this action has the effect  $Clear(Table)$ , but the table should not become clear; and when  $y=Table$ , it has the precondition  $Clear(Table)$ , but the table does not have to be clear for us to move a block onto it. To fix this, we do two things. First, we introduce another action to move a block  $b$  from  $x$  to the table:

```
Action( $MoveToTable(b,x)$ ),
  PRECOND: $On(b,x) \wedge Clear(b)$ ,
  EFFECT: $On(b,Table) \wedge Clear(x) \wedge \neg On(b,x)$ .
```

Second, we take the interpretation of  $Clear(x)$  to be “there is a clear space on  $x$  to hold a block.” Under this interpretation,  $Clear(Table)$  will always be true. The only problem is that nothing prevents the planner from using  $Move(b,x,Table)$  instead of  $MoveToTable(b,x)$ . We could live with this problem—it will lead to a larger-than-necessary search space, but will not lead to incorrect answers—or we could introduce the predicate  $Block$  and add  $Block(b) \wedge Block(y)$  to the precondition of  $Move$ , as shown in Figure 11.4.

## 11.2 Algorithms for Classical Planning

---

The description of a planning problem provides an obvious way to search from the initial state through the space of states, looking for a goal. A nice advantage of the declarative representation of action schemas is that we can also search backward from the goal, looking for the initial state (Figure 11.5 compares forward and backward searches). A third possibility is to translate the problem description into a set of logic sentences, to which we can apply a logical inference algorithm to find a solution.

### 11.2.1 Forward state-space search for planning

We can solve planning problems by applying any of the heuristic search algorithms from Chapter 3 or Chapter 4. The states in this search state space are ground states, where every fluent is either true or not. The goal is a state that has all the positive fluents in the problem’s goal and none of the negative fluents. The applicable actions in a state,  $Actions(s)$ , are grounded instantiations of the action schemas—that is, actions where the variables have all been replaced by constant values.

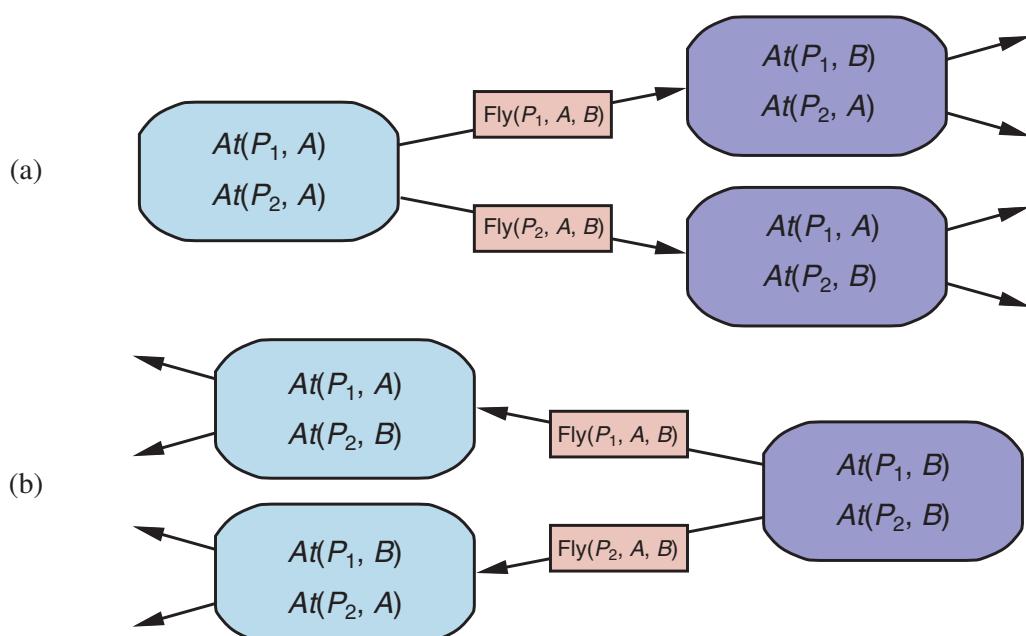

To determine the applicable actions we unify the current state against the preconditions of each action schema. For each unification that successfully results in a substitution, we

apply the substitution to the action schema to yield a ground action with no variables. (It is a requirement of action schemas that any variable in the effect must also appear in the precondition; that way, we are guaranteed that no variables remain after the substitution.)

Each schema may unify in multiple ways. In the spare tire example (page 364), the *Remove* action has the precondition  $At(obj, loc)$ , which matches against the initial state in two ways, resulting in the two substitutions  $\{obj/Flat, loc/Axle\}$  and  $\{obj/Spare, loc/Trunk\}$ ; applying these substitutions yields two ground actions. If an action has multiple literals in the precondition, then each of them can potentially be matched against the current state in multiple ways.

At first, it seems that the state space might be too big for many problems. Consider an air cargo problem with 10 airports, where each airport initially has 5 planes and 20 pieces of cargo. The goal is to move all the cargo at airport *A* to airport *B*. There is a 41-step solution to the problem: load the 20 pieces of cargo into one of the planes at *A*, fly the plane to *B*, and unload the 20 pieces.

Finding this apparently straightforward solution can be difficult because the average branching factor is huge: each of the 50 planes can fly to 9 other airports, and each of the 200 packages can be either unloaded (if it is loaded) or loaded into any plane at its airport (if it is unloaded). So in any state there is a minimum of 450 actions (when all the packages are at airports with no planes) and a maximum of 10,450 (when all packages and planes are at

**Figure 11.5** Two approaches to searching for a plan. (a) Forward (progression) search through the space of ground states, starting in the initial state and using the problem's actions to search forward for a member of the set of goal states. (b) Backward (regression) search through state descriptions, starting at the goal and using the inverse of the actions to search backward for the initial state.

the same airport). On average, let's say there are about 2000 possible actions per state, so the search graph up to the depth of the 41-step solution has about  $2000^{41}$  nodes.

Clearly, even this relatively small problem instance is hopeless without an accurate heuristic. Although many real-world applications of planning have relied on domain-specific heuristics, it turns out (as we see in Section 11.3) that strong domain-independent heuristics can be derived automatically; that is what makes forward search feasible.

### 11.2.2 Backward search for planning

[Regression search](#)

[Relevant action](#)

In backward search (also called **regression search**) we start at the goal and apply the actions backward until we find a sequence of steps that reaches the initial state. At each step we consider **relevant actions** (in contrast to forward search, which considers actions that are **applicable**). This reduces the branching factor significantly, particularly in domains with many possible actions.

A relevant action is one with an effect that **unifies** with one of the goal literals, but with no effect that negates any part of the goal. For example, with the goal  $\neg Poor \wedge Famous$ , an action with the sole effect *Famous* would be relevant, but one with the effect *Poor* and *Famous* is not considered relevant: even though that action might be used at some point in the plan (to establish *Famous*), it cannot appear at *this* point in the plan because then *Poor* would appear in the final state.

[Regression](#)

What does it mean to apply an action in the backward direction? Given a goal  $g$  and an action  $a$ , the **regression** from  $g$  over  $a$  gives us a state description  $g'$  whose positive and negative literals are given by

$$\begin{aligned} \text{POS}(g') &= (\text{POS}(g) - \text{ADD}(a)) \cup \text{POS}(\text{Precond}(a)) \\ \text{NEG}(g') &= (\text{NEG}(g) - \text{DEL}(a)) \cup \text{NEG}(\text{Precond}(a)). \end{aligned}$$

That is, the preconditions must have held before, or else the action could not have been executed, but the positive/negative literals that were added/deleted by the action need not have been true before.

These equations are straightforward for ground literals, but some care is required when there are variables in  $g$  and  $a$ . For example, suppose the goal is to deliver a specific piece of cargo to SFO:  $At(C_2, SFO)$ . The *Unload* action schema has the effect  $At(c, a)$ . When we unify that with the goal, we get the substitution  $\{c/C_2, a/SFO\}$ ; applying that substitution to the schema gives us a new schema which captures the idea of using any plane that is at SFO:

$$\begin{aligned} &\text{Action}(\text{Unload}(C_2, p', SFO)), \\ &\text{PRECOND: } In(C_2, p') \wedge At(p', SFO) \wedge Cargo(C_2) \wedge Plane(p') \wedge Airport(SFO) \\ &\text{EFFECT: } At(C_2, SFO) \wedge \neg In(C_2, p'). \end{aligned}$$

Here we replaced  $p$  with a new variable named  $p'$ . This is an instance of **standardizing apart** variable names so there will be no conflict between different variables that happen to have the same name (see page 302). The regressed state description gives us a new goal:

$$g' = In(C_2, p') \wedge At(p', SFO) \wedge Cargo(C_2) \wedge Plane(p') \wedge Airport(SFO).$$

As another example, consider the goal of owning a book with a specific ISBN number:  $Own(9780134610993)$ . Given a trillion 13-digit ISBNs and the single action schema

$$A = \text{Action}(\text{Buy}(i), \text{PRECOND: } ISBN(i), \text{EFFECT: } Own(i)).$$

a forward search without a heuristic would have to start enumerating the 10 billion ground *Buy* actions. But with backward search, we would unify the goal  $Own(9780134610993)$  with

the effect  $Own(i')$ , yielding the substitution  $\theta = \{i' / 9780134610993\}$ . Then we would regress over the action  $Subst(\theta, A)$  to yield the predecessor state description  $ISBN(9780134610993)$ . This is part of the initial state, so we have a solution and we are done, having considered just one action, not a trillion.

More formally, assume a goal description  $g$  that contains a goal literal  $g_i$  and an action schema  $A$ . If  $A$  has an effect literal  $e'_j$  where  $Unify(g_i, e'_j) = \theta$  and where we define  $A' = \text{SUBST}(\theta, A)$  and if there is no effect in  $A'$  that is the negation of a literal in  $g$ , then  $A'$  is a relevant action towards  $g$ .

For most problem domains backward search keeps the branching factor lower than forward search. However, the fact that backward search uses states with variables rather than ground states makes it harder to come up with good heuristics. That is the main reason why the majority of current systems favor forward search.

### 11.2.3 Planning as Boolean satisfiability

In Section 7.7.4 we showed how some clever axiom-rewriting could turn a wumpus world problem into a propositional logic satisfiability problem that could be handed to an efficient satisfiability solver. SAT-based planners such as SATPLAN operate by translating a PDDL problem description into propositional form. The translation involves a series of steps:

- Propositionalize the actions: for each action schema, form ground propositions by substituting constants for each of the variables. So instead of a single  $Unload(c, p, a)$  schema, we would have separate action propositions for each combination of cargo, plane, and airport (here written with subscripts), and for each time step (here written as a superscript).
- Add action exclusion axioms saying that no two actions can occur at the same time, e.g.  $\neg(FlyP_1SFOJFK^1 \wedge FlyP_1SFOPUH^1)$ .
- Add precondition axioms: For each ground action  $A^t$ , add the axiom  $A^t \Rightarrow \text{PRE}(A)^t$ , that is, if an action is taken at time  $t$ , then the preconditions must have been true. For example,  $FlyP_1SFOJFK^1 \Rightarrow At(P_1, SFO) \wedge Plane(P_1) \wedge Airport(SFO) \wedge Airport(JFK)$ .
- Define the initial state: assert  $F^0$  for every fluent  $F$  in the problem's initial state, and  $\neg F^0$  for every fluent not mentioned in the initial state.
- Propositionalize the goal: the goal becomes a disjunction over all of its ground instances, where variables are replaced by constants. For example, the goal of having block  $A$  on another block,  $On(A, x) \wedge Block(x)$  in a world with objects  $A, B$  and  $C$ , would be replaced by the goal

$$(On(A, A) \wedge Block(A)) \vee (On(A, B) \wedge Block(B)) \vee (On(A, C) \wedge Block(C)).$$

- Add successor-state axioms: For each fluent  $F$ , add an axiom of the form

$$F^{t+1} \Leftrightarrow ActionCausesF^t \vee (F^t \wedge \neg ActionCausesNotF^t),$$

where  $ActionCausesF$  stands for a disjunction of all the ground actions that add  $F$ , and  $ActionCausesNotF$  stands for a disjunction of all the ground actions that delete  $F$ .

The resulting translation is typically much larger than the original PDDL, but the efficiency of modern SAT solvers often more than makes up for this.

### 11.2.4 Other classical planning approaches

**Planning graph**

**Situation calculus**

**Partial-order planning**

The three approaches we covered above are not the only ones tried in the 50-year history of automated planning. We briefly describe some others here.

An approach called Graphplan uses a specialized data structure, a **planning graph**, to encode constraints on how actions are related to their preconditions and effects, and on which things are mutually exclusive.

**Situation calculus** is a method of describing planning problems in first-order logic. It uses successor-state axioms just as SATPLAN does, but first-order logic allows for more flexibility and more succinct axioms. Overall the approach has contributed to our theoretical understanding of planning, but has not made a big impact in practical applications, perhaps because first-order provers are not as well developed as propositional satisfiability programs.

It is possible to encode a bounded planning problem (i.e., the problem of finding a plan of length  $k$ ) as a **constraint satisfaction problem** (CSP). The encoding is similar to the encoding to a SAT problem (Section 11.2.3), with one important simplification: at each time step we need only a single variable,  $Action^t$ , whose domain is the set of possible actions. We no longer need one variable for every action, and we don't need the action exclusion axioms.

All the approaches we have seen so far construct *totally ordered* plans consisting of strictly linear sequences of actions. But if an air cargo problem has 30 packages being loaded onto one plane and 50 packages being loaded onto another, it seems pointless to decree a specific linear ordering of the 80 load actions.

An alternative called **partial-order planning** represents a plan as a graph rather than a linear sequence: each action is a node in the graph, and for each precondition of the action there is an edge from another action (or from the initial state) that indicates that the predecessor action establishes the precondition. So we could have a partial-order plan that says that actions *Remove(Spare, Trunk)* and *Remove(Flat, Axle)* must come before *PutOn(Spare, Axle)*, but without saying which of the two *Remove* actions should come first. We search in the space of plans rather than world-states, inserting actions to satisfy conditions.

In the 1980s and 1990s, partial-order planning was seen as the best way to handle planning problems with independent subproblems. By 2000, forward-search planners had developed excellent heuristics that allowed them to efficiently discover the independent subproblems that partial-order planning was designed for. Moreover, SATPLAN was able to take advantage of Moore's law: a propositionalization that was hopelessly large in 1980 now looks tiny, because computers have 10,000 times more memory today. As a result, partial-order planners are not competitive on fully automated classical planning problems.

Nonetheless, partial-order planning remains an important part of the field. For some specific tasks, such as operations scheduling, partial-order planning with domain-specific heuristics is the technology of choice. Many of these systems use libraries of high-level plans, as described in Section 11.4.

Partial-order planning is also often used in domains where it is important for humans to understand the plans. For example, operational plans for spacecraft and Mars rovers are generated by partial-order planners and are then checked by human operators before being uploaded to the vehicles for execution. The plan refinement approach makes it easier for the humans to understand what the planning algorithms are doing and to verify that the plans are correct before they are executed.

## 11.3 Heuristics for Planning

---

Neither forward nor backward search is efficient without a good heuristic function. Recall from Chapter 3 that a heuristic function  $h(s)$  estimates the distance from a state  $s$  to the goal, and that if we can derive an **admissible** heuristic for this distance—one that does not overestimate—then we can use A\* search to find optimal solutions.

By definition, there is no way to analyze an atomic state, and thus it requires some ingenuity by an analyst (usually human) to define good domain-specific heuristics for search problems with atomic states. But planning uses a factored representation for states and actions, which makes it possible to define good domain-independent heuristics.

Recall that an admissible heuristic can be derived by defining a **relaxed problem** that is easier to solve. The exact cost of a solution to this easier problem then becomes the heuristic for the original problem. A search problem is a graph where the nodes are states and the edges are actions. The problem is to find a path connecting the initial state to a goal state. There are two main ways we can relax this problem to make it easier: by adding more edges to the graph, making it strictly easier to find a path, or by grouping multiple nodes together, forming an abstraction of the state space that has fewer states, and thus is easier to search.

We look first at heuristics that add edges to the graph. Perhaps the simplest is the **ignore-preconditions heuristic**, which drops all preconditions from actions. Every action becomes applicable in every state, and any single goal fluent can be achieved in one step (if there are any applicable actions—if not, the problem is impossible). This almost implies that the number of steps required to solve the relaxed problem is the number of unsatisfied goals—almost but not quite, because (1) some action may achieve multiple goals and (2) some actions may undo the effects of others.

For many problems an accurate heuristic is obtained by considering (1) and ignoring (2). First, we relax the actions by removing all preconditions and all effects except those that are literals in the goal. Then, we count the minimum number of actions required such that the union of those actions' effects satisfies the goal. This is an instance of the **set-cover problem**. There is one minor irritation: the set-cover problem is NP-hard. Fortunately a simple greedy algorithm is guaranteed to return a set covering whose size is within a factor of  $\log n$  of the true minimum covering, where  $n$  is the number of literals in the goal. Unfortunately, the greedy algorithm loses the guarantee of admissibility.

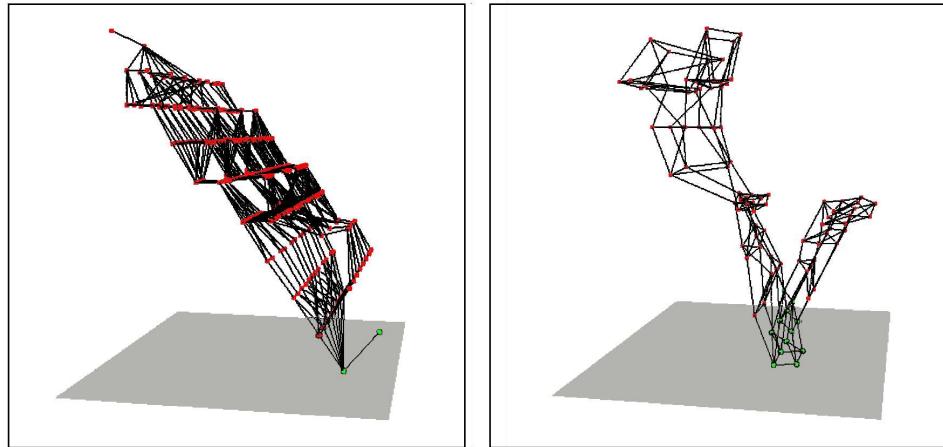

It is also possible to ignore only *selected* preconditions of actions. Consider the sliding-tile puzzle (8-puzzle or 15-puzzle) from Section 3.2. We could encode this as a planning problem involving tiles with a single schema *Slide*:

```
Action(Slide( $t, s_1, s_2$ ),  
    PRECOND: $On(t, s_1) \wedge Tile(t) \wedge Blank(s_2) \wedge Adjacent(s_1, s_2)$   
    EFFECT: $On(t, s_2) \wedge Blank(s_1) \wedge \neg On(t, s_1) \wedge \neg Blank(s_2)$ )
```

As we saw in Section 3.6, if we remove the preconditions  $Blank(s_2) \wedge Adjacent(s_1, s_2)$  then any tile can move in one action to any space and we get the number-of-misplaced-tiles heuristic. If we remove only the  $Blank(s_2)$  precondition then we get the Manhattan-distance heuristic. It is easy to see how these heuristics could be derived automatically from the action schema description. The ease of manipulating the action schemas is the great advantage of the factored representation of planning problems, as compared with the atomic representation of search problems.

Ignore-preconditions heuristic

Set-cover problem

**Figure 11.6** Two state spaces from planning problems with the ignore-delete-lists heuristic. The height above the bottom plane is the heuristic score of a state; states on the bottom plane are goals. There are no local minima, so search for the goal is straightforward. From Hoffmann (2005).

#### Ignore-delete-lists heuristic

Another possibility is the **ignore-delete-lists heuristic**. Assume for a moment that all goals and preconditions contain only positive literals.<sup>2</sup> We want to create a relaxed version of the original problem that will be easier to solve, and where the length of the solution will serve as a good heuristic. We can do that by removing the delete lists from all actions (i.e., removing all negative literals from effects). That makes it possible to make monotonic progress towards the goal—no action will ever undo progress made by another action. It turns out it is still NP-hard to find the optimal solution to this relaxed problem, but an approximate solution can be found in polynomial time by hill climbing.

Figure 11.6 diagrams part of the state space for two planning problems using the ignore-delete-lists heuristic. The dots represent states and the edges actions, and the height of each dot above the bottom plane represents the heuristic value. States on the bottom plane are solutions. In both of these problems, there is a wide path to the goal. There are no dead ends, so no need for backtracking; a simple hill-climbing search will easily find a solution to these problems (although it may not be an optimal solution).

### 11.3.1 Domain-independent pruning

Factored representations make it obvious that many states are just variants of other states. For example, suppose we have a dozen blocks on a table, and the goal is to have block A on top of a three-block tower. The first step in a solution is to place some block  $x$  on top of block  $y$  (where  $x$ ,  $y$ , and A are all different). After that, place A on top of  $x$  and we're done. There are 11 choices for  $x$ , and given  $x$ , 10 choices for  $y$ , and thus 110 states to consider. But all these states are symmetric: choosing one over another makes no difference, and thus a planner should only consider one of them. This is the process of **symmetry reduction**: we prune out

#### Symmetry reduction

<sup>2</sup> Many problems are written with this convention. For problems that aren't, replace every negative literal  $\neg P$  in a goal or precondition with a new positive literal,  $P'$ , and modify the initial state and the action effects accordingly.

of consideration all symmetric branches of the search tree except for one. For many domains, this makes the difference between intractable and efficient solving.

Another possibility is to do forward pruning, accepting the risk that we might prune away an optimal solution, in order to focus the search on promising branches. We can define a **preferred action** as follows: First, define a relaxed version of the problem, and solve it to get a **relaxed plan**. Then a preferred action is either a step of the relaxed plan, or it achieves some precondition of the relaxed plan.

Sometimes it is possible to solve a problem efficiently by recognizing that negative interactions can be ruled out. We say that a problem has **serializable subgoals** if there exists an order of subgoals such that the planner can achieve them in that order without having to undo any of the previously achieved subgoals. For example, in the blocks world, if the goal is to build a tower (e.g., *A* on *B*, which in turn is on *C*, which in turn is on the *Table*, as in Figure 11.3 on page 365), then the subgoals are serializable bottom to top: if we first achieve *C* on *Table*, we will never have to undo it while we are achieving the other subgoals. A planner that uses the bottom-to-top trick can solve any problem in the blocks world without backtracking (although it might not always find the shortest plan). As another example, if there is a room with  $n$  light switches, each controlling a separate light, and the goal is to have them all on, then we don't have to consider permutations of the order; we could arbitrarily restrict ourselves to plans that flip switches in, say, ascending order.

For the Remote Agent planner that commanded NASA's Deep Space One spacecraft, it was determined that the propositions involved in commanding a spacecraft are serializable. This is perhaps not too surprising, because a spacecraft is *designed* by its engineers to be as easy as possible to control (subject to other constraints). Taking advantage of the serialized ordering of goals, the Remote Agent planner was able to eliminate most of the search. This meant that it was fast enough to control the spacecraft in real time, something previously considered impossible.

### 11.3.2 State abstraction in planning

A relaxed problem leaves us with a simplified planning problem just to calculate the value of the heuristic function. Many planning problems have  $10^{100}$  states or more, and relaxing the *actions* does nothing to reduce the number of states, which means that it may still be expensive to compute the heuristic. Therefore, we now look at relaxations that decrease the number of states by forming a **state abstraction**—a many-to-one mapping from states in the ground representation of the problem to the abstract representation.

The easiest form of state abstraction is to ignore some fluents. For example, consider an air cargo problem with 10 airports, 50 planes, and 200 pieces of cargo. Each plane can be at one of 10 airports and each package can be either in one of the planes or unloaded at one of the airports. So there are  $10^{50} \times (50 + 10)^{200} \approx 10^{405}$  states. Now consider a particular problem in that domain in which it happens that all the packages are at just 5 of the airports, and all packages at a given airport have the same destination. Then a useful abstraction of the problem is to drop all the *At* fluents except for the ones involving one plane and one package at each of the 5 airports. Now there are only  $10^5 \times (5 + 10)^5 \approx 10^{11}$  states. A solution in this abstract state space will be shorter than a solution in the original space (and thus will be an admissible heuristic), and the abstract solution is easy to extend to a solution to the original problem (by adding additional *Load* and *Unload* actions).

Preferred action

Serializable subgoals

State abstraction

A key idea in defining heuristics is **decomposition**: dividing a problem into parts, solving each part independently, and then combining the parts. The **subgoal independence** assumption is that the cost of solving a conjunction of subgoals is approximated by the sum of the costs of solving each subgoal *independently*. The subgoal independence assumption can be optimistic or pessimistic. It is optimistic when there are negative interactions between the subplans for each subgoal—for example, when an action in one subplan deletes a goal achieved by another subplan. It is pessimistic, and therefore inadmissible, when subplans contain redundant actions—for instance, two actions that could be replaced by a single action in the merged plan.

Suppose the goal is a set of fluents  $G$ , which we divide into disjoint subsets  $G_1, \dots, G_n$ . We then find optimal plans  $P_1, \dots, P_n$  that solve the respective subgoals. What is an estimate of the cost of the plan for achieving all of  $G$ ? We can think of each  $\text{COST}(P_i)$  as a heuristic estimate, and we know that if we combine estimates by taking their maximum value, we always get an admissible heuristic. So  $\max_i \text{COST}(P_i)$  is admissible, and sometimes it is exactly correct: it could be that  $P_1$  serendipitously achieves all the  $G_i$ . But usually the estimate is too low. Could we sum the costs instead? For many problems that is a reasonable estimate, but it is not admissible. The best case is when  $G_i$  and  $G_j$  are independent, in the sense that plans for one cannot reduce the cost of plans for the other. In that case, the estimate  $\text{COST}(P_i) + \text{COST}(P_j)$  is admissible, and more accurate than the max estimate.

It is clear that there is great potential for cutting down the search space by forming abstractions. The trick is choosing the right abstractions and using them in a way that makes the total cost—defining an abstraction, doing an abstract search, and mapping the abstraction back to the original problem—less than the cost of solving the original problem. The techniques of **pattern databases** from Section 3.6.3 can be useful, because the cost of creating the pattern database can be amortized over multiple problem instances.

A system that makes use of effective heuristics is FF, or FASTFORWARD (Hoffmann, 2005), a forward state-space searcher that uses the ignore-delete-lists heuristic, estimating the heuristic with the help of a planning graph. FF then uses hill climbing search (modified to keep track of the plan) with the heuristic to find a solution. FF’s hill climbing algorithm is nonstandard: it avoids local maxima by running a breadth-first search from the current state until a better one is found. If this fails, FF switches to a greedy best-first search instead.

## 11.4 Hierarchical Planning

---

The problem-solving and planning methods of the preceding chapters all operate with a fixed set of atomic actions. Actions can be strung together, and state-of-the-art algorithms can generate solutions containing thousands of actions. That’s fine if we are planning a vacation and the actions are at the level of “fly from San Francisco to Honolulu,” but at the motor-control level of “bend the left knee by 5 degrees” we would need to string together millions or billions of actions, not thousands.

Bridging this gap requires planning at higher levels of abstraction. A high-level plan for a Hawaii vacation might be “Go to San Francisco airport; take flight HA 11 to Honolulu; do vacation stuff for two weeks; take HA 12 back to San Francisco; go home.” Given such a plan, the action “Go to San Francisco airport” can be viewed as a planning task in itself, with a solution such as “Choose a ride-hailing service; order a car; ride to airport.” Each of

these actions, in turn, can be decomposed further, until we reach the low-level motor control actions like a button-press.

In this example, planning and acting are interleaved; for example, one would defer the problem of planning the walk from the curb to the gate until after being dropped off. Thus, that particular action will remain at an abstract level prior to the execution phase. We defer discussion of this topic until Section 11.5. Here, we concentrate on the idea of **hierarchical decomposition**, an idea that pervades almost all attempts to manage complexity. For example, complex software is created from a hierarchy of subroutines and classes; armies, governments and corporations have organizational hierarchies. The key benefit of hierarchical structure is that at each level of the hierarchy, a computational task, military mission, or administrative function is reduced to a *small* number of activities at the next lower level, so the computational cost of finding the correct way to arrange those activities for the current problem is small.

Hierarchical decomposition

### 11.4.1 High-level actions

The basic formalism we adopt to understand hierarchical decomposition comes from the area of **hierarchical task networks** or HTN planning. For now we assume full observability and determinism and a set of actions, now called **primitive actions**, with standard precondition–effect schemas. The key additional concept is the **high-level action** or HLA—for example, the action “Go to San Francisco airport.” Each HLA has one or more possible **refinements**, into a sequence of actions, each of which may be an HLA or a primitive action. For example, the action “Go to San Francisco airport,” represented formally as  $Go(Home, SFO)$ , might have two possible refinements, as shown in Figure 11.7. The same figure shows a **recursive** refinement for navigation in the vacuum world: to get to a destination, take a step, and then go to the destination.

Hierarchical task network  
Primitive action  
High-level action  
Refinement

These examples show that high-level actions and their refinements embody knowledge about *how to do things*. For instance, the refinements for  $Go(Home, SFO)$  say that to get to the airport you can drive or take a ride-hailing service; buying milk, sitting down, and moving the knight to e4 are not to be considered.

An HLA refinement that contains only primitive actions is called an **implementation** of the HLA. In a grid world, the sequences  $[Right, Right, Down]$  and  $[Down, Right, Right]$  both implement the HLA  $Navigate([1, 3], [3, 2])$ . An implementation of a high-level plan (a sequence of HLAs) is the concatenation of implementations of each HLA in the sequence. Given the precondition–effect definitions of each primitive action, it is straightforward to determine whether any given implementation of a high-level plan achieves the goal.

Implementation

We can say, then, that *a high-level plan achieves the goal from a given state if at least one of its implementations achieves the goal from that state*. The “at least one” in this definition is crucial—not *all* implementations need to achieve the goal, because the agent gets to decide which implementation it will execute. Thus, the set of possible implementations in HTN planning—each of which may have a different outcome—is not the same as the set of possible outcomes in nondeterministic planning. There, we required that a plan work for *all* outcomes because the agent doesn’t get to choose the outcome; nature does.

The simplest case is an HLA that has exactly one implementation. In that case, we can compute the preconditions and effects of the HLA from those of the implementation (see Exercise 11.HLAU) and then treat the HLA exactly as if it were a primitive action itself. It

---

---

can be shown that the right collection of HLAs can result in the time complexity of blind search dropping from exponential in the solution depth to linear in the solution depth, although devising such a collection of HLAs may be a nontrivial task in itself. When HLAs have multiple possible implementations, there are two options: one is to search among the implementations for one that works, as in Section 11.4.2; the other is to reason directly about the HLAs—despite the multiplicity of implementations—as explained in Section 11.4.3. The latter method enables the derivation of provably correct abstract plans, without the need to consider their implementations.

### 11.4.2 Searching for primitive solutions

HTN planning is often formulated with a single “top level” action called *Act*, where the aim is to find an implementation of *Act* that achieves the goal. This approach is entirely general. For example, classical planning problems can be defined as follows: for each primitive action  $a_i$ , provide one refinement of *Act* with steps  $[a_i, Act]$ . That creates a recursive definition of *Act* that lets us add actions. But we need some way to stop the recursion; we do that by providing one more refinement for *Act*, one with an empty list of steps and with a precondition equal to the goal of the problem. This says that if the goal is already achieved, then the right implementation is to do nothing.

The approach leads to a simple algorithm: repeatedly choose an HLA in the current plan and replace it with one of its refinements, until the plan achieves the goal. One possible implementation based on breadth-first tree search is shown in Figure 11.8. Plans are considered in order of depth of nesting of the refinements, rather than number of primitive steps. It is straightforward to design a graph-search version of the algorithm as well as depth-first and iterative deepening versions.

---

```

function HIERARCHICAL-SEARCH(problem, hierarchy) returns a solution or failure
  frontier  $\leftarrow$  a FIFO queue with [Act] as the only element
  while true do
    if Is-EMPTY(frontier) then return failure
    plan  $\leftarrow$  POP(frontier)           // chooses the shallowest plan in frontier
    hla  $\leftarrow$  the first HLA in plan, or null if none
    prefix,suffix  $\leftarrow$  the action subsequences before and after hla in plan
    outcome  $\leftarrow$  RESULT(problem.INITIAL, prefix)
    if hla is null then      // so plan is primitive and outcome is its result
      if problem.IS-GOAL(outcome) then return plan
    else for each sequence in REFINEMENTS(hla, outcome, hierarchy) do
      add APPEND(prefix, sequence, suffix) to frontier

```

**Figure 11.8** A breadth-first implementation of hierarchical forward planning search. The initial plan supplied to the algorithm is [*Act*]. The REFINEMENTS function returns a set of action sequences, one for each refinement of the HLA whose preconditions are satisfied by the specified state, *outcome*.

---

In essence, this form of hierarchical search explores the space of sequences that conform to the knowledge contained in the HLA library about how things are to be done. A great deal of knowledge can be encoded, not just in the action sequences specified in each refinement but also in the preconditions for the refinements. For some domains, HTN planners have been able to generate huge plans with very little search. For example, O-PLAN (Bell and Tate, 1985), which combines HTN planning with scheduling, has been used to develop production plans for Hitachi. A typical problem involves a product line of 350 different products, 35 assembly machines, and over 2000 different operations. The planner generates a 30-day schedule with three 8-hour shifts a day, involving tens of millions of steps. Another important aspect of HTN plans is that they are, by definition, hierarchically structured; usually this makes them easy for humans to understand.

The computational benefits of hierarchical search can be seen by examining an idealized case. Suppose that a planning problem has a solution with  $d$  primitive actions. For a nonhierarchical, forward state-space planner with  $b$  allowable actions at each state, the cost is  $O(b^d)$ , as explained in Chapter 3. For an HTN planner, let us suppose a very regular refinement structure: each nonprimitive action has  $r$  possible refinements, each into  $k$  actions at the next lower level. We want to know how many different refinement trees there are with this structure. Now, if there are  $d$  actions at the primitive level, then the number of levels below the root is  $\log_k d$ , so the number of internal refinement nodes is  $1 + k + k^2 + \dots + k^{\log_k d - 1} = (d - 1)/(k - 1)$ . Each internal node has  $r$  possible refinements, so  $r^{(d-1)/(k-1)}$  possible decomposition trees could be constructed.

Examining this formula, we see that keeping  $r$  small and  $k$  large can result in huge savings: we are taking the  $k$ th root of the nonhierarchical cost, if  $b$  and  $r$  are comparable. Small  $r$  and large  $k$  means a library of HLAs with a small number of refinements each yielding a long action sequence. This is not always possible: long action sequences that are usable across a wide range of problems are extremely rare.

The key to HTN planning is a plan library containing known methods for implementing complex, high-level actions. One way to construct the library is to *learn* the methods from problem-solving experience. After the excruciating experience of constructing a plan from scratch, the agent can save the plan in the library as a method for implementing the high-level action defined by the task. In this way, the agent can become more and more competent over time as new methods are built on top of old methods. One important aspect of this learning process is the ability to *generalize* the methods that are constructed, eliminating detail that is specific to the problem instance (e.g., the name of the builder or the address of the plot of land) and keeping just the key elements of the plan. It seems to us inconceivable that humans could be as competent as they are without some such mechanism.

### 11.4.3 Searching for abstract solutions

The hierarchical search algorithm in the preceding section refines HLAs all the way to primitive action sequences to determine if a plan is workable. This contradicts common sense: one should be able to determine that the two-HLA high-level plan

[*Drive(Home, SFOLongTermParking), Shuttle(SFOLongTermParking, SFO)*]

gets one to the airport without having to determine a precise route, choice of parking spot, and so on. The solution is to write precondition–effect descriptions of the HLAs, just as we do for primitive actions. From the descriptions, it ought to be easy to prove that the high-level plan achieves the goal. This is the holy grail, so to speak, of hierarchical planning, because if we derive a high-level plan that provably achieves the goal, working in a small search space of high-level actions, then we can commit to that plan and work on the problem of refining each step of the plan. This gives us the exponential reduction we seek.

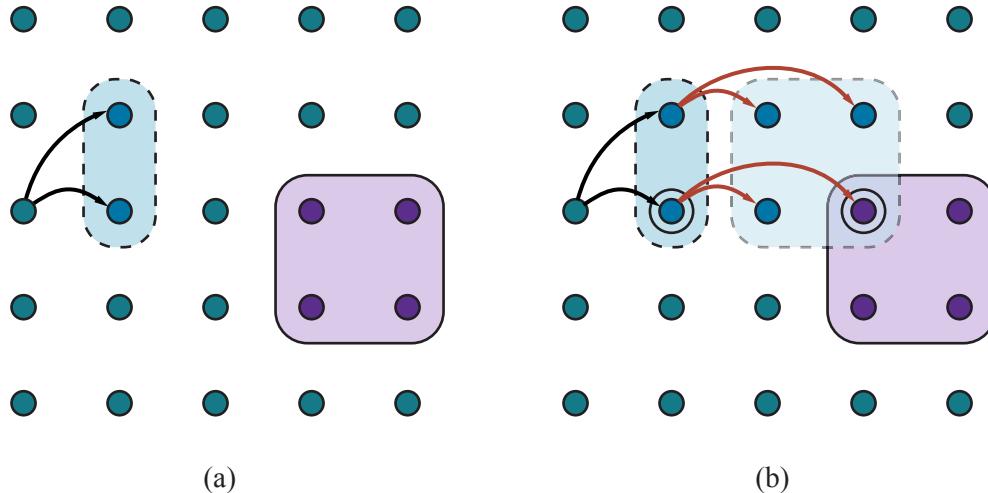

For this to work, it has to be the case that every high-level plan that “claims” to achieve the goal (by virtue of the descriptions of its steps) does in fact achieve the goal in the sense defined earlier: it must have at least one implementation that does achieve the goal. This property has been called the **downward refinement property** for HLA descriptions.

Downward refinement property

Writing HLA descriptions that satisfy the downward refinement property is, in principle, easy: as long as the descriptions are *true*, then any high-level plan that claims to achieve the goal must in fact do so—otherwise, the descriptions are making some false claim about what the HLAs do. We have already seen how to write true descriptions for HLAs that have exactly one implementation (Exercise 11.HLAU); a problem arises when the HLA has *multiple* implementations. How can we describe the effects of an action that can be implemented in many different ways?

One safe answer (at least for problems where all preconditions and goals are positive) is to include only the positive effects that are achieved by *every* implementation of the HLA and the negative effects of *any* implementation. Then the downward refinement property would be satisfied. Unfortunately, this semantics for HLAs is much too conservative.

Consider again the HLA *Go(Home, SFO)*, which has two refinements, and suppose, for the sake of argument, a simple world in which one can always drive to the airport and park, but taking a taxi requires *Cash* as a precondition. In that case, *Go(Home, SFO)* doesn’t always get you to the airport. In particular, it fails if *Cash* is false, and so we cannot assert *At(Agent, SFO)* as an effect of the HLA. This makes no sense, however; if the agent didn’t have *Cash*, it would drive itself. Requiring that an effect hold for *every* implementation is equivalent to assuming that *someone else*—an adversary—will choose the implementation.

**Figure 11.9** Schematic examples of reachable sets. The set of goal states is shaded in purple. Black and red arrows indicate possible implementations of  $h_1$  and  $h_2$ , respectively. (a) The reachable set of an HLA  $h_1$  in a state  $s$ . (b) The reachable set for the sequence  $[h_1, h_2]$ . Because this intersects the goal set, the sequence achieves the goal.

It treats the HLA’s multiple outcomes exactly as if the HLA were a **nondeterministic** action, as in Section 4.3. For our case, the agent itself will choose the implementation.

The programming languages community has coined the term **demonic nondeterminism** for the case where an adversary makes the choices, contrasting this with **angelic nondeterminism**, where the agent itself makes the choices. We borrow this term to define **angelic semantics** for HLA descriptions. The basic concept required for understanding angelic semantics is the **reachable set** of an HLA: given a state  $s$ , the reachable set for an HLA  $h$ , written as  $\text{REACH}(s, h)$ , is the set of states reachable by any of the HLA’s implementations.

The key idea is that the agent can choose *which* element of the reachable set it ends up in when it executes the HLA; thus, an HLA with multiple refinements is more “powerful” than the same HLA with fewer refinements. We can also define the reachable set of a sequence of HLAs. For example, the reachable set of a sequence  $[h_1, h_2]$  is the union of all the reachable sets obtained by applying  $h_2$  in each state in the reachable set of  $h_1$ :

$$\text{REACH}(s, [h_1, h_2]) = \bigcup_{s' \in \text{REACH}(s, h_1)} \text{REACH}(s', h_2).$$

Given these definitions, a high-level plan—a sequence of HLAs—achieves the goal if its reachable set *intersects* the set of goal states. (Compare this to the much stronger condition for demonic semantics, where every member of the reachable set has to be a goal state.) Conversely, if the reachable set doesn’t intersect the goal, then the plan definitely doesn’t work. Figure 11.9 illustrates these ideas.

The notion of reachable sets yields a straightforward algorithm: search among high-level plans, looking for one whose reachable set intersects the goal; once that happens, the algorithm can *commit* to that abstract plan, knowing that it works, and focus on refining the plan further. We will return to the algorithmic issues later; for now consider how the effects

Demonic  
nondeterminism  
  
Angelic  
nondeterminism  
Angelic semantics  
  
Reachable set

of an HLA—the reachable set for each possible initial state—are represented. A primitive action can set a fluent to *true* or *false* or leave it *unchanged*. (With conditional effects (see Section 11.5.1) there is a fourth possibility: flipping a variable to its opposite.)

An HLA under angelic semantics can do more: it can *control* the value of a fluent, setting it to true or false depending on which implementation is chosen. That means that an HLA can have nine different effects on a fluent: if the variable starts out true, it can always keep it true, always make it false, or have a choice; if the fluent starts out false, it can always keep it false, always make it true, or have a choice; and the three choices for both cases can be combined arbitrarily, making nine.

Notationally, this is a bit challenging. We'll use the language of add lists and delete lists (rather than true/false fluents) along with the  $\sim$  symbol to mean “possibly, if the agent so chooses.” Thus, the effect  $\tilde{+}A$  means “possibly add  $A$ ,” that is, either leave  $A$  unchanged or make it true. Similarly,  $\tilde{-}A$  means “possibly delete  $A$ ” and  $\tilde{\pm}A$  means “possibly add or delete  $A$ .” For example, the HLA  $Go(Home, SFO)$ , with the two refinements shown in Figure 11.7, possibly deletes *Cash* (if the agent decides to take a taxi), so it should have the effect  $\tilde{-}Cash$ . Thus, we see that the descriptions of HLAs are *derivable* from the descriptions of their refinements. Now, suppose we have the following schemas for the HLAs  $h_1$  and  $h_2$ :

$$\begin{aligned} Action(h_1, \text{PRECOND: } \neg A, \text{EFFECT: } A \wedge \tilde{-}B), \\ Action(h_2, \text{PRECOND: } \neg B, \text{EFFECT: } \tilde{+}A \wedge \tilde{\pm}C). \end{aligned}$$

That is,  $h_1$  adds  $A$  and possibly deletes  $B$ , while  $h_2$  possibly adds  $A$  and has full control over  $C$ . Now, if only  $B$  is true in the initial state and the goal is  $A \wedge C$  then the sequence  $[h_1, h_2]$  achieves the goal: we choose an implementation of  $h_1$  that makes  $B$  false, then choose an implementation of  $h_2$  that leaves  $A$  true and makes  $C$  true.

The preceding discussion assumes that the effects of an HLA—the reachable set for any given initial state—can be described exactly by describing the effect on each fluent. It would be nice if this were always true, but in many cases we can only approximate the effects because an HLA may have infinitely many implementations and may produce arbitrarily wiggly reachable sets—rather like the wiggly-belief-state problem illustrated in Figure 7.21 on page 261. For example, we said that  $Go(Home, SFO)$  possibly deletes *Cash*; it also possibly adds  $At(Car, SFOLongTermParking)$ ; but it cannot do both—in fact, it must do exactly one. As with belief states, we may need to write *approximate* descriptions. We will use two kinds of approximation: an **optimistic description**  $\text{REACH}^+(s, h)$  of an HLA  $h$  may overstate the reachable set, while a **pessimistic description**  $\text{REACH}^-(s, h)$  may underestimate the reachable set. Thus, we have

$$\text{REACH}^-(s, h) \subseteq \text{REACH}(s, h) \subseteq \text{REACH}^+(s, h).$$

Optimistic description  
Pessimistic description

For example, an optimistic description of  $Go(Home, SFO)$  says that it possibly deletes *Cash* and possibly adds  $At(Car, SFOLongTermParking)$ . Another good example arises in the 8-puzzle, half of whose states are unreachable from any given state (see Exercise 11.PART): the optimistic description of *Act* might well include the whole state space, since the exact reachable set is quite wiggly.

With approximate descriptions, the test for whether a plan achieves the goal needs to be modified slightly. If the optimistic reachable set for the plan doesn't intersect the goal, then the plan doesn't work; if the pessimistic reachable set intersects the goal, then the plan does work (Figure 11.10(a)). With exact descriptions, a plan either works or it doesn't, but

**Figure 11.10** Goal achievement for high-level plans with approximate descriptions. The set of goal states is shaded in purple. For each plan, the pessimistic (solid lines, light blue) and optimistic (dashed lines, light green) reachable sets are shown. (a) The plan indicated by the black arrow definitely achieves the goal, while the plan indicated by the red arrow definitely doesn't. (b) A plan that *possibly* achieves the goal (the optimistic reachable set intersects the goal) but does not *necessarily* achieve the goal (the pessimistic reachable set does not intersect the goal). The plan would need to be refined further to determine if it really does achieve the goal.

with approximate descriptions, there is a middle ground: if the optimistic set intersects the goal but the pessimistic set doesn't, then we cannot tell if the plan works (Figure 11.10(b)). When this circumstance arises, the uncertainty can be resolved by refining the plan. This is a very common situation in human reasoning. For example, in planning the aforementioned two-week Hawaii vacation, one might propose to spend two days on each of seven islands. Prudence would indicate that this ambitious plan needs to be refined by adding details of inter-island transportation.

An algorithm for hierarchical planning with approximate angelic descriptions is shown in Figure 11.11. For simplicity, we have kept to the same overall scheme used previously in Figure 11.8, that is, a breadth-first search in the space of refinements. As just explained, the algorithm can detect plans that will and won't work by checking the intersections of the optimistic and pessimistic reachable sets with the goal. (The details of how to compute the reachable sets of a plan, given approximate descriptions of each step, are covered in Exercise 11.HLP.)

When a workable abstract plan is found, the algorithm *decomposes* the original problem into subproblems, one for each step of the plan. The initial state and goal for each subproblem are obtained by regressing a guaranteed-reachable goal state through the action schemas for each step of the plan. (See Section 11.2.2 for a discussion of how regression works.) Figure 11.9(b) illustrates the basic idea: the right-hand circled state is the guaranteed-reachable goal state, and the left-hand circled state is the intermediate goal obtained by regressing the goal through the final action.

---

```

function ANGELIC-SEARCH(problem, hierarchy, initialPlan) returns a solution or fail
  frontier  $\leftarrow$  a FIFO queue with initialPlan as the only element
  while true do
    if IS-EMPTY?(frontier) then return fail
    plan  $\leftarrow$  POP(frontier)           // chooses the shallowest node in frontier
    if REACH+(problem.INITIAL, plan) intersects problem.GOAL then
      if plan is primitive then return plan          // REACH+ is exact for primitive plans
      guaranteed  $\leftarrow$  REACH-(problem.INITIAL, plan)  $\cap$  problem.GOAL
      if guaranteed $\neq\{\}$  and MAKING-PROGRESS(plan, initialPlan) then
        finalState  $\leftarrow$  any element of guaranteed
        return DECOMPOSE(hierarchy, problem.INITIAL, plan, finalState)
      hla  $\leftarrow$  some HLA in plan
      prefix, suffix  $\leftarrow$  the action subsequences before and after hla in plan
      outcome  $\leftarrow$  RESULT(problem.INITIAL, prefix)

    action  $\leftarrow$  REMOVE-LAST(plan)
    si  $\leftarrow$  a state in REACH-(s0, plan) such that sf $\in$ REACH-(si, action)
    problem  $\leftarrow$  a problem with INITIAL = si and GOAL = sf
    solution  $\leftarrow$  APPEND(ANGELIC-SEARCH(problem, hierarchy, action), solution)
    sf  $\leftarrow$  si
  return solution

```

**Figure 11.11** A hierarchical planning algorithm that uses angelic semantics to identify and commit to high-level plans that work while avoiding high-level plans that don't. The predicate MAKING-PROGRESS checks to make sure that we aren't stuck in an infinite regression of refinements. At top level, call ANGELIC-SEARCH with [Act] as the *initialPlan*.

---

The ability to commit to or reject high-level plans can give ANGELIC-SEARCH a significant computational advantage over HIERARCHICAL-SEARCH, which in turn may have a large advantage over plain old BREADTH-FIRST-SEARCH. Consider, for example, cleaning up a large vacuum world consisting of an arrangement of rooms connected by narrow corridors, where each room is a  $w \times h$  rectangle of squares. It makes sense to have an HLA for *Navigate* (as shown in Figure 11.7) and one for *CleanWholeRoom*. (Cleaning the room could be implemented with the repeated application of another HLA to clean each row.) Since there are five primitive actions, the cost for BREADTH-FIRST-SEARCH grows as  $5^d$ , where  $d$  is the length of the shortest solution (roughly twice the total number of squares); the algorithm cannot manage even two  $3 \times 3$  rooms. HIERARCHICAL-SEARCH is more efficient, but still suffers from exponential growth because it tries all ways of cleaning that are consistent with the hierarchy. ANGELIC-SEARCH scales approximately linearly in the number of squares—it commits to a good high-level sequence of room-cleaning and navigation steps and prunes away the other options.

Cleaning a set of rooms by cleaning each room in turn is hardly rocket science: it is easy for humans because of the hierarchical structure of the task. When we consider how difficult humans find it to solve small puzzles such as the 8-puzzle, it seems likely that the human capacity for solving complex problems derives not from considering combinatorics, but rather from skill in abstracting and decomposing problems to eliminate combinatorics.

The angelic approach can be extended to find least-cost solutions by generalizing the notion of reachable set. Instead of a state being reachable or not, each state will have a cost for the most efficient way to get there. (The cost is infinite for unreachable states.) The optimistic and pessimistic descriptions bound these costs. In this way, angelic search can find provably optimal abstract plans without having to consider their implementations. The same approach can be used to obtain effective **hierarchical look-ahead** algorithms for online search, in the style of LRTA\* (page 158).

Hierarchical  
look-ahead

In some ways, such algorithms mirror aspects of human deliberation in tasks such as planning a vacation to Hawaii—consideration of alternatives is done initially at an abstract level over long time scales; some parts of the plan are left quite abstract until execution time, such as how to spend two lazy days on Moloka‘i, while others parts are planned in detail, such as the flights to be taken and lodging to be reserved—without these latter refinements, there is no guarantee that the plan would be feasible.

## 11.5 Planning and Acting in Nondeterministic Domains

In this section we extend planning to handle partially observable, nondeterministic, and unknown environments. The basic concepts mirror those in Chapter 4, but there are differences arising from the use of factored representations rather than atomic representations. This affects the way we represent the agent’s capability for action and observation and the way we represent **belief states**—the sets of possible physical states the agent might be in—for partially observable environments. We can also take advantage of many of the domain-independent methods given in Section 11.3 for calculating search heuristics.

We will cover **sensorless planning** (also known as **conformant planning**) for environments with no observations; **contingency planning** for partially observable and nondeterministic environments; and **online planning** and **replanning** for unknown environments. This will allow us to tackle sizable real-world problems.

Consider this problem: given a chair and a table, the goal is to have them match—have the same color. In the initial state we have two cans of paint, but the colors of the paint and the furniture are unknown. Only the table is initially in the agent’s field of view:

$$\begin{aligned} \text{Init}(\text{Object}(\text{Table}) \wedge \text{Object}(\text{Chair}) \wedge \text{Can}(C_1) \wedge \text{Can}(C_2) \wedge \text{InView}(\text{Table})) \\ \text{Goal}(\text{Color}(\text{Chair}, c) \wedge \text{Color}(\text{Table}, c)) \end{aligned}$$

There are two actions: removing the lid from a paint can and painting an object using the paint from an open can.

$$\begin{aligned} \text{Action}(\text{RemoveLid}(can), \\ \quad \text{PRECOND: } \text{Can}(can) \\ \quad \text{EFFECT: } \text{Open}(can)) \\ \text{Action}(\text{Paint}(x, can), \\ \quad \text{PRECOND: } \text{Object}(x) \wedge \text{Can}(can) \wedge \text{Color}(can, c) \wedge \text{Open}(can) \\ \quad \text{EFFECT: } \text{Color}(x, c)) \end{aligned}$$

The action schemas are straightforward, with one exception: preconditions and effects now may contain variables that are not part of the action's variable list. That is,  $\text{Paint}(x, can)$  does not mention the variable  $c$ , representing the color of the paint in the can. In the fully observable case, this is not allowed—we would have to name the action  $\text{Paint}(x, can, c)$ . But in the partially observable case, we might or might not know what color is in the can.

To solve a partially observable problem, the agent will have to reason about the percepts it will obtain when it is executing the plan. The percept will be supplied by the agent's sensors when it is actually acting, but when it is planning it will need a model of its sensors. In Chapter 4, this model was given by a function,  $\text{PERCEPT}(s)$ . For planning, we augment PDDL with a new type of schema, the **percept schema**:

*Percept*(Color( $x, c$ ),  
 PRECOND:*Object*( $x$ )  $\wedge$  *InView*( $x$ )  
*Percept*(Color( $can, c$ ),  
 PRECOND:*Can*( $can$ )  $\wedge$  *InView*( $can$ )  $\wedge$  *Open*( $can$ ))

The first schema says that whenever an object is in view, the agent will perceive the color of the object (that is, for the object  $x$ , the agent will learn the truth value of  $\text{Color}(x, c)$  for all  $c$ ). The second schema says that if an open can is in view, then the agent perceives the color of the paint in the can. Because there are no exogenous events in this world, the color of an object will remain the same, even if it is not being perceived, until the agent performs an action to change the object's color. Of course, the agent will need an action that causes objects (one at a time) to come into view:

*Action*(LookAt( $x$ ),  
 PRECOND:*InView*( $y$ )  $\wedge$  ( $x \neq y$ )  
 EFFECT:*InView*( $x$ )  $\wedge$   $\neg$ *InView*( $y$ ))

For a fully observable environment, we would have a *Percept* schema with no preconditions for each fluent. A sensorless agent, on the other hand, has no *Percept* schemas at all. Note that even a sensorless agent can solve the painting problem. One solution is to open any can of paint and apply it to both chair and table, thus **coercing** them to be the same color (even though the agent doesn't know what the color is).

A contingent planning agent with sensors can generate a better plan. First, look at the table and chair to obtain their colors; if they are already the same then the plan is done. If not, look at the paint cans; if the paint in a can is the same color as one piece of furniture, then apply that paint to the other piece. Otherwise, paint both pieces with any color.

Finally, an online planning agent might generate a contingent plan with fewer branches at first—perhaps ignoring the possibility that no cans match any of the furniture—and deal with problems when they arise by replanning. It could also deal with incorrectness of its action schemas. Whereas a contingent planner simply assumes that the effects of an action always succeed—that painting the chair does the job—a replanning agent would check the result and make an additional plan to fix any unexpected failure, such as an unpainted area or the original color showing through.

In the real world, agents use a combination of approaches. Car manufacturers sell spare tires and air bags, which are physical embodiments of contingent plan branches designed to handle punctures or crashes. On the other hand, most car drivers never consider these possibilities; when a problem arises they respond as replanning agents. In general, agents

plan only for contingencies that have important consequences and a nonnegligible chance of happening. Thus, a car driver contemplating a trip across the Sahara desert should make explicit contingency plans for breakdowns, whereas a trip to the supermarket requires less advance planning. We next look at each of the three approaches in more detail.

### 11.5.1 Sensorless planning

Section 4.4.1 (page 144) introduced the basic idea of searching in belief-state space to find a solution for sensorless problems. Conversion of a sensorless planning problem to a belief-state planning problem works much the same way as it did in Section 4.4.1; the main differences are that the underlying physical transition model is represented by a collection of action schemas, and the belief state can be represented by a logical formula instead of by an explicitly enumerated set of states. We assume that the underlying planning problem is deterministic.

The initial belief state for the sensorless painting problem can ignore *InView* fluents because the agent has no sensors. Furthermore, we take as given the unchanging facts  $\text{Object(Table)} \wedge \text{Object(Chair)} \wedge \text{Can(C}_1\text{)} \wedge \text{Can(C}_2\text{)}$  because these hold in every belief state. The agent doesn't know the colors of the cans or the objects, or whether the cans are open or closed, but it does know that objects and cans have colors:  $\forall x \exists c \text{ Color}(x, c)$ . After Skolemizing (see Section 9.5.1), we obtain the initial belief state:

$$b_0 = \text{Color}(x, C(x)).$$

In classical planning, where the **closed-world assumption** is made, we would assume that any fluent not mentioned in a state is false, but in sensorless (and partially observable) planning we have to switch to an **open-world assumption** in which states contain both positive and negative fluents, and if a fluent does not appear, its value is unknown. Thus, the belief state corresponds exactly to the set of possible worlds that satisfy the formula. Given this initial belief state, the following action sequence is a solution:

$$[\text{RemoveLid}(\text{Can}_1), \text{Paint}(\text{Chair}, \text{Can}_1), \text{Paint}(\text{Table}, \text{Can}_1)].$$

We now show how to progress the belief state through the action sequence to show that the final belief state satisfies the goal.

First, note that in a given belief state  $b$ , the agent can consider any action whose pre-conditions are satisfied by  $b$ . (The other actions cannot be used because the transition model doesn't define the effects of actions whose preconditions might be unsatisfied.) According to Equation (4.4) (page 145), the general formula for updating the belief state  $b$  given an applicable action  $a$  in a deterministic world is as follows:

$$b' = \text{RESULT}(b, a) = \{s' : s' = \text{RESULT}_P(s, a) \text{ and } s \in b\}$$

where  $\text{RESULT}_P$  defines the physical transition model. For the time being, we assume that the initial belief state is always a conjunction of literals, that is, a 1-CNF formula. To construct the new belief state  $b'$ , we must consider what happens to each literal  $\ell$  in each physical state  $s$  in  $b$  when action  $a$  is applied. For literals whose truth value is already known in  $b$ , the truth value in  $b'$  is computed from the current value and the add list and delete list of the action. (For example, if  $\ell$  is in the delete list of the action, then  $\neg\ell$  is added to  $b'$ .) What about a literal whose truth value is unknown in  $b$ ? There are three cases:

1. If the action adds  $\ell$ , then  $\ell$  will be true in  $b'$  regardless of its initial value.

2. If the action deletes  $\ell$ , then  $\ell$  will be false in  $b'$  regardless of its initial value.
3. If the action does not affect  $\ell$ , then  $\ell$  will retain its initial value (which is unknown) and will not appear in  $b'$ .

Hence, we see that the calculation of  $b'$  is almost identical to the observable case, which was specified by Equation (11.1) on page 363:

$$b' = \text{RESULT}(b, a) = (b - \text{DEL}(a)) \cup \text{ADD}(a).$$

We cannot quite use the set semantics because (1) we must make sure that  $b'$  does not contain both  $\ell$  and  $\neg\ell$ , and (2) atoms may contain unbound variables. But it is still the case that  $\text{RESULT}(b, a)$  is computed by starting with  $b$ , setting any atom that appears in  $\text{DEL}(a)$  to false, and setting any atom that appears in  $\text{ADD}(a)$  to true. For example, if we apply  $\text{RemoveLid}(\text{Can}_1)$  to the initial belief state  $b_0$ , we get

$$b_1 = \text{Color}(x, C(x)) \wedge \text{Open}(\text{Can}_1).$$

When we apply the action  $\text{Paint}(\text{Chair}, \text{Can}_1)$ , the precondition  $\text{Color}(\text{Can}_1, c)$  is satisfied by the literal  $\text{Color}(x, C(x))$  with binding  $\{x/\text{Can}_1, c/C(\text{Can}_1)\}$  and the new belief state is

$$b_2 = \text{Color}(x, C(x)) \wedge \text{Open}(\text{Can}_1) \wedge \text{Color}(\text{Chair}, C(\text{Can}_1)).$$

Finally, we apply the action  $\text{Paint}(\text{Table}, \text{Can}_1)$  to obtain

$$\begin{aligned} b_3 = & \text{Color}(x, C(x)) \wedge \text{Open}(\text{Can}_1) \wedge \text{Color}(\text{Chair}, C(\text{Can}_1)) \\ & \wedge \text{Color}(\text{Table}, C(\text{Can}_1)). \end{aligned}$$

The final belief state satisfies the goal,  $\text{Color}(\text{Table}, c) \wedge \text{Color}(\text{Chair}, c)$ , with the variable  $c$  bound to  $C(\text{Can}_1)$ .

The preceding analysis of the update rule has shown a very important fact: *the family of belief states defined as conjunctions of literals is closed under updates defined by PDDL action schemas*. That is, if the belief state starts as a conjunction of literals, then any update will yield a conjunction of literals. That means that in a world with  $n$  fluents, any belief state can be represented by a conjunction of size  $O(n)$ . This is a very comforting result, considering that there are  $2^n$  states in the world. It says we can compactly represent all the subsets of those  $2^n$  states that we will ever need. Moreover, the process of checking for belief states that are subsets or supersets of previously visited belief states is also easy, at least in the propositional case.

The fly in the ointment of this pleasant picture is that it only works for action schemas that have the *same effects* for all states in which their preconditions are satisfied. It is this property that enables the preservation of the 1-CNF belief-state representation. As soon as the effect can depend on the state, dependencies are introduced between fluents, and the 1-CNF property is lost.

Consider, for example, the simple vacuum world defined in Section 3.2.1. Let the fluents be  $\text{AtL}$  and  $\text{AtR}$  for the location of the robot and  $\text{CleanL}$  and  $\text{CleanR}$  for the state of the squares. According to the definition of the problem, the  $\text{Suck}$  action has no precondition—it can always be done. The difficulty is that its effect depends on the robot's location: when the robot is  $\text{AtL}$ , the result is  $\text{CleanL}$ , but when it is  $\text{AtR}$ , the result is  $\text{CleanR}$ . For such actions, our action schemas will need something new: a **conditional effect**. These have the syntax

“**when condition: effect**,” where *condition* is a logical formula to be compared against the current state, and *effect* is a formula describing the resulting state. For the vacuum world:

*Action(Suck,*  
*EFFECT:when AtL: CleanL  $\wedge$  when AtR: CleanR).*

When applied to the initial belief state *True*, the resulting belief state is  $(AtL \wedge CleanL) \vee (AtR \wedge CleanR)$ , which is no longer in 1-CNF. (This transition can be seen in Figure 4.14 on page 147.) In general, conditional effects can induce arbitrary dependencies among the fluents in a belief state, leading to belief states of exponential size in the worst case.

It is important to understand the difference between preconditions and conditional effects. All conditional effects whose conditions are satisfied have their effects applied to generate the resulting belief state; if none are satisfied, then the resulting state is unchanged. On the other hand, if a *precondition* is unsatisfied, then the action is inapplicable and the resulting state is undefined. From the point of view of sensorless planning, it is better to have conditional effects than an inapplicable action. For example, we could split *Suck* into two actions with unconditional effects as follows:

*Action(SuckL,*  
*PRECOND:AtL; EFFECT:CleanL)*  
*Action(SuckR,*  
*PRECOND:AtR; EFFECT:CleanR).*

Now we have only unconditional schemas, so the belief states all remain in 1-CNF; unfortunately, we cannot determine the applicability of *SuckL* and *SuckR* in the initial belief state.

It seems inevitable, then, that nontrivial problems will involve wiggly belief states, just like those encountered when we considered the problem of state estimation for the wumpus world (see Figure 7.21 on page 261). The solution suggested then was to use a **conservative approximation** to the exact belief state; for example, the belief state can remain in 1-CNF if it contains all literals whose truth values can be determined and treats all other literals as unknown. While this approach is *sound*, in that it never generates an incorrect plan, it is *incomplete* because it may be unable to find solutions to problems that necessarily involve interactions among literals. To give a trivial example, if the goal is for the robot to be on a clean square, then [*Suck*] is a solution but a sensorless agent that insists on 1-CNF belief states will not find it.

Perhaps a better solution is to look for action sequences that keep the belief state as simple as possible. In the sensorless vacuum world, the action sequence [*Right, Suck, Left, Suck*] generates the following sequence of belief states:

$b_0 = \text{True}$   
 $b_1 = AtR$   
 $b_2 = AtR \wedge CleanR$   
 $b_3 = AtL \wedge CleanR$   
 $b_4 = AtL \wedge CleanR \wedge CleanL$

That is, the agent *can* solve the problem while retaining a 1-CNF belief state, even though some sequences (e.g., those beginning with *Suck*) go outside 1-CNF. The general lesson is not lost on humans: we are always performing little actions (checking the time, patting our

pockets to make sure we have the car keys, reading street signs as we navigate through a city) to eliminate uncertainty and keep our belief state manageable.

There is another, quite different approach to the problem of unmanageably wiggly belief states: don't bother computing them at all. Suppose the initial belief state is  $b_0$  and we would like to know the belief state resulting from the action sequence  $[a_1, \dots, a_m]$ . Instead of computing it explicitly, just represent it as “ $b_0$  then  $[a_1, \dots, a_m]$ .” This is a lazy but unambiguous representation of the belief state, and it's quite concise— $O(n + m)$  where  $n$  is the size of the initial belief state (assumed to be in 1-CNF) and  $m$  is the maximum length of an action sequence. As a belief-state representation, it suffers from one drawback, however: determining whether the goal is satisfied, or an action is applicable, may require a lot of computation.

The computation can be implemented as an entailment test: if  $A_m$  represents the collection of successor-state axioms required to define occurrences of the actions  $a_1, \dots, a_m$ —as explained for SATPLAN in Section 11.2.3—and  $G_m$  asserts that the goal is true after  $m$  steps, then the plan achieves the goal if  $b_0 \wedge A_m \models G_m$ —that is, if  $b_0 \wedge A_m \wedge \neg G_m$  is unsatisfiable. Given a modern SAT solver, it may be possible to do this much more quickly than computing the full belief state. For example, if none of the actions in the sequence has a particular goal fluent in its add list, the solver will detect this immediately. It also helps if partial results about the belief state—for example, fluents known to be true or false—are cached to simplify subsequent computations.

The final piece of the sensorless planning puzzle is a heuristic function to guide the search. The meaning of the heuristic function is the same as for classical planning: an estimate (perhaps admissible) of the cost of achieving the goal from the given belief state. With belief states, we have one additional fact: solving any subset of a belief state is necessarily easier than solving the belief state:

$$\text{if } b_1 \subseteq b_2 \text{ then } h^*(b_1) \leq h^*(b_2).$$

Hence, any admissible heuristic computed for a subset is admissible for the belief state itself. The most obvious candidates are the singleton subsets, that is, individual physical states. We can take any random collection of states  $s_1, \dots, s_N$  that are in the belief state  $b$ , apply any admissible heuristic  $h$ , and return

$$H(b) = \max\{h(s_1), \dots, h(s_N)\}$$

as the heuristic estimate for solving  $b$ . We can also use inadmissible heuristics such as the ignore-delete-lists heuristic (page 372), which seems to work quite well in practice.

### 11.5.2 Contingent planning

We saw in Chapter 4 that contingency planning—the generation of plans with conditional branching based on percepts—is appropriate for environments with partial observability, non-determinism, or both. For the partially observable painting problem with the percept schemas given earlier, one possible conditional solution is as follows:

```
[LookAt(Table), LookAt(Chair),
  if Color(Table, c) and Color(Chair, c) then NoOp
  else [RemoveLid(Can1), LookAt(Can1), RemoveLid(Can2), LookAt(Can2),
    if Color(Table, c) and Color(can, c) then Paint(Chair, can)
    else if Color(Chair, c) and Color(can, c) then Paint(Table, can)
    else [Paint(Chair, Can1), Paint(Table, Can1)]]]
```

Variables in this plan should be considered existentially quantified; the second line says that if there exists some color  $c$  that is the color of the table and the chair, then the agent need not do anything to achieve the goal. When executing this plan, a contingent-planning agent can maintain its belief state as a logical formula and evaluate each branch condition by determining if the belief state entails the condition formula or its negation. (It is up to the contingent-planning algorithm to make sure that the agent will never end up in a belief state where the condition formula's truth value is unknown.) Note that with first-order conditions, the formula may be satisfied in more than one way; for example, the condition  $\text{Color}(\text{Table}, c) \wedge \text{Color}(\text{can}, c)$  might be satisfied by  $\{\text{can}/\text{Can}_1\}$  and by  $\{\text{can}/\text{Can}_2\}$  if both cans are the same color as the table. In that case, the agent can choose any satisfying substitution to apply to the rest of the plan.

As shown in Section 4.4.2, calculating the new belief state  $\hat{b}$  after an action  $a$  and subsequent percept is done in two stages. The first stage calculates the belief state after the action, just as for the sensorless agent:

$$\hat{b} = (b - \text{DEL}(a)) \cup \text{ADD}(a)$$

where, as before, we have assumed a belief state represented as a conjunction of literals. The second stage is a little trickier. Suppose that percept literals  $p_1, \dots, p_k$  are received. One might think that we simply need to add these into the belief state; in fact, we can also infer that the preconditions for sensing are satisfied. Now, if a percept  $p$  has exactly one percept schema,  $\text{Percept}(p, \text{PRECOND}:c)$ , where  $c$  is a conjunction of literals, then those literals can be thrown into the belief state along with  $p$ . On the other hand, if  $p$  has more than one percept schema whose preconditions might hold according to the predicted belief state  $\hat{b}$ , then we have to add in the *disjunction* of the preconditions. Obviously, this takes the belief state outside 1-CNF and brings up the same complications as conditional effects, with much the same classes of solutions.

Given a mechanism for computing exact or approximate belief states, we can generate contingent plans with an extension of the AND–OR forward search over belief states used in Section 4.4. Actions with nondeterministic effects—which are defined simply by using a disjunction in the EFFECT of the action schema—can be accommodated with minor changes to the belief-state update calculation and no change to the search algorithm.<sup>3</sup> For the heuristic function, many of the methods suggested for sensorless planning are also applicable in the partially observable, nondeterministic case.

### 11.5.3 Online planning

Imagine watching a spot-welding robot in a car plant. The robot's fast, accurate motions are repeated over and over again as each car passes down the line. Although technically impressive, the robot probably does not seem at all *intelligent* because the motion is a fixed, preprogrammed sequence; the robot obviously doesn't “know what it's doing” in any meaningful sense. Now suppose that a poorly attached door falls off the car just as the robot is about to apply a spot-weld. The robot quickly replaces its welding actuator with a gripper, picks up the door, checks it for scratches, reattaches it to the car, sends an email to the floor supervisor, switches back to the welding actuator, and resumes its work. All of a sudden,

<sup>3</sup> If cyclic solutions are required for a nondeterministic problem, AND–OR search must be generalized to a loopy version such as LAO\* (Hansen and Zilberstein, 2001).

the robot's behavior seems *purposive* rather than *rote*; we assume it results not from a vast, precomputed contingent plan but from an online replanning process—which means that the robot *does* need to know what it's trying to do.

Replanning presupposes some form of **execution monitoring** to determine the need for a new plan. One such need arises when a contingent planning agent gets tired of planning for every little contingency, such as whether the sky might fall on its head.<sup>4</sup> This means that the contingent plan is left in an incomplete form. For example, some branches of a partially constructed contingent plan can simply say *Replan*; if such a branch is reached during execution, the agent reverts to planning mode. As we mentioned earlier, the decision as to how much of the problem to solve in advance and how much to leave to replanning is one that involves tradeoffs among possible events with different costs and probabilities of occurring. Nobody wants to have a car break down in the middle of the Sahara desert and only then think about having enough water.

Missing precondition

Replanning may be needed if the agent's model of the world is incorrect. The model for an action may have a **missing precondition**—for example, the agent may not know that removing the lid of a paint can often requires a screwdriver. The model may have a **missing effect**—painting an object may get paint on the floor as well. Or the model may have a **missing fluent** that is simply absent from the representation altogether—for example, the model given earlier has no notion of the amount of paint in a can, of how its actions affect this amount, or of the need for the amount to be nonzero. The model may also lack provision for **exogenous events** such as someone knocking over the paint can. Exogenous events can also include changes in the goal, such as the addition of the requirement that the table and chair not be painted black. Without the ability to monitor and replan, an agent's behavior is likely to be fragile if it relies on absolute correctness of its model.

Missing effect

Missing fluent

Exogenous event

The online agent has a choice of (at least) three different approaches for monitoring the environment during plan execution:

Action monitoring

Plan monitoring

Goal monitoring

- **Action monitoring:** before executing an action, the agent verifies that all the preconditions still hold.
- **Plan monitoring:** before executing an action, the agent verifies that the remaining plan will still succeed.
- **Goal monitoring:** before executing an action, the agent checks to see if there is a better set of goals it could be trying to achieve.

In Figure 11.12 we see a schematic of action monitoring. The agent keeps track of both its original plan, *whole plan*, and the part of the plan that has not been executed yet, which is denoted by *plan*. After executing the first few steps of the plan, the agent expects to be in state *E*. But the agent observes that it is actually in state *O*. It then needs to repair the plan by finding some point *P* on the original plan that it can get back to. (It may be that *P* is the goal state, *G*.) The agent tries to minimize the total cost of the plan: the repair part (from *O* to *P*) plus the continuation (from *P* to *G*).

<sup>4</sup> In 1954, a Mrs. Hodges of Alabama was hit by meteorite that crashed through her roof. In 1992, a piece of the Mbale meteorite hit a small boy on the head; fortunately, its descent was slowed by banana leaves (Jenniskens *et al.*, 1994). And in 2009, a German boy claimed to have been hit in the hand by a pea-sized meteorite. No serious injuries resulted from any of these incidents, suggesting that the need for preplanning against such contingencies is sometimes overstated.

**Figure 11.12** At first, the sequence “whole plan” is expected to get the agent from  $S$  to  $G$ . The agent executes steps of the plan until it expects to be in state  $E$ , but observes that it is actually in  $O$ . The agent then replans for the minimal *repair* plus *continuation* to reach  $G$ .

Now let’s return to the example problem of achieving a chair and table of matching color. Suppose the agent comes up with this plan:

```
[LookAt(Table), LookAt(Chair),
  if Color(Table, c) ∧ Color(Chair, c) then NoOp
  else [RemoveLid(Can1), LookAt(Can1),
    if Color(Table, c) ∧ Color(Can1, c) then Paint(Chair, Can1)
    else REPLAN]].
```

Now the agent is ready to execute the plan. The agent observes that the table and can of paint are white and the chair is black. It then executes  $\text{Paint}(\text{Chair}, \text{Can}_1)$ . At this point a classical planner would declare victory; the plan has been executed. But an online execution monitoring agent needs to check that the action succeeded.

Suppose the agent perceives that the chair is a mottled gray because the black paint is showing through. The agent then needs to figure out a recovery position in the plan to aim for and a repair action sequence to get there. The agent notices that the current state is identical to the precondition before the  $\text{Paint}(\text{Chair}, \text{Can}_1)$  action, so the agent chooses the empty sequence for *repair* and makes its *plan* be the same [ $\text{Paint}$ ] sequence that it just attempted. With this new plan in place, execution monitoring resumes, and the  $\text{Paint}$  action is retried. This behavior will loop until the chair is perceived to be completely painted. But notice that the loop is created by a process of plan–execute–replan, rather than by an explicit loop in a plan. Note also that the original plan need not cover every contingency. If the agent reaches the step marked REPLAN, it can then generate a new plan (perhaps involving  $\text{Can}_2$ ).

Action monitoring is a simple method of execution monitoring, but it can sometimes lead to less than intelligent behavior. For example, suppose there is no black or white paint, and the agent constructs a plan to solve the painting problem by painting both the chair and table red. Suppose that there is only enough red paint for the chair. With action monitoring, the agent would go ahead and paint the chair red, then notice that it is out of paint and cannot paint the table, at which point it would replan a repair—perhaps painting both chair and table green. A plan-monitoring agent can detect failure whenever the current state is such that the remaining plan no longer works. Thus, it would not waste time painting the chair red.

Plan monitoring achieves this by checking the preconditions for success of the entire remaining plan—that is, the preconditions of each step in the plan, except those preconditions that are achieved by another step in the remaining plan. Plan monitoring cuts off execution of a doomed plan as soon as possible, rather than continuing until the failure actually occurs.<sup>5</sup> Plan monitoring also allows for **serendipity**—accidental success. If someone comes along and paints the table red at the same time that the agent is painting the chair red, then the final plan preconditions are satisfied (the goal has been achieved), and the agent can go home early.

It is straightforward to modify a planning algorithm so that each action in the plan is annotated with the action’s preconditions, thus enabling action monitoring. It is slightly more complex to enable plan monitoring. Partial-order planners have the advantage that they have already built up structures that contain the relations necessary for plan monitoring. Augmenting state-space planners with the necessary annotations can be done by careful bookkeeping as the goal fluents are regressed through the plan.

Now that we have described a method for monitoring and replanning, we need to ask, “Does it work?” This is a surprisingly tricky question. If we mean, “Can we guarantee that the agent will always achieve the goal?” then the answer is no, because the agent could inadvertently arrive at a dead end from which there is no repair. For example, the vacuum agent might have a faulty model of itself and not know that its batteries can run out. Once they do, it cannot repair any plans. If we rule out dead ends—assume that there exists a plan to reach the goal from *any* state in the environment—and assume that the environment is really nondeterministic, in the sense that such a plan always has *some* chance of success on any given execution attempt, then the agent will eventually reach the goal.

Trouble occurs when a seemingly-nondeterministic action is not actually random, but rather depends on some precondition that the agent does not know about. For example, sometimes a paint can may be empty, so painting from that can has no effect. No amount of retrying is going to change this.<sup>6</sup> One solution is to choose randomly from among the set of possible repair plans, rather than to try the same one each time. In this case, the repair plan of opening another can might work. A better approach is to **learn** a better model. Every prediction failure is an opportunity for learning; an agent should be able to modify its model of the world to accord with its percepts. From then on, the replanner will be able to come up with a repair that gets at the root problem, rather than relying on luck to choose a good repair.

## 11.6 Time, Schedules, and Resources

---

Classical planning talks about *what to do*, in *what order*, but does not talk about time: *how long* an action takes and *when* it occurs. For example, in the airport domain we could produce a plan saying what planes go where, carrying what, but could not specify departure and arrival times. This is the subject matter of **scheduling**.

Scheduling

Resource constraint

The real world also imposes **resource constraints**: an airline has a limited number of staff, and staff who are on one flight cannot be on another at the same time. This section introduces techniques for planning and scheduling problems with resource constraints.

<sup>5</sup> Plan monitoring means that finally, after 374 pages, we have an agent that is smarter than a dung beetle (see page 59). A plan-monitoring agent would notice that the dung ball was missing from its grasp and would replan to get another ball and plug its hole.

<sup>6</sup> Futile repetition of a plan repair is exactly the behavior exhibited by the sphex wasp (page 59).

    CONSUME:LugNuts(20), USE:WheelStations(1))
Action(AddWheels2, DURATION:15,
    CONSUME:LugNuts(20), USE:WheelStations(1))
Action(Inspecti, DURATION:10,
    USE:Inspectors(1)))

```

**Figure 11.13** A job-shop scheduling problem for assembling two cars, with resource constraints. The notation  $A \prec B$  means that action  $A$  must precede action  $B$ .

---

The approach we take is “plan first, schedule later”: divide the overall problem into a *planning* phase in which actions are selected, with some ordering constraints, to meet the goals of the problem, and a later *scheduling* phase, in which temporal information is added to the plan to ensure that it meets resource and deadline constraints. This approach is common in real-world manufacturing and logistical settings, where the planning phase is sometimes automated, and sometimes performed by human experts.

### 11.6.1 Representing temporal and resource constraints

A typical **job-shop scheduling problem** (see Section 5.1.2), consists of a set of **jobs**, each of which has a collection of **actions** with ordering constraints among them. Each action has a **duration** and a set of resource constraints required by the action. A constraint specifies a *type* of resource (e.g., bolts, wrenches, or pilots), the number of that resource required, and whether that resource is **consumable** (e.g., the bolts are no longer available for use) or **Reusable** (e.g., a pilot is occupied during a flight but is available again when the flight is over). Actions can also produce resources (e.g., manufacturing and resupply actions).

Job-shop scheduling problem

Job

Duration

Consumable

Reusable

Makespan

A solution to a job-shop scheduling problem specifies the start times for each action and must satisfy all the temporal ordering constraints and resource constraints. As with search and planning problems, solutions can be evaluated according to a cost function; this can be quite complicated, with nonlinear resource costs, time-dependent delay costs, and so on. For simplicity, we assume that the cost function is just the total duration of the plan, which is called the **makespan**.

Figure 11.13 shows a simple example: a problem involving the assembly of two cars. The problem consists of two jobs, each of the form [*AddEngine*,*AddWheels*,*Inspect*]. Then the *Resources* statement declares that there are four types of resources, and gives the number of each type available at the start: 1 engine hoist, 1 wheel station, 2 inspectors, and 500 lug nuts. The action schemas give the duration and resource needs of each action. The lug nuts

Aggregation

are *consumed* as wheels are added to the car, whereas the other resources are “borrowed” at the start of an action and released at the action’s end.

The representation of resources as numerical quantities, such as *Inspectors*(2), rather than as named entities, such as *Inspector*( $I_1$ ) and *Inspector*( $I_2$ ), is an example of a technique called **aggregation**: grouping individual objects into quantities when the objects are all indistinguishable. In our assembly problem, it does not matter *which* inspector inspects the car, so there is no need to make the distinction. Aggregation is essential for reducing complexity. Consider what happens when a proposed schedule has 10 concurrent *Inspect* actions but only 9 inspectors are available. With inspectors represented as quantities, a failure is detected immediately and the algorithm backtracks to try another schedule. With inspectors represented as individuals, the algorithm would try all  $9!$  ways of assigning inspectors to actions before noticing that none of them work.

Critical path method

Critical path

Slack

Schedule

### 11.6.2 Solving scheduling problems

We begin by considering just the temporal scheduling problem, ignoring resource constraints. To minimize makespan (plan duration), we must find the earliest start times for all the actions consistent with the ordering constraints supplied with the problem. It is helpful to view these ordering constraints as a directed graph relating the actions, as shown in Figure 11.14. We can apply the **critical path method** (CPM) to this graph to determine the possible start and end times of each action. A **path** through a graph representing a partial-order plan is a linearly ordered sequence of actions beginning with *Start* and ending with *Finish*. (For example, there are two paths in the partial-order plan in Figure 11.14.)

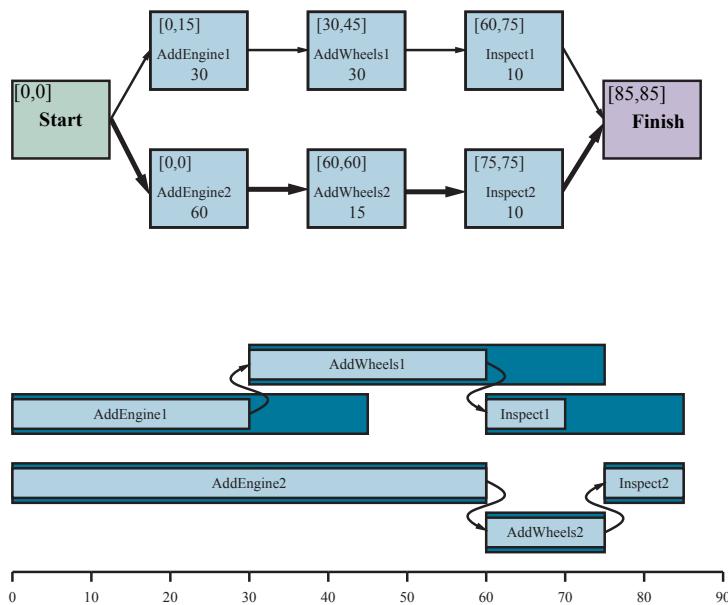

The **critical path** is that path whose total duration is longest; the path is “critical” because it determines the duration of the entire plan—shortening other paths doesn’t shorten the plan as a whole, but delaying the start of any action on the critical path slows down the whole plan. Actions that are off the critical path have a window of time in which they can be executed. The window is specified in terms of an earliest possible start time, *ES*, and a latest possible start time, *LS*. The quantity  $LS - ES$  is known as the **slack** of an action. We can see in Figure 11.14 that the whole plan will take 85 minutes, that each action in the top job has 15 minutes of slack, and that each action on the critical path has no slack (by definition). Together the *ES* and *LS* times for all the actions constitute a **schedule** for the problem.

The following formulas define *ES* and *LS* and constitute a dynamic-programming algorithm to compute them.  $A$  and  $B$  are actions, and  $A \prec B$  means that  $A$  precedes  $B$ :

$$\begin{aligned} ES(Start) &= 0 \\ ES(B) &= \max_{A \prec B} ES(A) + Duration(A) \\ LS(Finish) &= ES(Finish) \\ LS(A) &= \min_{B \succ A} LS(B) - Duration(A). \end{aligned}$$

The idea is that we start by assigning  $ES(Start)$  to be 0. Then, as soon as we get an action  $B$  such that all the actions that come immediately before  $B$  have *ES* values assigned, we set  $ES(B)$  to be the maximum of the earliest finish times of those immediately preceding actions, where the earliest finish time of an action is defined as the earliest start time plus the duration. This process repeats until every action has been assigned an *ES* value. The *LS* values are computed in a similar manner, working backward from the *Finish* action.

The complexity of the critical path algorithm is just  $O(Nb)$ , where  $N$  is the number of actions and  $b$  is the maximum branching factor into or out of an action. (To see this, note

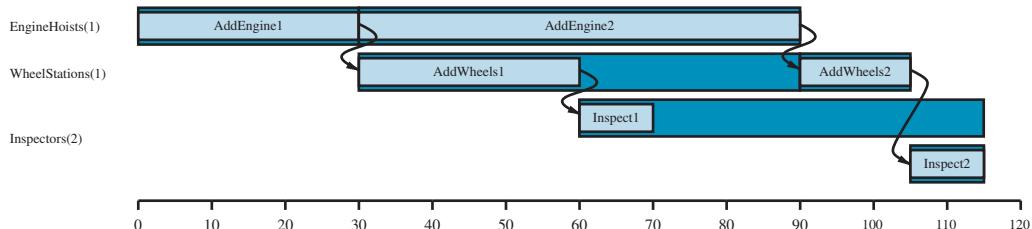

**Figure 11.14** Top: a representation of the temporal constraints for the job-shop scheduling problem of Figure 11.13. The duration of each action is given at the bottom of each rectangle. In solving the problem, we compute the earliest and latest start times as the pair  $[ES, LS]$ , displayed in the upper left. The difference between these two numbers is the *slack* of an action; actions with zero slack are on the critical path, shown with bold arrows. Bottom: the same solution shown as a timeline. Blue rectangles represent time intervals during which an action may be executed, provided that the ordering constraints are respected. The unoccupied portion of a blue rectangle indicates the slack.

that the  $LS$  and  $ES$  computations are done once for each action, and each computation iterates over at most  $b$  other actions.) Therefore, finding a minimum-duration schedule, given a partial ordering on the actions and no resource constraints, is quite easy.

Mathematically speaking, critical-path problems are easy to solve because they are defined as a *conjunction* of *linear* inequalities on the start and end times. When we introduce resource constraints, the resulting constraints on start and end times become more complicated. For example, the *AddEngine* actions, which begin at the same time in Figure 11.14, require the same *EngineHoist* and so cannot overlap. The “cannot overlap” constraint is a *disjunction* of two linear inequalities, one for each possible ordering. The introduction of disjunctions turns out to make scheduling with resource constraints NP-hard.

Figure 11.15 shows the solution with the fastest completion time, 115 minutes. This is 30 minutes longer than the 85 minutes required for a schedule without resource constraints. Notice that there is no time at which both inspectors are required, so we can immediately move one of our two inspectors to a more productive position.

There is a long history of work on optimal scheduling. A challenge problem posed in 1963—to find the optimal schedule for a problem involving just 10 machines and 10 jobs of 100 actions each—went unsolved for 23 years (Lawler *et al.*, 1993). Many approaches have been tried, including branch-and-bound, simulated annealing, tabu search, and constraint sat-

**Figure 11.15** A solution to the job-shop scheduling problem from Figure 11.13, taking into account resource constraints. The left-hand margin lists the three reusable resources, and actions are shown aligned horizontally with the resources they use. There are two possible schedules, depending on which assembly uses the engine hoist first; we've shown the shortest-duration solution, which takes 115 minutes.

#### Minimum slack

isfaction. One popular approach is the **minimum slack** heuristic: on each iteration, schedule for the earliest possible start whichever unscheduled action has all its predecessors scheduled and has the least slack; then update the *ES* and *LS* times for each affected action and repeat. This greedy heuristic resembles the minimum-remaining-values (MRV) heuristic in constraint satisfaction. It often works well in practice, but for our assembly problem it yields a 130-minute solution, not the 115-inute solution of Figure 11.15.

Up to this point, we have assumed that the set of actions and ordering constraints is fixed. Under these assumptions, every scheduling problem can be solved by a nonoverlapping sequence that avoids all resource conflicts, provided that each action is feasible by itself. However if a scheduling problem is proving very difficult, it may not be a good idea to solve it this way—it may be better to reconsider the actions and constraints, in case that leads to a much easier scheduling problem. Thus, it makes sense to *integrate* planning and scheduling by taking into account durations and overlaps during the construction of a plan. Several of the planning algorithms in Section 11.2 can be augmented to handle this information.

## 11.7 Analysis of Planning Approaches

Planning combines the two major areas of AI we have covered so far: *search* and *logic*. A planner can be seen either as a program that searches for a solution or as one that (constructively) proves the existence of a solution. The cross-fertilization of ideas from the two areas has allowed planners to scale up from toy problems where the number of actions and states was limited to around a dozen, to real-world industrial applications with millions of states and thousands of actions.

Planning is foremost an exercise in controlling combinatorial explosion. If there are  $n$  propositions in a domain, then there are  $2^n$  states. Against such pessimism, the identification of independent subproblems can be a powerful weapon. In the best case—full decomposability of the problem—we get an exponential speedup. Decomposability is destroyed, however, by negative interactions between actions. SATPLAN can encode logical relations between subproblems. Forward search addresses the problem heuristically by trying to find patterns (subsets of propositions) that cover the independent subproblems. Since this approach is heuristic, it can work even when the subproblems are not completely independent.

Unfortunately, we do not yet have a clear understanding of which techniques work best on which kinds of problems. Quite possibly, new techniques will emerge, perhaps providing a synthesis of highly expressive first-order and hierarchical representations with the highly efficient factored and propositional representations that dominate today. We are seeing examples of **portfolio** planning systems, where a collection of algorithms are available to apply to any given problem. This can be done selectively (the system classifies each new problem to choose the best algorithm for it), or in parallel (all the algorithms run concurrently, each on a different CPU), or by interleaving the algorithms according to a schedule.

Portfolio

## Summary

---

In this chapter, we described the PDDL representation for both classical and extended planning problems, and presented several algorithmic approaches for finding solutions. The points to remember:

- Planning systems are problem-solving algorithms that operate on explicit factored representations of states and actions. These representations make possible the derivation of effective domain-independent heuristics and the development of powerful and flexible algorithms for solving problems.
- PDDL, the Planning Domain Definition Language, describes the initial and goal states as conjunctions of literals, and actions in terms of their preconditions and effects. Extensions represent time, resources, percepts, contingent plans, and hierarchical plans.
- State-space search can operate in the forward direction (**progression**) or the backward direction (**regression**). Effective heuristics can be derived by subgoal independence assumptions and by various relaxations of the planning problem.
- Other approaches include encoding a planning problem as a Boolean satisfiability problem or as a constraint satisfaction problem; and explicitly searching through the space of partially ordered plans.
- **Hierarchical task network** (HTN) planning allows the agent to take advice from the domain designer in the form of **high-level actions** (HLAs) that can be implemented in various ways by lower-level action sequences. The effects of HLAs can be defined with **angelic semantics**, allowing provably correct high-level plans to be derived without consideration of lower-level implementations. HTN methods can create the very large plans required by many real-world applications.
- **Contingent plans** allow the agent to sense the world during execution to decide what branch of the plan to follow. In some cases, **sensorless** or **conformant planning** can be used to construct a plan that works without the need for perception. Both conformant and contingent plans can be constructed by search in the space of **belief states**. Efficient representation or computation of belief states is a key problem.
- An **online planning agent** uses execution monitoring and splices in repairs as needed to recover from unexpected situations, which can be due to nondeterministic actions, exogenous events, or incorrect models of the environment.
- Many actions consume **resources**, such as money, gas, or raw materials. It is convenient to treat these resources as numeric measures in a pool rather than try to reason about,

say, each individual coin and bill in the world. Time is one of the most important resources. It can be handled by specialized scheduling algorithms, or scheduling can be integrated with planning.

- This chapter extends classical planning to cover nondeterministic environments (where outcomes of actions are uncertain), but it is not the last word on planning. Chapter 16 describes techniques for stochastic environments (in which outcomes of actions have probabilities associated with them): Markov decision processes, partially observable Markov decision processes, and game theory. In Chapter 23 we show that reinforcement learning allows an agent to learn how to behave from past successes and failures.

## Bibliographical and Historical Notes

---

AI planning arose from investigations into state-space search, theorem proving, and control theory. STRIPS (Fikes and Nilsson, 1971, 1993), the first major planning system, was designed as the planner for the Shakey robot at SRI. The first version of the program ran on a computer with only 192 KB of memory. Its overall control structure was modeled on GPS, the General Problem Solver (Newell and Simon, 1961), a state-space search system that used means–ends analysis.

The STRIPS representation language evolved into the Action Description Language, or ADL (Pednault, 1986), and then the Problem Domain Description Language, or PDDL (Ghallab *et al.*, 1998), which has been used for the International Planning Competition since 1998. The most recent version is PDDL 3.1 (Kovacs, 2011).

Planners in the early 1970s decomposed problems by computing a subplan for each subgoal and then stringing the subplans together in some order. This approach, called **linear planning** by Sacerdoti (1975), was soon discovered to be incomplete. It cannot solve some very simple problems, such as the Sussman anomaly (see Exercise 11.SUSS), found by Allen Brown during experimentation with the HACKER system (Sussman, 1975). A complete planner must allow for **interleaving** of actions from different subplans within a single sequence. Warren’s (1974) WARPLAN system achieved that, and demonstrated how the logic programming language Prolog can produce concise programs; WARPLAN is only 100 lines of code.

Partial-order planning dominated the next 20 years of research, with theoretical work describing the detection of conflicts (Tate, 1975a) and the protection of achieved conditions (Sussman, 1975), and implementations including NOAH (Sacerdoti, 1977) and NONLIN (Tate, 1977). That led to formal models (Chapman, 1987; McAllester and Rosenblitt, 1991) that allowed for theoretical analysis of various algorithms and planning problems, and to a widely distributed system, UCPOP (Penberthy and Weld, 1992).

Drew McDermott suspected that the emphasis on partial-order planning was crowding out other techniques that should perhaps be reconsidered now that computers had 100 times the memory of Shakey’s day. His UNPOP (McDermott, 1996) was a state-space planning program employing the ignore-delete-list heuristic. HSP, the Heuristic Search Planner (Bonet and Geffner, 1999; Haslum, 2006) made state-space search practical for large planning problems. The FF or Fast Forward planner (Hoffmann, 2001; Hoffmann and Nebel, 2001; Hoffmann, 2005) and the FASTDOWNWARD variant (Helmert, 2006) won international planning competitions in the 2000s.

Bidirectional search (see Section 3.4.5) has also been known to suffer from a lack of heuristics, but some success has been obtained by using backward search to create a **perimeter** around the goal, and then refining a heuristic to search forward towards that perimeter (Torralba *et al.*, 2016). The SYMBA\* bidirectional search planner (Torralba *et al.*, 2016) won the 2016 competition.

Researchers turned to PDDL and the planning paradigm so that they could use domain independent heuristics. Hoffmann (2005) analyzes the search space of the ignore-delete-list heuristic. Edelkamp (2009) and Haslum *et al.* (2007) describe how to construct pattern databases for planning heuristics. Felner *et al.* (2004) show encouraging results using pattern databases for sliding-tile puzzles, which can be thought of as a planning domain, but Hoffmann *et al.* (2006) show some limitations of abstraction for classical planning problems. (Rintanen, 2012) discusses planning-specific variable-selection heuristics for SAT solving.

Helmert *et al.* (2011) describe the Fast Downward Stone Soup (FDSS) system, a portfolio planner that, as in the fable of stone soup, invites us to throw in as many planning algorithms as possible. The system maintains a set of training problems, and for each problem and each algorithm records the run time and resulting plan cost of the problem’s solution. Then when faced with a new problem, it uses the past experience to decide which algorithm(s) to try, with what time limits, and takes the solution with minimal cost. FDSS was a winner in the 2018 International Planning Competition (Seipp and Röger, 2018). Seipp *et al.* (2015) describe a machine learning approach to automatically learn a good portfolio, given a new problem. Vallati *et al.* (2015) give an overview of portfolio planning. The idea of algorithm portfolios for combinatorial search problems goes back to Gomes and Selman (2001).

Sistla and Godefroid (2004) cover symmetry reduction, and Godefroid (1990) covers heuristics for partial ordering. Richter and Helmert (2009) demonstrate the efficiency gains of forward pruning using preferred actions.

Blum and Furst (1997) revitalized the field of planning with their Graphplan system, which was orders of magnitude faster than the partial-order planners of the time. Bryce and Kambhampati (2007) give an overview of planning graphs. The use of situation calculus for planning was introduced by John McCarthy (1963) and refined by Ray Reiter (2001).

Kautz *et al.* (1996) investigated various ways to propositionalize action schemas, finding that the most compact forms did not necessarily lead to the fastest solution times. A systematic analysis was carried out by Ernst *et al.* (1997), who also developed an automatic “compiler” for generating propositional representations from PDDL problems. The BLACKBOX planner, which combines ideas from Graphplan and SATPLAN, was developed by Kautz and Selman (1998). Planners based on constraint satisfaction include CPLAN van Beek and Chen (1999) and GP-CSP (Do and Kambhampati, 2003).

There has also been interest in the representation of a plan as a **binary decision diagram (BDD)**, a compact data structure for Boolean expressions widely studied in the hardware verification community (Clarke and Grumberg, 1987; McMillan, 1993). There are techniques for proving properties of binary decision diagrams, including the property of being a solution to a planning problem. Cimatti *et al.* (1998) present a planner based on this approach. Other representations have also been used, such as integer programming (Vossen *et al.*, 2001).

There are some interesting comparisons of the various approaches to planning. Helmert (2001) analyzes several classes of planning problems, and shows that constraint-based approaches such as Graphplan and SATPLAN are best for NP-hard domains, while search-based

[Binary decision diagram \(BDD\)](#)

approaches do better in domains where feasible solutions can be found without backtracking. Graphplan and SATPLAN have trouble in domains with many objects because that means they must create many actions. In some cases the problem can be delayed or avoided by generating the propositionalized actions dynamically, only as needed, rather than instantiating them all before the search begins.

Macrops

Abstraction hierarchy

Case-based planning

The first mechanism for hierarchical planning was a facility in the STRIPS program for learning **macrops**—“macro-operators” consisting of a sequence of primitive steps (Fikes *et al.*, 1972). The ABSTRIPS system (Sacerdoti, 1974) introduced the idea of an **abstraction hierarchy**, whereby planning at higher levels was permitted to ignore lower-level preconditions of actions in order to derive the general structure of a working plan. Austin Tate’s Ph.D. thesis (1975b) and work by Earl Sacerdoti (1977) developed the basic ideas of HTN planning. Erol, Hendler, and Nau (1994, 1996) present a complete hierarchical decomposition planner as well as a range of complexity results for pure HTN planners. Our presentation of HLAs and angelic semantics is due to Marthi *et al.* (2007, 2008).

One of the goals of hierarchical planning has been the reuse of previous planning experience in the form of generalized plans. The technique of **explanation-based learning** has been used as a means of generalizing previously computed plans in systems such as SOAR (Laird *et al.*, 1986) and PRODIGY (Carbonell *et al.*, 1989). An alternative approach is to store previously computed plans in their original form and then reuse them to solve new, similar problems by analogy to the original problem. This is the approach taken by the field called **case-based planning** (Carbonell, 1983; Alterman, 1988). Kambhampati (1994) argues that case-based planning should be analyzed as a form of refinement planning and provides a formal foundation for case-based partial-order planning.

Early planners lacked conditionals and loops, but some could use coercion to form conformant plans. Sacerdoti’s NOAH solved the “keys and boxes” problem (in which the planner knows little about the initial state) using coercion. Mason (1993) argued that sensing often can and should be dispensed with in robotic planning, and described a sensorless plan that can move a tool into a specific position on a table by a sequence of tilting actions, *regardless* of the initial position.

Goldman and Boddy (1996) introduced the term **conformant planning**, noting that sensorless plans are often effective even if the agent has sensors. The first moderately efficient conformant planner was Smith and Weld’s (1998) Conformant Graphplan (CGP). Ferraris and Giunchiglia (2000) and Rintanen (1999) independently developed SATPLAN-based conformant planners. Bonet and Geffner (2000) describe a conformant planner based on heuristic search in the space of belief states, drawing on ideas first developed in the 1960s for partially observable Markov decision processes, or POMDPs (see Chapter 16).

Currently, there are three main approaches to conformant planning. The first two use heuristic search in belief-state space: HSCP (Bertoli *et al.*, 2001a) uses binary decision diagrams (BDDs) to represent belief states, whereas Hoffmann and Brafman (2006) adopt the lazy approach of computing precondition and goal tests on demand using a SAT solver.

The third approach, championed primarily by Jussi Rintanen (2007), formulates the entire sensorless planning problem as a quantified Boolean formula (QBF) and solves it using a general-purpose QBF solver. Current conformant planners are five orders of magnitude faster than CGP. The winner of the 2006 conformant-planning track at the International Planning Competition was *T*<sub>0</sub> (Palacios and Geffner, 2007), which uses heuristic search in belief-state

space while keeping the belief-state representation simple by defining derived literals that cover conditional effects. Bryce and Kambhampati (2007) discuss how a planning graph can be generalized to generate good heuristics for conformant and contingent planning.

The contingent-planning approach described in the chapter is based on Hoffmann and Brafman (2005), and was influenced by the efficient search algorithms for cyclic AND–OR graphs developed by Jimenez and Torras (2000) and Hansen and Zilberstein (2001). The problem of contingent planning received more attention after the publication of Drew McDermott's (1978a) influential article, *Planning and Acting*. Bertoli *et al.* (2001b) describe MBP (Model-Based Planner), which uses binary decision diagrams to do conformant and contingent planning. Some authors use “conditional planning” and “contingent planning” as synonyms; others make the distinction that “conditional” refers to actions with nondeterministic effects, and “contingent” means using sensing to overcome partial observability.

In retrospect, it is now possible to see how the major classical planning algorithms led to extended versions for uncertain domains. Fast-forward heuristic search through state space led to forward search in belief space (Bonet and Geffner, 2000; Hoffmann and Brafman, 2005); SATPLAN led to stochastic SATPLAN (Majercik and Littman, 2003) and to planning with quantified Boolean logic (Rintanen, 2007); partial order planning led to UWL (Etzioni *et al.*, 1992) and CNLP (Peot and Smith, 1992); Graphplan led to Sensory Graphplan or SGP (Weld *et al.*, 1998).

The first online planner with execution monitoring was PLANEX (Fikes *et al.*, 1972), which worked with the STRIPS planner to control the robot Shakey. SIPE (System for Interactive Planning and Execution monitoring) (Wilkins, 1988) was the first planner to deal systematically with the problem of replanning. It has been used in demonstration projects in several domains, including planning operations on the flight deck of an aircraft carrier, job-shop scheduling for an Australian beer factory, and planning the construction of multistory buildings (Kartam and Levitt, 1990).

In the mid-1980s, pessimism about the slow run times of planning systems led to the proposal of reflex agents called **reactive planning** systems (Brooks, 1986; Agre and Chapman, 1987). “Universal plans” (Schoppers, 1989) were developed as a lookup-table method for reactive planning, but turned out to be a rediscovery of the idea of **policies** that had long been used in Markov decision processes (see Chapter 16). Koenig (2001) surveys online planning techniques, under the name *Agent-Centered Search*.

Planning with time constraints was first dealt with by DEVISER (Vere, 1983). The representation of time in plans was addressed by Allen (1984) and by Dean *et al.* (1990) in the FORBIN system. NONLIN+ (Tate and Whiter, 1984) and SIPE (Wilkins, 1990) could reason about the allocation of limited resources to various plan steps. O-PLAN (Bell and Tate, 1985) has been applied to resource problems such as software procurement planning at Price Waterhouse and back-axle assembly planning at Jaguar Cars.

The two planners SAPA (Do and Kambhampati, 2001) and T4 (Haslum and Geffner, 2001) both used forward state-space search with sophisticated heuristics to handle actions with durations and resources. An alternative is to use very expressive action languages, but guide them by human-written, domain-specific heuristics, as is done by ASPEN (Fukunaga *et al.*, 1997), HSTS (Jonsson *et al.*, 2000), and IxTeT (Ghallab and Laruelle, 1994).

A number of hybrid planning-and-scheduling systems have been deployed: ISIS (Fox *et al.*, 1982; Fox, 1990) has been used for job-shop scheduling at Westinghouse, GARI (De-

[Reactive planning](#)

scotte and Latombe, 1985) planned the machining and construction of mechanical parts, FORBIN was used for factory control, and NONLIN+ was used for naval logistics planning. We chose to present planning and scheduling as two separate problems; Cushing *et al.* (2007) show that this can lead to incompleteness on certain problems.

There is a long history of scheduling in aerospace. T-SCHED (Drabble, 1990) was used to schedule mission-command sequences for the UOSAT-II satellite. OPTIMUM-AIV (Aarup *et al.*, 1994) and PLAN-ERS1 (Fuchs *et al.*, 1990), both based on O-PLAN, were used for spacecraft assembly and observation planning, respectively, at the European Space Agency. SPIKE (Johnston and Adorf, 1992) was used for observation planning at NASA for the Hubble Space Telescope, while the Space Shuttle Ground Processing Scheduling System (Deale *et al.*, 1994) does job-shop scheduling of up to 16,000 worker-shifts. Remote Agent (Muscettola *et al.*, 1998) became the first autonomous planner–scheduler to control a spacecraft, when it flew onboard the Deep Space One probe in 1999. Space applications have driven the development of algorithms for resource allocation; see Laborie (2003) and Muscettola (2002). The literature on scheduling is presented in a classic survey article (Lawler *et al.*, 1993), a book (Pinedo, 2008), and an edited handbook (Blazewicz *et al.*, 2007).

The computational complexity of planning has been analyzed by several authors (Bylander, 1994; Ghallab *et al.*, 2004; Rintanen, 2016). There are two main tasks: **PlanSAT** is the question of whether there exists any plan that solves a planning problem. **Bounded PlanSAT** asks whether there is a solution of length  $k$  or less; this can be used to find an optimal plan. Both are decidable for classical planning (because the number of states is finite). But if we add function symbols to the language, then the number of states becomes infinite, and PlanSAT becomes only semidecidable. For propositionalized problems both are in the complexity class PSPACE, a class that is larger (and hence more difficult) than NP and refers to problems that can be solved by a deterministic Turing machine with a polynomial amount of space. These theoretical results are discouraging, but in practice, the problems we want to solve tend to be not so bad. The true advantage of the classical planning formalism is that it has facilitated the development of very accurate domain-independent heuristics; other approaches have not been as fruitful.

*Readings in Planning* (Allen *et al.*, 1990) is a comprehensive anthology of early work in the field. Weld (1994, 1999) provides two excellent surveys of planning algorithms of the 1990s. It is interesting to see the change in the five years between the two surveys: the first concentrates on partial-order planning, and the second introduces Graphplan and SATPLAN. *Automated Planning and Acting* (Ghallab *et al.*, 2016) is an excellent textbook on all aspects of the field. LaValle’s text *Planning Algorithms* (2006) covers both classical and stochastic planning, with extensive coverage of robot motion planning.

Planning research has been central to AI since its inception, and papers on planning are a staple of mainstream AI journals and conferences. There are also specialized conferences such as the International Conference on Automated Planning and Scheduling and the International Workshop on Planning and Scheduling for Space.

# CHAPTER 12

## QUANTIFYING UNCERTAINTY

*In which we see how to tame uncertainty with numeric degrees of belief.*

### 12.1 Acting under Uncertainty

Agents in the real world need to handle **uncertainty**, whether due to partial observability, nondeterminism, or adversaries. An agent may never know for sure what state it is in now or where it will end up after a sequence of actions. Uncertainty

We have seen problem-solving and logical agents handle uncertainty by keeping track of a **belief state**—a representation of the set of all possible world states that it might be in—and generating a contingency plan that handles every possible eventuality that its sensors may report during execution. This approach works on simple problems, but it has drawbacks:

- The agent must consider *every possible* explanation for its sensor observations, no matter how unlikely. This leads to a large belief-state full of unlikely possibilities.
- A correct contingent plan that handles every eventuality can grow arbitrarily large and must consider arbitrarily unlikely contingencies.
- Sometimes there is no plan that is guaranteed to achieve the goal—yet the agent must act. It must have some way to compare the merits of plans that are not guaranteed.

Suppose, for example, that an automated taxi has the goal of delivering a passenger to the airport on time. The taxi forms a plan,  $A_{90}$ , that involves leaving home 90 minutes before the flight departs and driving at a reasonable speed. Even though the airport is only 5 miles away, a logical agent will not be able to conclude with absolute certainty that “Plan  $A_{90}$  will get us to the airport in time.” Instead, it reaches the weaker conclusion “Plan  $A_{90}$  will get us to the airport in time, as long as the car doesn’t break down, and I don’t get into an accident, and the road isn’t closed, and no meteorite hits the car, and . . . .” None of these conditions can be deduced for sure, so we can’t infer that the plan succeeds. This is the logical **qualification problem** (page 259), for which we so far have seen no real solution.

Nonetheless, in some sense  $A_{90}$  *is* in fact the right thing to do. What do we mean by this? As we discussed in Chapter 2, we mean that out of all the plans that could be executed,  $A_{90}$  is expected to maximize the agent’s performance measure (where the expectation is relative to the agent’s knowledge about the environment). The performance measure includes getting to the airport in time for the flight, avoiding a long, unproductive wait at the airport, and avoiding speeding tickets along the way. The agent’s knowledge cannot guarantee any of these outcomes for  $A_{90}$ , but it can provide some degree of belief that they will be achieved. Other plans, such as  $A_{180}$ , might increase the agent’s belief that it will get to the airport on time, but also increase the likelihood of a long, boring wait. *The right thing to do—the rational decision—therefore depends on both the relative importance of various goals and*

*the likelihood that, and degree to which, they will be achieved.* The remainder of this section hones these ideas, in preparation for the development of the general theories of uncertain reasoning and rational decisions that we present in this and subsequent chapters.

### 12.1.1 Summarizing uncertainty

Let's consider an example of uncertain reasoning: diagnosing a dental patient's toothache. Diagnosis—whether for medicine, automobile repair, or whatever—almost always involves uncertainty. Let us try to write rules for dental diagnosis using propositional logic, so that we can see how the logical approach breaks down. Consider the following simple rule:

$$\text{Toothache} \Rightarrow \text{Cavity}.$$

The problem is that this rule is wrong. Not all patients with toothaches have cavities; some of them have gum disease, an abscess, or one of several other problems:

$$\text{Toothache} \Rightarrow \text{Cavity} \vee \text{GumProblem} \vee \text{Abscess} \dots$$

Unfortunately, in order to make the rule true, we have to add an almost unlimited list of possible problems. We could try turning the rule into a causal rule:

$$\text{Cavity} \Rightarrow \text{Toothache}.$$

But this rule is not right either; not all cavities cause pain. The only way to fix the rule is to make it logically exhaustive: to augment the left-hand side with all the qualifications required for a cavity to cause a toothache. Trying to use logic to cope with a domain like medical diagnosis thus fails for three main reasons:

Laziness

- **Laziness:** It is too much work to list the complete set of antecedents or consequents needed to ensure an exceptionless rule and too hard to use such rules.
- **Theoretical ignorance:** Medical science has no complete theory for the domain.
- **Practical ignorance:** Even if we know all the rules, we might be uncertain about a particular patient because not all the necessary tests have been or can be run.

Theoretical ignorance

Practical ignorance

Degree of belief

Probability theory

The connection between toothaches and cavities is not a strict logical consequence in either direction. This is typical of the medical domain, as well as most other judgmental domains: law, business, design, automobile repair, gardening, dating, and so on. The agent's knowledge can at best provide only a **degree of belief** in the relevant sentences. Our main tool for dealing with degrees of belief is **probability theory**. In the terminology of Section 8.1, the **ontological commitments** of logic and probability theory are the same—that the world is composed of facts that do or do not hold in any particular case—but the **epistemological commitments** are different: a logical agent believes each sentence to be true or false or has no opinion, whereas a probabilistic agent may have a numerical degree of belief between 0 (for sentences that are certainly false) and 1 (certainly true).

The theory of *probability provides a way of summarizing the uncertainty that comes from our laziness and ignorance*, thereby solving the qualification problem. We might not know for sure what afflicts a particular patient, but we believe that there is, say, an 80% chance—that is, a probability of 0.8—that the patient who has a toothache has a cavity. That is, we expect that out of all the situations that are indistinguishable from the current situation as far as our knowledge goes, the patient will have a cavity in 80% of them. This belief could be derived from statistical data—80% of the toothache patients seen so far have had cavities—or from some general dental knowledge, or from a combination of evidence sources.

One confusing point is that at the time of our diagnosis, there is no uncertainty in the actual world: the patient either has a cavity or doesn't. So what does it mean to say the probability of a cavity is 0.8? Shouldn't it be either 0 or 1? The answer is that probability statements are made with respect to a knowledge state, not with respect to the real world. We say "The probability that the patient has a cavity, *given that she has a toothache*, is 0.8." If we later learn that the patient has a history of gum disease, we can make a different statement: "The probability that the patient has a cavity, given that she has a toothache and a history of gum disease, is 0.4." If we gather further conclusive evidence against a cavity, we can say "The probability that the patient has a cavity, given all we now know, is almost 0." Note that these statements do not contradict each other; each is a separate assertion about a different knowledge state.

### 12.1.2 Uncertainty and rational decisions

Consider again the  $A_{90}$  plan for getting to the airport. Suppose it gives us a 97% chance of catching our flight. Does this mean it is a rational choice? Not necessarily: there might be other plans, such as  $A_{180}$ , with higher probabilities. If it is *vital* not to miss the flight, then it is worth risking the longer wait at the airport. What about  $A_{1440}$ , a plan that involves leaving home 24 hours in advance? In most circumstances, this is not a good choice, because although it almost guarantees getting there on time, it involves an intolerable wait—not to mention a possibly unpleasant diet of airport food.

To make such choices, an agent must first have **preferences** among the different possible **outcomes** of the various plans. An outcome is a completely specified state, including such factors as whether the agent arrives on time and the length of the wait at the airport. We use **utility theory** to represent preferences and reason quantitatively with them. (The term **utility** is used here in the sense of "the quality of being useful," not in the sense of the electric company or water works.) Utility theory says that every state (or state sequence) has a degree of usefulness, or utility, to an agent and that the agent will prefer states with higher utility.

The utility of a state is relative to an agent. For example, the utility of a state in which White has checkmated Black in a game of chess is obviously high for the agent playing White, but low for the agent playing Black. But we can't go strictly by the scores of 1, 1/2, and 0 that are dictated by the rules of tournament chess—some players (including the authors) might be thrilled with a draw against the world champion, whereas other players (including the former world champion) might not. There is no accounting for taste or preferences: you might think that an agent who prefers jalapeño bubble-gum ice cream to chocolate chip is odd, but you could not say the agent is irrational. A utility function can account for any set of preferences—quirky or typical, noble or perverse. Note that utilities can account for altruism, simply by including the welfare of others as one of the factors.

Preferences, as expressed by utilities, are combined with probabilities in the general theory of rational decisions called **decision theory**:

$$\text{Decision theory} = \text{probability theory} + \text{utility theory}.$$

The fundamental idea of decision theory is that *an agent is rational if and only if it chooses the action that yields the highest expected utility, averaged over all the possible outcomes of the action*. This is called the principle of **maximum expected utility (MEU)**. Here, "expected" means the "average," or "statistical mean" of the outcome utilities, weighted by the probability of the outcome. We saw this principle in action in Chapter 6 when we touched

    given probabilities of outcomes and utility information
  return action

```

**Figure 12.1** A decision-theoretic agent that selects rational actions.

---

briefly on optimal decisions in backgammon; it is in fact a completely general principle for single-agent decision making.

Figure 12.1 sketches the structure of an agent that uses decision theory to select actions. The agent is identical, at an abstract level, to the agents described in Chapters 4 and 7 that maintain a belief state reflecting the history of percepts to date. The primary difference is that the decision-theoretic agent's belief state represents not just the *possibilities* for world states but also their *probabilities*. Given the belief state and some knowledge of the effects of actions, the agent can make probabilistic predictions of action outcomes and hence select the action with the highest expected utility.

This chapter and the next concentrate on the task of representing and computing with probabilistic information in general. Chapter 14 deals with methods for the specific tasks of representing and updating the belief state over time and predicting outcomes. Chapter 18 looks at ways of combining probability theory with expressive formal languages such as first-order logic and general-purpose programming languages. Chapter 15 covers utility theory in more depth, and Chapter 16 develops algorithms for planning sequences of actions in stochastic environments. Chapter 17 covers the extension of these ideas to multiagent environments.

## 12.2 Basic Probability Notation

---

For our agent to represent and use probabilistic information, we need a formal language. The language of probability theory has traditionally been informal, written by human mathematicians for other human mathematicians. Appendix A includes a standard introduction to elementary probability theory; here, we take an approach more suited to the needs of AI and connect it with the concepts of formal logic.

### 12.2.1 What probabilities are about

Like logical assertions, probabilistic assertions are about possible worlds. Whereas logical assertions say which possible worlds are strictly ruled out (all those in which the assertion is false), probabilistic assertions talk about how probable the various worlds are. In probability theory, the set of all possible worlds is called the **sample space**. The possible worlds are *mutually exclusive* and *exhaustive*—two possible worlds cannot both be the case, and one

possible world must be the case. For example, if we are about to roll two (distinguishable) dice, there are 36 possible worlds to consider: (1,1), (1,2), ..., (6,6). The Greek letter  $\Omega$  (uppercase omega) is used to refer to the sample space, and  $\omega$  (lowercase omega) refers to elements of the space, that is, particular possible worlds.

A fully specified **probability model** associates a numerical probability  $P(\omega)$  with each possible world.<sup>1</sup> The basic axioms of probability theory say that every possible world has a probability between 0 and 1 and that the total probability of the set of possible worlds is 1:

$$0 \leq P(\omega) \leq 1 \text{ for every } \omega \text{ and } \sum_{\omega \in \Omega} P(\omega) = 1. \quad (12.1)$$

For example, if we assume that each die is fair and the rolls don't interfere with each other, then each of the possible worlds (1,1), (1,2), ..., (6,6) has probability 1/36. If the dice are loaded then some worlds will have higher probabilities and some lower, but they will all still sum to 1.

Probabilistic assertions and queries are not usually about particular possible worlds, but about sets of them. For example, we might ask for the probability that the two dice add up to 11, the probability that doubles are rolled, and so on. In probability theory, these sets are called **events**—a term already used extensively in Chapter 10 for a different concept. In logic, a set of worlds corresponds to a **proposition** in a formal language; specifically, for each proposition, the corresponding set contains just those possible worlds in which the proposition holds. (Hence, “event” and “proposition” mean roughly the same thing in this context, except that a proposition is expressed in a formal language.) The probability associated with a proposition is defined to be the sum of the probabilities of the worlds in which it holds:

$$\text{For any proposition } \phi, P(\phi) = \sum_{\omega \in \phi} P(\omega). \quad (12.2)$$

For example, when rolling fair dice, we have  $P(\text{Total}=11) = P((5,6)) + P((6,5)) = 1/36 + 1/36 = 1/18$ . Note that probability theory does not require complete knowledge of the probabilities of each possible world. For example, if we believe the dice conspire to produce the same number, we might *assert* that  $P(\text{doubles}) = 1/4$  without knowing whether the dice prefer double 6 to double 2. Just as with logical assertions, this assertion *constrains* the underlying probability model without fully determining it.

Probabilities such as  $P(\text{Total}=11)$  and  $P(\text{doubles})$  are called **unconditional** or **prior probabilities** (and sometimes just “priors” for short); they refer to degrees of belief in propositions *in the absence of any other information*. Most of the time, however, we have *some* information, usually called **evidence**, that has already been revealed. For example, the first die may already be showing a 5 and we are waiting with bated breath for the other one to stop spinning. In that case, we are interested not in the unconditional probability of rolling doubles, but the **conditional** or **posterior** probability (or just “posterior” for short) of rolling doubles *given that the first die is a 5*. This probability is written  $P(\text{doubles} | \text{Die}_1=5)$ , where the “|” is pronounced “given.”<sup>2</sup>

Similarly, if I am going to the dentist for a regularly scheduled checkup, then the prior probability  $P(\text{cavity})=0.2$  might be of interest; but if I go to the dentist because I have a toothache, it's the conditional probability  $P(\text{cavity} | \text{toothache})=0.6$  that matters.

<sup>1</sup> For now, we assume a discrete, countable set of worlds. The proper treatment of the continuous case brings in certain complications that are less relevant for most purposes in AI.

<sup>2</sup> Note that the precedence of “|” is such that any expression of the form  $P(\dots | \dots)$  always means  $P((\dots) | (\dots))$ .

Probability model

Event

Unconditional probability  
Prior probability

Evidence

Conditional probability  
Posterior probability

It is important to understand that  $P(cavity) = 0.2$  is still *valid* after *toothache* is observed; it just isn't especially useful. When making decisions, an agent needs to condition on *all* the evidence it has observed. It is also important to understand the difference between conditioning and logical implication. The assertion that  $P(cavity | toothache) = 0.6$  does not mean “Whenever *toothache* is true, conclude that *cavity* is true with probability 0.6” rather it means “Whenever *toothache* is true *and we have no further information*, conclude that *cavity* is true with probability 0.6.” The extra condition is important; for example, if we had the further information that the dentist found no cavities, we definitely would not want to conclude that *cavity* is true with probability 0.6; instead we need to use  $P(cavity | toothache \wedge \neg cavity) = 0$ .

Mathematically speaking, conditional probabilities are defined in terms of unconditional probabilities as follows: for any propositions  $a$  and  $b$ , we have

$$P(a | b) = \frac{P(a \wedge b)}{P(b)}, \quad (12.3)$$

which holds whenever  $P(b) > 0$ . For example,

$$P(doubles | Die_1 = 5) = \frac{P(doubles \wedge Die_1 = 5)}{P(Die_1 = 5)}.$$

The definition makes sense if you remember that observing  $b$  rules out all those possible worlds where  $b$  is false, leaving a set whose total probability is just  $P(b)$ . Within that set, the worlds where  $a$  is true must satisfy  $a \wedge b$  and constitute a fraction  $P(a \wedge b)/P(b)$ .

The definition of conditional probability, Equation (12.3), can be written in a different form called the **product rule**:

$$P(a \wedge b) = P(a | b)P(b). \quad (12.4)$$

The product rule is perhaps easier to remember: it comes from the fact that for  $a$  and  $b$  to be true, we need  $b$  to be true, and we also need  $a$  to be true given  $b$ .

### 12.2.2 The language of propositions in probability assertions

In this chapter and the next, propositions describing sets of possible worlds are usually written in a notation that combines elements of propositional logic and constraint satisfaction notation. In the terminology of Section 2.4.7, it is a **factored representation**, in which a possible world is represented by a set of variable/value pairs. A more expressive **structured representation** is also possible, as shown in Chapter 18.

**Random variable**

Variables in probability theory are called **random variables**, and their names begin with an uppercase letter. Thus, in the dice example, *Total* and *Die<sub>1</sub>* are random variables. Every random variable is a function that maps from the domain of possible worlds  $\Omega$  to some **range**—the set of possible values it can take on. The range of *Total* for two dice is the set  $\{2, \dots, 12\}$  and the range of *Die<sub>1</sub>* is  $\{1, \dots, 6\}$ . Names for values are always lowercase, so we might write  $\sum_x P(X=x)$  to sum over the values of  $X$ . A Boolean random variable has the range  $\{\text{true}, \text{false}\}$ . For example, the proposition that doubles are rolled can be written as *Doubles=true*. (An alternative range for Boolean variables is the set  $\{0, 1\}$ , in which case the variable is said to have a **Bernoulli distribution**.) By convention, propositions of the form  $A=\text{true}$  are abbreviated simply as  $a$ , while  $A=\text{false}$  is abbreviated as  $\neg a$ . (The uses of *doubles*, *cavity*, and *toothache* in the preceding section are abbreviations of this kind.)

**Range**

**Bernoulli**

Ranges can be sets of arbitrary tokens. We might choose the range of *Age* to be the set  $\{\text{juvenile}, \text{teen}, \text{adult}\}$  and the range of *Weather* might be  $\{\text{sun}, \text{rain}, \text{cloud}, \text{snow}\}$ . When no

ambiguity is possible, it is common to use a value by itself to stand for the proposition that a particular variable has that value; thus, *sun* can stand for *Weather = sun*.<sup>3</sup>

The preceding examples all have finite ranges. Variables can have infinite ranges, too—either discrete (like the integers) or continuous (like the reals). For any variable with an ordered range, inequalities are also allowed, such as *NumberOfAtomsInUniverse*  $\geq 10^{70}$ .

Finally, we can combine these sorts of elementary propositions (including the abbreviated forms for Boolean variables) by using the connectives of propositional logic. For example, we can express “The probability that the patient has a cavity, given that she is a teenager with no toothache, is 0.1” as follows:

$$P(\text{cavity} \mid \neg\text{toothache} \wedge \text{teen}) = 0.1.$$

In probability notation, it is also common to use a comma for conjunction, so we could write  $P(\text{cavity} \mid \neg\text{toothache}, \text{teen})$ .

Sometimes we will want to talk about the probabilities of *all* the possible values of a random variable. We could write:

$$\begin{aligned} P(\text{Weather} = \text{sun}) &= 0.6 \\ P(\text{Weather} = \text{rain}) &= 0.1 \\ P(\text{Weather} = \text{cloud}) &= 0.29 \\ P(\text{Weather} = \text{snow}) &= 0.01, \end{aligned}$$

but as an abbreviation we will allow

$$\mathbf{P}(\text{Weather}) = \langle 0.6, 0.1, 0.29, 0.01 \rangle,$$

where the bold **P** indicates that the result is a vector of numbers, and where we assume a predefined ordering  $\langle \text{sun}, \text{rain}, \text{cloud}, \text{snow} \rangle$  on the range of *Weather*. We say that the **P** statement defines a **probability distribution** for the random variable *Weather*—that is, an assignment of a probability for each possible value of the random variable. (In this case, with a finite, discrete range, the distribution is called a **categorical distribution**.) The **P** notation is also used for conditional distributions:  $\mathbf{P}(X \mid Y)$  gives the values of  $P(X = x_i \mid Y = y_j)$  for each possible  $i, j$  pair.

For continuous variables, it is not possible to write out the entire distribution as a vector, because there are infinitely many values. Instead, we can define the probability that a random variable takes on some value  $x$  as a parameterized function of  $x$ , usually called a **probability density function**. For example, the sentence

$$P(\text{NoonTemp} = x) = \text{Uniform}(x; 18C, 26C)$$

expresses the belief that the temperature at noon is distributed uniformly between 18 and 26 degrees Celsius.

Probability density functions (sometimes called **pdfs**) differ in meaning from discrete distributions. Saying that the probability density is uniform from 18C to 26C means that there is a 100% chance that the temperature will fall somewhere in that 8C-wide region and a 50% chance that it will fall in any 4C-wide sub-region, and so on. We write the probability density for a continuous random variable  $X$  at value  $x$  as  $P(X = x)$  or just  $P(x)$ ; the intuitive

Probability distribution

Categorical distribution

Probability density function

<sup>3</sup> These conventions taken together lead to a potential ambiguity in notation when summing over values of a Boolean variable:  $P(a)$  is the probability that  $A$  is *true*, whereas in the expression  $\sum_a P(a)$  it just refers to the probability of one of the values  $a$  of  $A$ .

definition of  $P(x)$  is the probability that  $X$  falls within an arbitrarily small region beginning at  $x$ , divided by the width of the region:

$$P(x) = \lim_{dx \rightarrow 0} P(x \leq X \leq x + dx)/dx.$$

For *NoonTemp* we have

$$P(\text{NoonTemp} = x) = \text{Uniform}(x; 18C, 26C) = \begin{cases} \frac{1}{8C} & \text{if } 18C \leq x \leq 26C \\ 0 & \text{otherwise} \end{cases},$$

where  $C$  stands for centigrade (not for a constant). In  $P(\text{NoonTemp} = 20.18C) = \frac{1}{8C}$ , note that  $\frac{1}{8C}$  is not a probability, it is a probability density. The probability that *NoonTemp* is *exactly*  $20.18C$  is zero, because  $20.18C$  is a region of width 0. Some authors use different symbols for discrete probabilities and probability densities; we use  $P$  for specific probability values and  $\mathbf{P}$  for vectors of values in both cases, since confusion seldom arises and the equations are usually identical. Note that probabilities are unitless numbers, whereas density functions are measured with a unit, in this case reciprocal degrees centigrade. If the same temperature interval were to be expressed in degrees Fahrenheit, it would have a width of 14.4 degrees, and the density would be  $1/14.4F$ .

In addition to distributions on single variables, we need notation for distributions on multiple variables. Commas are used for this. For example,  $\mathbf{P}(\text{Weather}, \text{Cavity})$  denotes the probabilities of all combinations of the values of *Weather* and *Cavity*. This is a  $4 \times 2$  table of probabilities called the **joint probability distribution** of *Weather* and *Cavity*. We can also mix variables and specific values;  $\mathbf{P}(\text{sun}, \text{Cavity})$  would be a two-element vector giving the probabilities of a cavity with a sunny day and no cavity with a sunny day.

The  $\mathbf{P}$  notation makes certain expressions much more concise than they might otherwise be. For example, the product rules (see Equation (12.4)) for all possible values of *Weather* and *Cavity* can be written as a single equation:

$$\mathbf{P}(\text{Weather}, \text{Cavity}) = \mathbf{P}(\text{Weather} | \text{Cavity}) \mathbf{P}(\text{Cavity}),$$

instead of as these  $4 \times 2 = 8$  equations (using abbreviations  $W$  and  $C$ ):

$$\begin{aligned} P(W = \text{sun} \wedge C = \text{true}) &= P(W = \text{sun} | C = \text{true}) P(C = \text{true}) \\ P(W = \text{rain} \wedge C = \text{true}) &= P(W = \text{rain} | C = \text{true}) P(C = \text{true}) \\ P(W = \text{cloud} \wedge C = \text{true}) &= P(W = \text{cloud} | C = \text{true}) P(C = \text{true}) \\ P(W = \text{snow} \wedge C = \text{true}) &= P(W = \text{snow} | C = \text{true}) P(C = \text{true}) \\ P(W = \text{sun} \wedge C = \text{false}) &= P(W = \text{sun} | C = \text{false}) P(C = \text{false}) \\ P(W = \text{rain} \wedge C = \text{false}) &= P(W = \text{rain} | C = \text{false}) P(C = \text{false}) \\ P(W = \text{cloud} \wedge C = \text{false}) &= P(W = \text{cloud} | C = \text{false}) P(C = \text{false}) \\ P(W = \text{snow} \wedge C = \text{false}) &= P(W = \text{snow} | C = \text{false}) P(C = \text{false}). \end{aligned}$$

As a degenerate case,  $\mathbf{P}(\text{sun}, \text{cavity})$  has no variables and thus is a zero-dimensional vector, which we can think of as a scalar value.

Now we have defined a syntax for propositions and probability assertions and we have given part of the semantics: Equation (12.2) defines the probability of a proposition as the sum of the probabilities of worlds in which it holds. To complete the semantics, we need to say what the worlds are and how to determine whether a proposition holds in a world. We borrow this part directly from the semantics of propositional logic, as follows. A *possible world* is defined to be an assignment of values to all of the random variables under consideration.

It is easy to see that this definition satisfies the basic requirement that possible worlds be mutually exclusive and exhaustive (Exercise 12.EXEX). For example, if the random variables

are *Cavity*, *Toothache*, and *Weather*, then there are  $2 \times 2 \times 4 = 16$  possible worlds. Furthermore, the truth of any given proposition can be determined easily in such worlds by the same recursive truth calculation we used for propositional logic (see page 236).

Note that some random variables may be redundant, in that their values can be obtained in all cases from the values of other variables. For example, the *Doubles* variable in the two-dice world is true exactly when  $\text{Die}_1 = \text{Die}_2$ . Including *Doubles* as one of the random variables, in addition to *Die*<sub>1</sub> and *Die*<sub>2</sub>, seems to increase the number of possible worlds from 36 to 72, but of course exactly half of the 72 will be logically impossible and will have probability 0.

From the preceding definition of possible worlds, it follows that a probability model is completely determined by the joint distribution for all of the random variables—the so-called **full joint probability distribution**. For example, given *Cavity*, *Toothache*, and *Weather*, the full joint distribution is  $\mathbf{P}(\text{Cavity}, \text{Toothache}, \text{Weather})$ . This joint distribution can be represented as a  $2 \times 2 \times 4$  table with 16 entries. Because every proposition's probability is a sum over possible worlds, a full joint distribution suffices, in principle, for calculating the probability of any proposition. We will see examples of how to do this in Section 12.3.

Full joint probability distribution

### 12.2.3 Probability axioms and their reasonableness

The basic axioms of probability (Equations (12.1) and (12.2)) imply certain relationships among the degrees of belief that can be accorded to logically related propositions. For example, we can derive the familiar relationship between the probability of a proposition and the probability of its negation:

$$\begin{aligned} P(\neg a) &= \sum_{\omega \in \neg a} P(\omega) && \text{by Equation (12.2)} \\ &= \sum_{\omega \in \neg a} P(\omega) + \sum_{\omega \in a} P(\omega) - \sum_{\omega \in a} P(\omega) \\ &= \sum_{\omega \in \Omega} P(\omega) - \sum_{\omega \in a} P(\omega) && \text{grouping the first two terms} \\ &= 1 - P(a) && \text{by (12.1) and (12.2).} \end{aligned}$$

We can also derive the well-known formula for the probability of a disjunction, sometimes called the **inclusion–exclusion principle**:

$$P(a \vee b) = P(a) + P(b) - P(a \wedge b). \quad (12.5)$$

Inclusion–exclusion principle

This rule is easily remembered by noting that the cases where  $a$  holds, together with the cases where  $b$  holds, certainly cover all the cases where  $a \vee b$  holds; but summing the two sets of cases counts their intersection twice, so we need to subtract  $P(a \wedge b)$ .

Equations (12.1) and (12.5) are often called **Kolmogorov's axioms** in honor of the mathematician Andrei Kolmogorov, who showed how to build up the rest of probability theory from this simple foundation and how to handle the difficulties caused by continuous variables.<sup>4</sup> While Equation (12.2) has a definitional flavor, Equation (12.5) reveals that the axioms really do constrain the degrees of belief an agent can have concerning logically related propositions. This is analogous to the fact that a logical agent cannot simultaneously believe  $A$ ,  $B$ , and  $\neg(A \wedge B)$ , because there is no possible world in which all three are true. With probabilities, however, statements refer not to the world directly, but to the agent's own state of knowledge. Why, then, can an agent not hold the following set of beliefs (even though they violate Kolmogorov's axioms)?

Kolmogorov's axioms

$$P(a) = 0.4 \quad P(b) = 0.3 \quad P(a \wedge b) = 0.0 \quad P(a \vee b) = 0.8. \quad (12.6)$$

<sup>4</sup> The difficulties include the **Vitali set**, a well-defined subset of the interval  $[0, 1]$  with no well-defined size.

Proposition	Agent 1's belief	Agent 2 bets	Agent 1 bets	Agent 1 payoffs for each outcome			
				$a, b$	$a, \neg b$	$\neg a, b$	$\neg a, \neg b$
$a$	0.4	\$4 on $a$	\$6 on $\neg a$	-\$6	-\$6	\$4	\$4
$b$	0.3	\$3 on $b$	\$7 on $\neg b$	-\$7	\$3	-\$7	\$3
$a \vee b$	0.8	\$2 on $\neg(a \vee b)$	\$8 on $a \vee b$	\$2	\$2	\$2	-\$8
				-\$11	-\$1	-\$1	-\$1

**Figure 12.2** Because Agent 1 has inconsistent beliefs, Agent 2 is able to devise a set of three bets that guarantees a loss for Agent 1, no matter what the outcome of  $a$  and  $b$ .

This kind of question has been the subject of decades of intense debate between those who advocate the use of probabilities as the only legitimate form for degrees of belief and those who advocate alternative approaches.

One argument for the axioms of probability, first stated in 1931 by Bruno de Finetti (see de Finetti, 1993, for an English translation), is as follows: If an agent has some degree of belief in a proposition  $a$ , then the agent should be able to state odds at which it is indifferent to a bet for or against  $a$ .<sup>5</sup> Think of it as a game between two agents: Agent 1 states, “my degree of belief in event  $a$  is 0.4.” Agent 2 is then free to choose whether to wager for or against  $a$  at stakes that are consistent with the stated degree of belief. That is, Agent 2 could choose to accept Agent 1’s bet that  $a$  will occur, offering \$6 against Agent 1’s \$4. Or Agent 2 could accept Agent 1’s bet that  $\neg a$  will occur, offering \$4 against Agent 1’s \$6. Then we observe the outcome of  $a$ , and whoever is right collects the money. If one’s degrees of belief do not accurately reflect the world, then one would expect to lose money over the long run to an opposing agent whose beliefs more accurately reflect the state of the world.

De Finetti’s theorem is not concerned with choosing the right values for individual probabilities, but with choosing values for the probabilities of logically related propositions: *If Agent 1 expresses a set of degrees of belief that violate the axioms of probability theory then there is a combination of bets by Agent 2 that guarantees that Agent 1 will lose money every time.* For example, suppose that Agent 1 has the set of degrees of belief from Equation (12.6). Figure 12.2 shows that if Agent 2 chooses to bet \$4 on  $a$ , \$3 on  $b$ , and \$2 on  $\neg(a \vee b)$ , then Agent 1 always loses money, regardless of the outcomes for  $a$  and  $b$ . De Finetti’s theorem implies that no rational agent can have beliefs that violate the axioms of probability.

One common objection to de Finetti’s theorem is that this betting game is rather contrived. For example, what if one refuses to bet? Does that end the argument? The answer is that the betting game is an abstract model for the decision-making situation in which every agent is *unavoidably* involved at every moment. Every action (including inaction) is a kind of bet, and every outcome can be seen as a payoff of the bet. Refusing to bet is like refusing to allow time to pass.

Other strong philosophical arguments have been put forward for the use of probabilities, most notably those of Cox (1946), Carnap (1950), and Jaynes (2003). They each construct a

<sup>5</sup> One might argue that the agent’s preferences for different bank balances are such that the possibility of losing \$1 is not counterbalanced by an equal possibility of winning \$1. One possible response is to make the bet amounts small enough to avoid this problem. Savage’s analysis (1954) circumvents the issue altogether.

set of axioms for reasoning with degrees of beliefs: no contradictions, correspondence with ordinary logic (for example, if belief in  $A$  goes up, then belief in  $\neg A$  must go down), and so on. The only controversial axiom is that degrees of belief must be numbers, or at least act like numbers in that they must be transitive (if belief in  $A$  is greater than belief in  $B$ , which is greater than belief in  $C$ , then belief in  $A$  must be greater than  $C$ ) and comparable (the belief in  $A$  must be one of equal to, greater than, or less than belief in  $B$ ). It can then be proved that probability is the only approach that satisfies these axioms.

The world being the way it is, however, practical demonstrations sometimes speak louder than proofs. The success of reasoning systems based on probability theory has been much more effective than philosophical arguments in making converts. We now look at how the axioms can be deployed to make inferences.

## 12.3 Inference Using Full Joint Distributions

In this section we describe a simple method for **probabilistic inference**—that is, the computation of posterior probabilities for **query** propositions given observed evidence. We use the full joint distribution as the “knowledge base” from which answers to all questions may be derived. Along the way we also introduce several useful techniques for manipulating equations involving probabilities.

We begin with a simple example: a domain consisting of just the three Boolean variables *Toothache*, *Cavity*, and *Catch* (the dentist’s nasty steel probe catches in my tooth). The full joint distribution is a  $2 \times 2 \times 2$  table as shown in Figure 12.3.

		toothache		$\neg$ toothache	
		catch	$\neg$ catch	catch	$\neg$ catch
cavity	catch	0.108	0.012	0.072	0.008
	$\neg$ cavity	0.016	0.064	0.144	0.576

**Figure 12.3** A full joint distribution for the *Toothache*, *Cavity*, *Catch* world.

Notice that the probabilities in the joint distribution sum to 1, as required by the axioms of probability. Notice also that Equation (12.2) gives us a direct way to calculate the probability of any proposition, simple or complex: simply identify those possible worlds in which the proposition is true and add up their probabilities. For example, there are six possible worlds in which *cavity*  $\vee$  *toothache* holds:

$$P(\text{cavity} \vee \text{toothache}) = 0.108 + 0.012 + 0.072 + 0.008 + 0.016 + 0.064 = 0.28.$$

One particularly common task is to extract the distribution over some subset of variables or a single variable. For example, adding the entries in the first row gives the unconditional or **marginal probability**<sup>6</sup> of *cavity*:

$$P(\text{cavity}) = 0.108 + 0.012 + 0.072 + 0.008 = 0.2.$$

<sup>6</sup> So called because of a common practice among actuaries of writing the sums of observed frequencies in the margins of insurance tables.

Probabilistic  
inference  
Query

Marginal probability

## Marginalization

This process is called **marginalization**, or **summing out**—because we sum up the probabilities for each possible value of the other variables, thereby taking them out of the equation. We can write the following general marginalization rule for any sets of variables  $\mathbf{Y}$  and  $\mathbf{Z}$ :

$$\mathbf{P}(\mathbf{Y}) = \sum_{\mathbf{z}} \mathbf{P}(\mathbf{Y}, \mathbf{Z}=\mathbf{z}), \quad (12.7)$$

where  $\sum_{\mathbf{z}}$  sums over all the possible combinations of values of the set of variables  $\mathbf{Z}$ . As usual we can abbreviate  $\mathbf{P}(\mathbf{Y}, \mathbf{Z}=\mathbf{z})$  in this equation by  $\mathbf{P}(\mathbf{Y}, \mathbf{z})$ . For the *Cavity* example, Equation (12.7) corresponds to the following equation:

$$\begin{aligned} \mathbf{P}(Cavity) &= \mathbf{P}(Cavity, toothache, catch) + \mathbf{P}(Cavity, toothache, \neg catch) \\ &\quad + \mathbf{P}(Cavity, \neg toothache, catch) + \mathbf{P}(Cavity, \neg toothache, \neg catch) \\ &= \langle 0.108, 0.016 \rangle + \langle 0.012, 0.064 \rangle + \langle 0.072, 0.144 \rangle + \langle 0.008, 0.576 \rangle \\ &= \langle 0.2, 0.8 \rangle. \end{aligned}$$

## Conditioning

Using the product rule (Equation (12.4)), we can replace  $\mathbf{P}(\mathbf{Y}, \mathbf{z})$  in Equation (12.7) by  $\mathbf{P}(\mathbf{Y} | \mathbf{z})P(\mathbf{z})$ , obtaining a rule called **conditioning**:

$$\mathbf{P}(\mathbf{Y}) = \sum_{\mathbf{z}} \mathbf{P}(\mathbf{Y} | \mathbf{z})P(\mathbf{z}). \quad (12.8)$$

Marginalization and conditioning turn out to be useful rules for all kinds of derivations involving probability expressions.

In most cases, we are interested in computing *conditional* probabilities of some variables, given evidence about others. Conditional probabilities can be found by first using Equation (12.3) to obtain an expression in terms of unconditional probabilities and then evaluating the expression from the full joint distribution. For example, we can compute the probability of a cavity, given evidence of a toothache, as follows:

$$\begin{aligned} P(cavity | toothache) &= \frac{P(cavity \wedge toothache)}{P(toothache)} \\ &= \frac{0.108 + 0.012}{0.108 + 0.012 + 0.016 + 0.064} = 0.6. \end{aligned}$$

Just to check, we can also compute the probability that there is no cavity, given a toothache:

$$\begin{aligned} P(\neg cavity | toothache) &= \frac{P(\neg cavity \wedge toothache)}{P(toothache)} \\ &= \frac{0.016 + 0.064}{0.108 + 0.012 + 0.016 + 0.064} = 0.4. \end{aligned}$$

The two values sum to 1.0, as they should. Notice that the term  $P(toothache)$  is in the denominator for both of these calculations. If the variable *Cavity* had more than two values, it would be in the denominator for all of them. In fact, it can be viewed as a **normalization** constant for the distribution  $\mathbf{P}(Cavity | toothache)$ , ensuring that it adds up to 1. Throughout the chapters dealing with probability, we use  $\alpha$  to denote such constants. With this notation, we can write the two preceding equations in one:

$$\begin{aligned} \mathbf{P}(Cavity | toothache) &= \alpha \mathbf{P}(Cavity, toothache) \\ &= \alpha [\mathbf{P}(Cavity, toothache, catch) + \mathbf{P}(Cavity, toothache, \neg catch)] \\ &= \alpha [\langle 0.108, 0.016 \rangle + \langle 0.012, 0.064 \rangle] = \alpha \langle 0.12, 0.08 \rangle = \langle 0.6, 0.4 \rangle. \end{aligned}$$

In other words, we can calculate  $\mathbf{P}(Cavity | toothache)$  even if we don't know the value of  $P(toothache)$ ! We temporarily forget about the factor  $1/P(toothache)$  and add up the values for *cavity* and  $\neg cavity$ , getting 0.12 and 0.08. Those are the correct relative proportions, but they don't sum to 1, so we normalize them by dividing each one by  $0.12 + 0.08$ , getting the true probabilities of 0.6 and 0.4. Normalization turns out to be a useful shortcut in many probability calculations, both to make the computation easier and to allow us to proceed when some probability assessment (such as  $P(toothache)$ ) is not available.

From the example, we can extract a general inference procedure. We begin with the case in which the query involves a single variable,  $X$  (*Cavity* in the example). Let  $\mathbf{E}$  be the list of evidence variables (just *Toothache* in the example), let  $\mathbf{e}$  be the list of observed values for them, and let  $\mathbf{Y}$  be the remaining unobserved variables (just *Catch* in the example). The query is  $\mathbf{P}(X | \mathbf{e})$  and can be evaluated as

$$\mathbf{P}(X | \mathbf{e}) = \alpha \mathbf{P}(X, \mathbf{e}) = \alpha \sum_{\mathbf{y}} \mathbf{P}(X, \mathbf{e}, \mathbf{y}), \quad (12.9)$$

where the summation is over all possible  $\mathbf{y}$ s (i.e., all possible combinations of values of the unobserved variables  $\mathbf{Y}$ ). Notice that together the variables  $X$ ,  $\mathbf{E}$ , and  $\mathbf{Y}$  constitute the complete set of variables for the domain, so  $\mathbf{P}(X, \mathbf{e}, \mathbf{y})$  is simply a subset of probabilities from the full joint distribution.

Given the full joint distribution to work with, Equation (12.9) can answer probabilistic queries for discrete variables. It does not scale well, however: for a domain described by  $n$  Boolean variables, it requires an input table of size  $O(2^n)$  and takes  $O(2^n)$  time to process the table. In a realistic problem we could easily have  $n = 100$ , making  $O(2^n)$  impractical—a table with  $2^{100} \approx 10^{30}$  entries! The problem is not just memory and computation: the real issue is that if each of the  $10^{30}$  probabilities has to be estimated separately from examples, the number of examples required will be astronomical.

For these reasons, the full joint distribution in tabular form is seldom a practical tool for building reasoning systems. Instead, it should be viewed as the theoretical foundation on which more effective approaches may be built, just as truth tables formed a theoretical foundation for more practical algorithms like DPLL in Chapter 7. The remainder of this chapter introduces some of the basic ideas required in preparation for the development of realistic systems in Chapter 13.

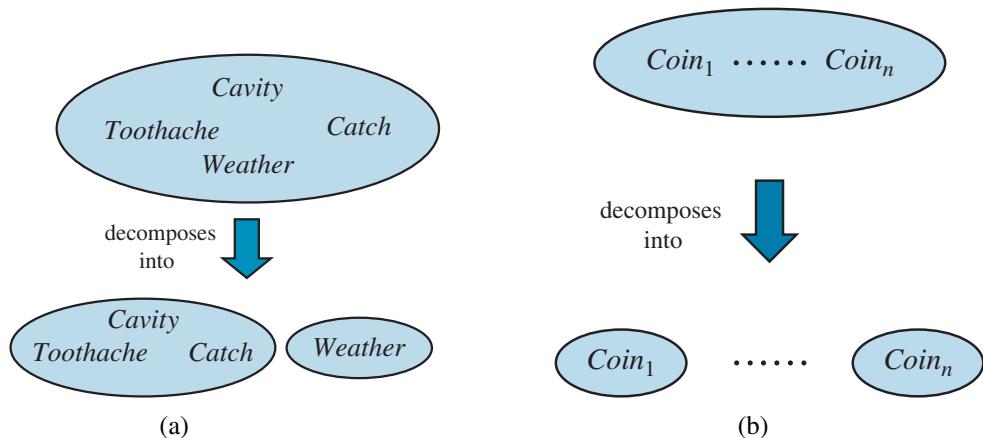

## 12.4 Independence

---

Let us expand the full joint distribution in Figure 12.3 by adding a fourth variable, *Weather*. The full joint distribution then becomes  $\mathbf{P}(Toothache, Catch, Cavity, Weather)$ , which has  $2 \times 2 \times 2 \times 4 = 32$  entries. It contains four “editions” of the table shown in Figure 12.3, one for each kind of weather. What relationship do these editions have to each other and to the original three-variable table? How is the value of  $P(toothache, catch, cavity, cloud)$  related to the value of  $P(toothache, catch, cavity)$ ? We can use the product rule (Equation (12.4)):

$$\begin{aligned} & P(toothache, catch, cavity, cloud) \\ &= P(cloud | toothache, catch, cavity)P(toothache, catch, cavity). \end{aligned}$$

Now, unless one is in the deity business, one should not imagine that one's dental problems influence the weather. And for indoor dentistry, at least, it seems safe to say that the weather

**Figure 12.4** Two examples of factoring a large joint distribution into smaller distributions, using absolute independence. (a) Weather and dental problems are independent. (b) Coin flips are independent.

does not influence the dental variables. Therefore, the following assertion seems reasonable:

$$P(\text{cloud} \mid \text{toothache}, \text{catch}, \text{cavity}) = P(\text{cloud}). \quad (12.10)$$

From this, we can deduce

$$P(\text{toothache}, \text{catch}, \text{cavity}, \text{cloud}) = P(\text{cloud})P(\text{toothache}, \text{catch}, \text{cavity}).$$

A similar equation exists for every entry in  $\mathbf{P}(\text{Toothache}, \text{Catch}, \text{Cavity}, \text{Weather})$ . In fact, we can write the general equation

$$\mathbf{P}(\text{Toothache}, \text{Catch}, \text{Cavity}, \text{Weather}) = \mathbf{P}(\text{Toothache}, \text{Catch}, \text{Cavity})\mathbf{P}(\text{Weather}).$$

Thus, the 32-element table for four variables can be constructed from one 8-element table and one 4-element table. This decomposition is illustrated schematically in Figure 12.4(a).

## Independence

The property we used in Equation (12.10) is called **independence** (also **marginal independence** and **absolute independence**). In particular, the weather is independent of one's dental problems. Independence between propositions  $a$  and  $b$  can be written as

$$P(a|b) = P(a) \quad \text{or} \quad P(b|a) = P(b) \quad \text{or} \quad P(a \wedge b) = P(a)P(b). \quad (12.11)$$

All these forms are equivalent (Exercise [12.INDI](#)). Independence between variables  $X$  and  $Y$  can be written as follows (again, these are all equivalent):

$$\mathbf{P}(X|Y) = \mathbf{P}(X) \quad \text{or} \quad \mathbf{P}(Y|X) = \mathbf{P}(Y) \quad \text{or} \quad \mathbf{P}(X,Y) = \mathbf{P}(X)\mathbf{P}(Y).$$

Independence assertions are usually based on knowledge of the domain. As the toothache-weather example illustrates, they can dramatically reduce the amount of information necessary to specify the full joint distribution. If the complete set of variables can be divided into independent subsets, then the full joint distribution can be *faktored* into separate joint distributions on those subsets. For example, the full joint distribution on the outcome of  $n$  independent coin flips,  $\mathbf{P}(C_1, \dots, C_n)$ , has  $2^n$  entries, but it can be represented as the product of  $n$  single-variable distributions  $\mathbf{P}(C_i)$ . In a more practical vein, the independence of dentistry and meteorology is a good thing, because otherwise the practice of dentistry might require intimate knowledge of meteorology, and vice versa.

When they are available, then, independence assertions can help in reducing the size of the domain representation and the complexity of the inference problem. Unfortunately, clean separation of entire sets of variables by independence is quite rare. Whenever a connection, however indirect, exists between two variables, independence will fail to hold. Moreover, even independent subsets can be quite large—for example, dentistry might involve dozens of diseases and hundreds of symptoms, all of which are interrelated. To handle such problems, we need more subtle methods than the straightforward concept of independence.

## 12.5 Bayes' Rule and Its Use

---

On page 408, we defined the **product rule** (Equation (12.4)). It can actually be written in two forms:

$$P(a \wedge b) = P(a|b)P(b) \quad \text{and} \quad P(a \wedge b) = P(b|a)P(a).$$

Equating the two right-hand sides and dividing by  $P(a)$ , we get

$$P(b|a) = \frac{P(a|b)P(b)}{P(a)}. \quad (12.12)$$

This equation is known as **Bayes' rule** (also Bayes' law or Bayes' theorem). This simple Bayes' rule equation underlies most modern AI systems for probabilistic inference.

The more general case of Bayes' rule for multivalued variables can be written in the **P** notation as follows:

$$\mathbf{P}(Y|X) = \frac{\mathbf{P}(X|Y)\mathbf{P}(Y)}{\mathbf{P}(X)}.$$

As before, this is to be taken as representing a set of equations, each dealing with specific values of the variables. We will also have occasion to use a more general version conditionalized on some background evidence **e**:

$$\mathbf{P}(Y|X, \mathbf{e}) = \frac{\mathbf{P}(X|Y, \mathbf{e})\mathbf{P}(Y|\mathbf{e})}{\mathbf{P}(X|\mathbf{e})}. \quad (12.13)$$

### 12.5.1 Applying Bayes' rule: The simple case

On the surface, Bayes' rule does not seem very useful. It allows us to compute the single term  $P(b|a)$  in terms of three terms:  $P(a|b)$ ,  $P(b)$ , and  $P(a)$ . That seems like two steps backwards; but Bayes' rule is useful in practice because there are many cases where we do have good probability estimates for these three numbers and need to compute the fourth. Often, we perceive as evidence the *effect* of some unknown *cause* and we would like to determine that cause. In that case, Bayes' rule becomes

$$P(\text{cause}|\text{effect}) = \frac{P(\text{effect}|\text{cause})P(\text{cause})}{P(\text{effect})}.$$

The conditional probability  $P(\text{effect}|\text{cause})$  quantifies the relationship in the **causal** direction, whereas  $P(\text{cause}|\text{effect})$  describes the **diagnostic** direction. In a task such as medical diagnosis, we often have conditional probabilities on causal relationships. The doctor knows  $P(\text{symptoms}|\text{disease})$  and wants to derive a diagnosis,  $P(\text{disease}|\text{symptoms})$ .

For example, a doctor knows that the disease meningitis causes a patient to have a stiff neck, say, 70% of the time. The doctor also knows some unconditional facts: the prior

probability that any patient has meningitis is 1/50,000, and the prior probability that any patient has a stiff neck is 1%. Letting  $s$  be the proposition that the patient has a stiff neck and  $m$  be the proposition that the patient has meningitis, we have

$$\begin{aligned} P(s|m) &= 0.7 \\ P(m) &= 1/50000 \\ P(s) &= 0.01 \\ P(m|s) &= \frac{P(s|m)P(m)}{P(s)} = \frac{0.7 \times 1/50000}{0.01} = 0.0014. \end{aligned} \quad (12.14)$$

That is, we expect only 0.14% of patients with a stiff neck to have meningitis. Notice that even though a stiff neck is quite strongly indicated by meningitis (with probability 0.7), the probability of meningitis in patients with stiff necks remains small. This is because the prior probability of stiff necks (from any cause) is much higher than the prior for meningitis.

Section 12.3 illustrated a process by which one can avoid assessing the prior probability of the evidence (here,  $P(s)$ ) by instead computing a posterior probability for each value of the query variable (here,  $m$  and  $\neg m$ ) and then normalizing the results. The same process can be applied when using Bayes' rule. We have

$$\mathbf{P}(M|s) = \alpha \langle P(s|m)P(m), P(s|\neg m)P(\neg m) \rangle.$$

Thus, to use this approach we need to estimate  $P(s|\neg m)$  instead of  $P(s)$ . There is no free lunch—sometimes this is easier, sometimes it is harder. The general form of Bayes' rule with normalization is

$$\mathbf{P}(Y|X) = \alpha \mathbf{P}(X|Y)\mathbf{P}(Y), \quad (12.15)$$

where  $\alpha$  is the normalization constant needed to make the entries in  $\mathbf{P}(Y|X)$  sum to 1.

One obvious question to ask about Bayes' rule is why one might have available the conditional probability in one direction, but not the other. In the meningitis domain, perhaps the doctor knows that a stiff neck implies meningitis in 1 out of 5000 cases; that is, the doctor has quantitative information in the **diagnostic** direction from symptoms to causes. Such a doctor has no need to use Bayes' rule.

 Unfortunately, *diagnostic knowledge is often more fragile than causal knowledge*. If there is a sudden epidemic of meningitis, the unconditional probability of meningitis,  $P(m)$ , will go up. The doctor who derived the diagnostic probability  $P(m|s)$  directly from statistical observation of patients before the epidemic will have no idea how to update the value, but the doctor who computes  $P(m|s)$  from the other three values will see that  $P(m|s)$  should go up proportionately with  $P(m)$ . Most important, the causal information  $P(s|m)$  is *unaffected* by the epidemic, because it simply reflects the way meningitis works. The use of this kind of direct causal or model-based knowledge provides the crucial robustness needed to make probabilistic systems feasible in the real world.

### 12.5.2 Using Bayes' rule: Combining evidence

We have seen that Bayes' rule can be useful for answering probabilistic queries conditioned on one piece of evidence—for example, the stiff neck. In particular, we have argued that probabilistic information is often available in the form  $P(effect|cause)$ . What happens when we have two or more pieces of evidence? For example, what can a dentist conclude if her

nasty steel probe catches in the aching tooth of a patient? If we know the full joint distribution (Figure 12.3), we can read off the answer:

$$\mathbf{P}(\text{Cavity} \mid \text{toothache} \wedge \text{catch}) = \alpha \langle 0.108, 0.016 \rangle \approx \langle 0.871, 0.129 \rangle.$$

We know, however, that such an approach does not scale up to larger numbers of variables. We can try using Bayes' rule to reformulate the problem:

$$\begin{aligned} \mathbf{P}(\text{Cavity} \mid \text{toothache} \wedge \text{catch}) \\ = \alpha \mathbf{P}(\text{toothache} \wedge \text{catch} \mid \text{Cavity}) \mathbf{P}(\text{Cavity}). \end{aligned} \quad (12.16)$$

For this reformulation to work, we need to know the conditional probabilities of the conjunction  $\text{toothache} \wedge \text{catch}$  for each value of  $\text{Cavity}$ . That might be feasible for just two evidence variables, but again it does not scale up. If there are  $n$  possible evidence variables (X rays, diet, oral hygiene, etc.), then there are  $O(2^n)$  possible combinations of observed values for which we would need to know conditional probabilities. This is no better than using the full joint distribution.

To make progress, we need to find some additional assertions about the domain that will enable us to simplify the expressions. The notion of **independence** in Section 12.4 provides a clue, but needs refining. It would be nice if *Toothache* and *Catch* were independent, but they are not: if the probe catches in the tooth, then it is likely that the tooth has a cavity and that the cavity causes a toothache. These variables *are* independent, however, *given the presence or the absence of a cavity*. Each is directly caused by the cavity, but neither has a direct effect on the other: toothache depends on the state of the nerves in the tooth, whereas the probe's accuracy depends primarily on the dentist's skill, to which the toothache is irrelevant.<sup>7</sup> Mathematically, this property is written as

$$\mathbf{P}(\text{toothache} \wedge \text{catch} \mid \text{Cavity}) = \mathbf{P}(\text{toothache} \mid \text{Cavity}) \mathbf{P}(\text{catch} \mid \text{Cavity}). \quad (12.17)$$

This equation expresses the **conditional independence** of *toothache* and *catch* given *Cavity*. We can plug it into Equation (12.16) to obtain the probability of a cavity:

$$\begin{aligned} \mathbf{P}(\text{Cavity} \mid \text{toothache} \wedge \text{catch}) \\ = \alpha \mathbf{P}(\text{toothache} \mid \text{Cavity}) \mathbf{P}(\text{catch} \mid \text{Cavity}) \mathbf{P}(\text{Cavity}). \end{aligned} \quad (12.18)$$

Conditional  
independence

Now the information requirements are the same as for inference, using each piece of evidence separately: the prior probability  $\mathbf{P}(\text{Cavity})$  for the query variable and the conditional probability of each effect, given its cause.

The general definition of **conditional independence** of two variables  $X$  and  $Y$ , given a third variable  $Z$ , is

$$\mathbf{P}(X, Y \mid Z) = \mathbf{P}(X \mid Z) \mathbf{P}(Y \mid Z).$$

In the dentist domain, for example, it seems reasonable to assert conditional independence of the variables *Toothache* and *Catch*, given *Cavity*:

$$\mathbf{P}(\text{Toothache}, \text{Catch} \mid \text{Cavity}) = \mathbf{P}(\text{Toothache} \mid \text{Cavity}) \mathbf{P}(\text{Catch} \mid \text{Cavity}). \quad (12.19)$$

Notice that this assertion is somewhat stronger than Equation (12.17), which asserts independence only for specific values of *Toothache* and *Catch*. As with absolute independence in Equation (12.11), the equivalent forms

$$\mathbf{P}(X \mid Y, Z) = \mathbf{P}(X \mid Z) \quad \text{and} \quad \mathbf{P}(Y \mid X, Z) = \mathbf{P}(Y \mid Z)$$

<sup>7</sup> We assume that the patient and dentist are distinct individuals.

can also be used (see Exercise 12.PXYZ). Section 12.4 showed that absolute independence assertions allow a decomposition of the full joint distribution into much smaller pieces. It turns out that the same is true for conditional independence assertions. For example, given the assertion in Equation (12.19), we can derive a decomposition as follows:

$$\begin{aligned} & \mathbf{P}(\text{Toothache}, \text{Catch}, \text{Cavity}) \\ &= \mathbf{P}(\text{Toothache}, \text{Catch} | \text{Cavity}) \mathbf{P}(\text{Cavity}) \quad (\text{product rule}) \\ &= \mathbf{P}(\text{Toothache} | \text{Cavity}) \mathbf{P}(\text{Catch} | \text{Cavity}) \mathbf{P}(\text{Cavity}) \quad (\text{using 12.19}). \end{aligned}$$

(The reader can easily check that this equation does in fact hold in Figure 12.3.) In this way, the original large table is decomposed into three smaller tables. The original table has 7 independent numbers. (The table has  $2^3 = 8$  entries, but they must sum to 1, so 7 are independent). The smaller tables contain a total of  $2 + 2 + 1 = 5$  independent numbers. (For a conditional probability distribution such as  $\mathbf{P}(\text{Toothache} | \text{Cavity})$  there are two rows of two numbers, and each row sums to 1, so that's two independent numbers; for a prior distribution such as  $\mathbf{P}(\text{Cavity})$  there is only one independent number.) Going from 7 to 5 might not seem like a major triumph, but the gains can be much greater with larger number of symptoms.

In general, for  $n$  symptoms that are all conditionally independent given *Cavity*, the size of the representation grows as  $O(n)$  instead of  $O(2^n)$ . That means that *conditional independence assertions can allow probabilistic systems to scale up; moreover, they are much more commonly available than absolute independence assertions*. Conceptually, *Cavity separates Toothache and Catch because it is a direct cause of both of them*. The decomposition of large probabilistic domains into weakly connected subsets through conditional independence is one of the most important developments in the recent history of AI.

Separation

## 12.6 Naive Bayes Models

The dentistry example illustrates a commonly occurring pattern in which a single cause directly influences a number of effects, all of which are conditionally independent, given the cause. The full joint distribution can be written as

$$\mathbf{P}(\text{Cause}, \text{Effect}_1, \dots, \text{Effect}_n) = \mathbf{P}(\text{Cause}) \prod_i \mathbf{P}(\text{Effect}_i | \text{Cause}). \quad (12.20)$$

Naive Bayes

Such a probability distribution is called a **naive Bayes** model—“naive” because it is often used (as a simplifying assumption) in cases where the “effect” variables are *not* strictly independent given the cause variable. (The naive Bayes model is sometimes called a **Bayesian classifier**, a somewhat careless usage that has prompted true Bayesians to call it the **idiot Bayes** model.) In practice, naive Bayes systems often work very well, even when the conditional independence assumption is not strictly true.

To use a naive Bayes model, we can apply Equation (12.20) to obtain the probability of the cause given some observed effects. Call the observed effects  $\mathbf{E} = \mathbf{e}$ , while the remaining effect variables  $\mathbf{Y}$  are unobserved. Then the standard method for inference from the joint distribution (Equation (12.9)) can be applied:

$$\mathbf{P}(\text{Cause} | \mathbf{e}) = \alpha \sum_{\mathbf{y}} \mathbf{P}(\text{Cause}, \mathbf{e}, \mathbf{y}).$$

From Equation (12.20), we then obtain

$$\begin{aligned}
 \mathbf{P}(\text{Cause} | \mathbf{e}) &= \alpha \sum_{\mathbf{y}} \mathbf{P}(\text{Cause}) \mathbf{P}(\mathbf{y} | \text{Cause}) \left( \prod_j \mathbf{P}(e_j | \text{Cause}) \right) \\
 &= \alpha \mathbf{P}(\text{Cause}) \left( \prod_j \mathbf{P}(e_j | \text{Cause}) \right) \sum_{\mathbf{y}} \mathbf{P}(\mathbf{y} | \text{Cause}) \\
 &= \alpha \mathbf{P}(\text{Cause}) \prod_j \mathbf{P}(e_j | \text{Cause})
 \end{aligned} \tag{12.21}$$

where the last line follows because the summation over  $\mathbf{y}$  is 1. Reinterpreting this equation in words: for each possible cause, multiply the prior probability of the cause by the product of the conditional probabilities of the observed effects given the cause; then normalize the result. The run time of this calculation is linear in the number of observed effects and does not depend on the number of unobserved effects (which may be very large in domains such as medicine). We will see in the next chapter that this is a common phenomenon in probabilistic inference: evidence variables whose values are unobserved usually “disappear” from the computation altogether.

### 12.6.1 Text classification with naive Bayes

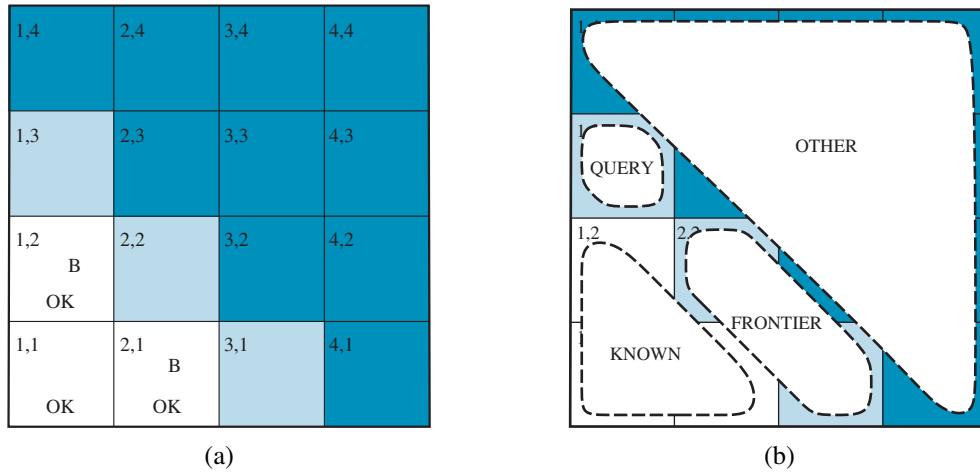

Let’s see how a naive Bayes model can be used for the task of **text classification**: given a text, decide which of a predefined set of classes or categories it belongs to. Here the “cause” is the *Category* variable, and the “effect” variables are the presence or absence of certain key words,  $\text{HasWord}_i$ . Consider these two example sentences, taken from newspaper articles:

1. Stocks rallied on Monday, with major indexes gaining 1% as optimism persisted over the first quarter earnings season.
2. Heavy rain continued to pound much of the east coast on Monday, with flood warnings issued in New York City and other locations.

The task is to classify each sentence into a *Category*—the major sections of the newspaper: *news*, *sports*, *business*, *weather*, or *entertainment*. The naive Bayes model consists of the prior probabilities  $\mathbf{P}(\text{Category})$  and the conditional probabilities  $\mathbf{P}(\text{HasWord}_i | \text{Category})$ . For each category  $c$ ,  $P(\text{Category} = c)$  is estimated as the fraction of all previously seen documents that are of category  $c$ . For example, if 9% of articles are about weather, we set  $P(\text{Category} = \text{weather}) = 0.09$ . Similarly,  $\mathbf{P}(\text{HasWord}_i | \text{Category})$  is estimated as the fraction of documents of each category that contain word  $i$ ; perhaps 37% of articles about business contain word 6, “stocks,” so  $P(\text{HasWord}_6 = \text{true} | \text{Category} = \text{business})$  is set to 0.37.<sup>8</sup>

To categorize a new document, we check which key words appear in the document and then apply Equation (12.21) to obtain the posterior probability distribution over categories. If we have to predict just one category, we take the one with the highest posterior probability. Notice that, for this task, every effect variable is observed, since we can always tell whether a given word appears in the document.

<sup>8</sup> One needs to be careful not to assign probability zero to words that have not been seen previously in a given category of documents, since the zero would wipe out all the other evidence in Equation (12.21). Just because you haven’t seen a word yet doesn’t mean you will *never* see it. Instead, reserve a small portion of the probability distribution to represent “previously unseen” words. See Chapter 21 for more on this issue in general, and Section 24.1.4 for the particular case of word models.

**Figure 12.5** (a) After finding a breeze in both [1,2] and [2,1], the agent is stuck—there is no safe place to explore. (b) Division of the squares into *Known*, *Frontier*, and *Other*, for a query about [1,3].

The naive Bayes model assumes that words occur independently in documents, with frequencies determined by the document category. This independence assumption is clearly violated in practice. For example, the phrase “first quarter” occurs more frequently in business (or sports) articles than would be suggested by multiplying the probabilities of “first” and “quarter.” The violation of independence usually means that the final posterior probabilities will be much closer to 1 or 0 than they should be; in other words, the model is overconfident in its predictions. On the other hand, even with these errors, the *ranking* of the possible categories is often quite accurate.

Naive Bayes models are widely used for language determination, document retrieval, spam filtering, and other classification tasks. For tasks such as medical diagnosis, where the actual values of the posterior probabilities really matter—for example, in deciding whether to perform an appendectomy—one would usually prefer to use the more sophisticated models described in the next chapter.

## 12.7 The Wumpus World Revisited

We can combine the ideas in this chapter to solve probabilistic reasoning problems in the wumpus world. (See Chapter 7 for a complete description of the wumpus world.) Uncertainty arises in the wumpus world because the agent’s sensors give only partial information about the world. For example, Figure 12.5 shows a situation in which each of the three unvisited but reachable squares—[1,3], [2,2], and [3,1]—might contain a pit. Pure logical inference can conclude nothing about which square is most likely to be safe, so a logical agent might have to choose randomly. We will see that a probabilistic agent can do much better than the logical agent.

Our aim is to calculate the probability that each of the three squares contains a pit. (For this example we ignore the wumpus and the gold.) The relevant properties of the wumpus

world are that (1) a pit causes breezes in all neighboring squares, and (2) each square other than [1,1] contains a pit with probability 0.2. The first step is to identify the set of random variables we need:

- As in the propositional logic case, we want one Boolean variable  $P_{ij}$  for each square, which is true iff square  $[i, j]$  actually contains a pit.
- We also have Boolean variables  $B_{ij}$  that are true iff square  $[i, j]$  is breezy; we include these variables only for the observed squares—in this case, [1,1], [1,2], and [2,1].

The next step is to specify the full joint distribution,  $\mathbf{P}(P_{1,1}, \dots, P_{4,4}, B_{1,1}, B_{1,2}, B_{2,1})$ . Applying the product rule, we have

$$\begin{aligned} \mathbf{P}(P_{1,1}, \dots, P_{4,4}, B_{1,1}, B_{1,2}, B_{2,1}) &= \\ \mathbf{P}(B_{1,1}, B_{1,2}, B_{2,1} | P_{1,1}, \dots, P_{4,4}) \mathbf{P}(P_{1,1}, \dots, P_{4,4}). \end{aligned}$$

This decomposition makes it easy to see what the joint probability values should be. The first term is the conditional probability distribution of a breeze configuration, given a pit configuration; its values are 1 if all the breezy squares are adjacent to the pits and 0 otherwise. The second term is the prior probability of a pit configuration. Each square contains a pit with probability 0.2, independently of the other squares; hence,

$$\mathbf{P}(P_{1,1}, \dots, P_{4,4}) = \prod_{i,j=1,1}^{4,4} \mathbf{P}(P_{i,j}). \quad (12.22)$$

For a particular configuration with exactly  $n$  pits, the probability is  $0.2^n \times 0.8^{16-n}$ .

In the situation in Figure 12.5(a), the evidence consists of the observed breeze (or its absence) in each square that is visited, combined with the fact that each such square contains no pit. We abbreviate these facts as  $b = \neg b_{1,1} \wedge b_{1,2} \wedge b_{2,1}$  and  $known = \neg p_{1,1} \wedge \neg p_{1,2} \wedge \neg p_{2,1}$ . We are interested in answering queries such as  $\mathbf{P}(P_{1,3} | known, b)$ : how likely is it that [1,3] contains a pit, given the observations so far?

To answer this query, we can follow the standard approach of Equation (12.9), namely, summing over entries from the full joint distribution. Let  $Unknown$  be the set of  $P_{i,j}$  variables for squares other than the known squares and the query square [1,3]. Then, by Equation (12.9), we have

$$\mathbf{P}(P_{1,3} | known, b) = \alpha \sum_{unknown} \mathbf{P}(P_{1,3}, known, b, unknown). \quad (12.23)$$

The full joint probabilities have already been specified, so we are done—that is, unless we care about computation. There are 12 unknown squares; hence the summation contains  $2^{12} = 4096$  terms. In general, the summation grows exponentially with the number of squares.

Surely, one might ask, aren't the other squares irrelevant? How could [4,4] affect whether [1,3] has a pit? Indeed, this intuition is roughly correct, but it needs to be made more precise. What we really mean is that if we knew the values of all the pit variables adjacent to the squares we care about, then pits (or their absence) in other, more distant squares could have no further effect on our belief.

Let  $Frontier$  be the pit variables (other than the query variable) that are adjacent to visited squares, in this case just [2,2] and [3,1]. Also, let  $Other$  be the pit variables for the other unknown squares; in this case, there are 10 other squares, as shown in Figure 12.5(b). With these definitions,  $Unknown = Frontier \cup Other$ . The key insight given above can now be stated as follows: the observed breezes are *conditionally independent* of the other variables, given

the known, frontier, and query variables. To use this insight, we manipulate the query formula into a form in which the breezes are conditioned on all the other variables, and then we apply conditional independence:

$$\begin{aligned}
 & \mathbf{P}(P_{1,3} | \text{known}, b) \\
 &= \alpha \sum_{\text{unknown}} \mathbf{P}(P_{1,3}, \text{known}, b, \text{unknown}) \quad (\text{from Equation (12.23)}) \\
 &= \alpha \sum_{\text{unknown}} \mathbf{P}(b | P_{1,3}, \text{known}, \text{unknown}) \mathbf{P}(P_{1,3}, \text{known}, \text{unknown}) \quad (\text{product rule}) \\
 &= \alpha \sum_{\text{frontier}} \sum_{\text{other}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}, \text{other}) \mathbf{P}(P_{1,3}, \text{known}, \text{frontier}, \text{other}) \\
 &= \alpha \sum_{\text{frontier}} \sum_{\text{other}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}) \mathbf{P}(P_{1,3}, \text{known}, \text{frontier}, \text{other}),
 \end{aligned}$$

where the final step uses conditional independence:  $b$  is independent of  $\text{other}$  given  $\text{known}$ ,  $P_{1,3}$ , and  $\text{frontier}$ . Now, the first term in this expression does not depend on the  $\text{Other}$  variables, so we can move the summation inward:

$$\begin{aligned}
 & \mathbf{P}(P_{1,3} | \text{known}, b) \\
 &= \alpha \sum_{\text{frontier}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}) \sum_{\text{other}} \mathbf{P}(P_{1,3}, \text{known}, \text{frontier}, \text{other}).
 \end{aligned}$$

By independence, as in Equation (12.22), the term on the right can be factored, and then the terms can be reordered:

$$\begin{aligned}
 & \mathbf{P}(P_{1,3} | \text{known}, b) \\
 &= \alpha \sum_{\text{frontier}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}) \sum_{\text{other}} \mathbf{P}(P_{1,3}) \mathbf{P}(\text{known}) \mathbf{P}(\text{frontier}) \mathbf{P}(\text{other}) \\
 &= \alpha \mathbf{P}(\text{known}) \mathbf{P}(P_{1,3}) \sum_{\text{frontier}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}) \mathbf{P}(\text{frontier}) \sum_{\text{other}} \mathbf{P}(\text{other}) \\
 &= \alpha' \mathbf{P}(P_{1,3}) \sum_{\text{frontier}} \mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier}) \mathbf{P}(\text{frontier}),
 \end{aligned}$$

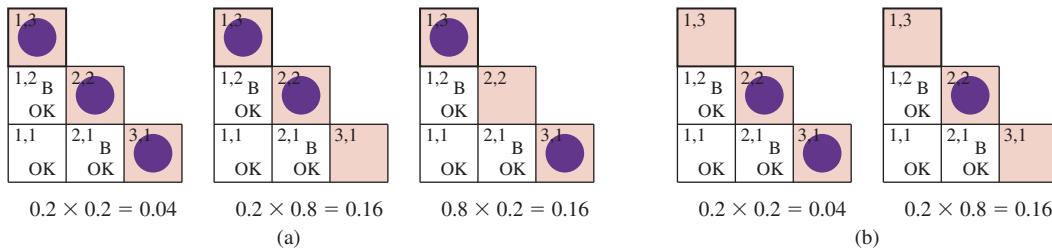

where the last step folds  $\mathbf{P}(\text{known})$  into the normalizing constant and uses the fact that  $\sum_{\text{other}} \mathbf{P}(\text{other})$  equals 1.

Now, there are just four terms in the summation over the frontier variables,  $P_{2,2}$  and  $P_{3,1}$ . The use of independence and conditional independence has completely eliminated the other squares from consideration.

Notice that the probabilities in  $\mathbf{P}(b | \text{known}, P_{1,3}, \text{frontier})$  are 1 when the breeze observations are consistent with the other variables and 0 otherwise. Thus, for each value of  $P_{1,3}$ , we sum over the *logical models* for the frontier variables that are consistent with the known facts. (Compare with the enumeration over models in Figure 7.5 on page 233.) The models and their associated prior probabilities— $\mathbf{P}(\text{frontier})$ —are shown in Figure 12.6. We have

$$\mathbf{P}(P_{1,3} | \text{known}, b) = \alpha' \langle 0.2(0.04 + 0.16 + 0.16), 0.8(0.04 + 0.16) \rangle \approx \langle 0.31, 0.69 \rangle.$$

That is, [1,3] (and [3,1] by symmetry) contains a pit with roughly 31% probability. A similar calculation, which the reader might wish to perform, shows that [2,2] contains a pit with roughly 86% probability. The wumpus agent should definitely avoid [2,2]! Note that our logical agent from Chapter 7 did not know that [2,2] was worse than the other squares. Logic

**Figure 12.6** Consistent models for the frontier variables,  $P_{2,2}$  and  $P_{3,1}$ , showing  $P(\text{frontier})$  for each model: (a) three models with  $P_{1,3} = \text{true}$  showing two or three pits, and (b) two models with  $P_{1,3} = \text{false}$  showing one or two pits.

can tell us that it is unknown whether there is a pit in [2, 2], but we need probability to tell us how likely it is.

What this section has shown is that even seemingly complicated problems can be formulated precisely in probability theory and solved with simple algorithms. To get *efficient* solutions, independence and conditional independence relationships can be used to simplify the summations required. These relationships often correspond to our natural understanding of how the problem should be decomposed. In the next chapter, we develop formal representations for such relationships as well as algorithms that operate on those representations to perform probabilistic inference efficiently.

## Summary

This chapter has suggested probability theory as a suitable foundation for uncertain reasoning and provided a gentle introduction to its use.

- Uncertainty arises because of both laziness and ignorance. It is inescapable in complex, nondeterministic, or partially observable environments.
- **Probabilities** express the agent's inability to reach a definite decision regarding the truth of a sentence. Probabilities summarize the agent's beliefs relative to the evidence.
- **Decision theory** combines the agent's beliefs and desires, defining the best action as the one that maximizes expected **utility**.
- Basic probability statements include **prior** or **unconditional probabilities** and **posterior** or **conditional probabilities** over simple and complex propositions.
- The axioms of probability constrain the probabilities of logically related propositions. An agent that violates the axioms must behave irrationally in some cases.
- The **full joint probability distribution** specifies the probability of each complete assignment of values to random variables. It is usually too large to create or use in its explicit form, but when it is available it can be used to answer queries simply by adding up entries for the possible worlds corresponding to the query propositions.
- **Absolute independence** between subsets of random variables allows the full joint distribution to be factored into smaller joint distributions, greatly reducing its complexity.

- **Bayes' rule** allows unknown probabilities to be computed from known conditional probabilities, usually in the causal direction. Applying Bayes' rule with many pieces of evidence runs into the same scaling problems as does the full joint distribution.
- **Conditional independence** brought about by direct causal relationships in the domain allows the full joint distribution to be factored into smaller, conditional distributions. The **naive Bayes** model assumes the conditional independence of all effect variables, given a single cause variable; its size grows linearly with the number of effects.
- A wumpus-world agent can calculate probabilities for unobserved aspects of the world, thereby improving on the decisions of a purely logical agent. Conditional independence makes these calculations tractable.

## Bibliographical and Historical Notes

---

Probability theory was invented as a way of analyzing games of chance. In about 850 CE the Indian mathematician Mahaviracarya described how to arrange a set of bets that can't lose (what we now call a Dutch book). In Europe, the first significant systematic analyses were produced by Girolamo Cardano around 1565, although publication was posthumous (1663). By that time, probability had been established as a mathematical discipline due to a series of results from a famous correspondence between Blaise Pascal and Pierre de Fermat in 1654. The first published textbook on probability was *De Ratiociniis in Ludo Aleae* (On Reasoning in a Game of Chance) by Huygens (1657). The “laziness and ignorance” view of uncertainty was described by John Arbuthnot in the preface of his translation of Huygens (Arbuthnot, 1692): “It is impossible for a Die, with such determin'd force and direction, not to fall on such determin'd side, only I don't know the force and direction which makes it fall on such determin'd side, and therefore I call it Chance, which is nothing but the want of art.”

The connection between probability and reasoning dates back at least to the nineteenth century: in 1819, Pierre Laplace said, “Probability theory is nothing but common sense reduced to calculation.” In 1850, James Maxwell said, “The true logic for this world is the calculus of Probabilities, which takes account of the magnitude of the probability which is, or ought to be, in a reasonable man's mind.”

Frequentist

There has been endless debate over the source and status of probability numbers. The **frequentist** position is that the numbers can come only from *experiments*: if we test 100 people and find that 10 of them have a cavity, then we can say that the probability of a cavity is approximately 0.1. In this view, the assertion “the probability of a cavity is 0.1” means that 0.1 is the fraction that would be observed in the limit of infinitely many samples. From any finite sample, we can estimate the true fraction and also calculate how accurate our estimate is likely to be.

Objectivist

The **objectivist** view is that probabilities are real aspects of the universe—propensities of objects to behave in certain ways—rather than being just descriptions of an observer's degree of belief. For example, the fact that a fair coin comes up heads with probability 0.5 is a propensity of the coin itself. In this view, frequentist measurements are attempts to observe these propensities. Most physicists agree that quantum phenomena are objectively probabilistic, but uncertainty at the macroscopic scale—e.g., in coin tossing—usually arises from ignorance of initial conditions and does not seem consistent with the propensity view.

The **subjectivist** view describes probabilities as a way of characterizing an agent's beliefs, rather than as having any external physical significance. The subjective **Bayesian** view allows any self-consistent ascription of prior probabilities to propositions, but then insists on proper Bayesian updating as evidence arrives.

Even a strict frequentist position involves subjectivity because of the **reference class** problem: in trying to determine the outcome probability of a *particular* experiment, the frequentist has to place it in a reference class of "similar" experiments with known outcome frequencies. But what's the right class? I. J. Good wrote, "every event in life is unique, and every real-life probability that we estimate in practice is that of an event that has never occurred before" (Good, 1983, p. 27).

For example, given a particular patient, a frequentist who wants to estimate the probability of a cavity will consider a reference class of other patients who are similar in important ways—age, symptoms, diet—and see what proportion of them had a cavity. If the dentist considers everything that is known about the patient—hair color, weight to the nearest gram, mother's maiden name—then the reference class becomes empty. This has been a vexing problem in the philosophy of science.

Pascal used probability in ways that required both the objective interpretation, as a property of the world based on symmetry or relative frequency, and the subjective interpretation, based on degree of belief—the former in his analyses of probabilities in games of chance, the latter in the famous "Pascal's wager" argument about the possible existence of God. However, Pascal did not clearly realize the distinction between these two interpretations. The distinction was first drawn clearly by James Bernoulli (1654–1705).

Leibniz introduced the "classical" notion of probability as a proportion of enumerated, equally probable cases, which was also used by Bernoulli, although it was brought to prominence by Laplace (1816). This notion is ambiguous between the frequency interpretation and the subjective interpretation. The cases can be thought to be equally probable either because of a natural, physical symmetry between them, or simply because we do not have any knowledge that would lead us to consider one more probable than another. The use of this latter, subjective consideration to justify assigning equal probabilities is known as the **principle of indifference**. The principle is often attributed to Laplace (1816), but he never used the name explicitly; Keynes (1921) did. George Boole and John Venn both referred to it as the **principle of insufficient reason**.

The debate between objectivists and subjectivists became sharper in the 20th century. Kolmogorov (1963), R. A. Fisher (1922), and Richard von Mises (1928) were advocates of the relative frequency interpretation. Karl Popper's "propensity" interpretation (1959, first published in German in 1934) traces relative frequencies to an underlying physical symmetry. Frank Ramsey (1931), Bruno de Finetti (1937), R. T. Cox (1946), Leonard Savage (1954), Richard Jeffrey (1983), and E. T. Jaynes (2003) interpreted probabilities as the degrees of belief of specific individuals. Their analyses of degree of belief were closely tied to utilities and to behavior—specifically, to the willingness to place bets.

Rudolf Carnap offered a different interpretation of probability—not as the degree of belief that an individual actually has, but as the degree of belief that an idealized reasoner *should* have in a particular proposition *a*, given a particular body of evidence *e*. Carnap attempted to make this notion of degree of **confirmation** mathematically precise, as a logical relation between *a* and *e*. Currently it is believed that there is no unique logic of this kind; rather, any

Subjectivist

Reference class

Principle of indifference

Principle of insufficient reason

such logic rests on a subjective prior probability distribution whose effect is diminished as more observations are collected.

The study of this relation was intended to constitute a mathematical discipline called **inductive logic**, analogous to ordinary deductive logic (Carnap, 1948, 1950). Carnap was not able to extend his inductive logic much beyond the propositional case, and Putnam (1963) showed by adversarial arguments that some difficulties were inherent. More recent work by Bacchus, Grove, Halpern, and Koller (1992) extends Carnap's methods to first-order theories.

The first rigorously axiomatic framework for probability theory was proposed by Kolmogorov (1950, first published in German in 1933). Rényi (1970) later gave an axiomatic presentation that took conditional probability, rather than absolute probability, as primitive.

In addition to de Finetti's arguments for the validity of the axioms, Cox (1946) showed that any system for uncertain reasoning that meets his set of assumptions is equivalent to probability theory. This gave renewed confidence to probability fans, but others were not convinced, objecting to the assumption that belief must be represented by a single number. Halpern (1999) describes the assumptions and shows some gaps in Cox's original formulation. Horn (2003) shows how to patch up the difficulties. Jaynes (2003) has a similar argument that is easier to read.

The Rev. Thomas Bayes (1702–1761) introduced the rule for reasoning about conditional probabilities that was posthumously named after him (Bayes, 1763). Bayes only considered the case of uniform priors; it was Laplace who independently developed the general case. Bayesian probabilistic reasoning has been used in AI since the 1960s, especially in medical diagnosis. It was used not only to make a diagnosis from available evidence, but also to select further questions and tests by using the theory of information value (Section 15.6) when available evidence was inconclusive (Gorry, 1968; Gorry *et al.*, 1973). One system outperformed human experts in the diagnosis of acute abdominal illnesses (de Dombal *et al.*, 1974). Lucas *et al.* (2004) provide an overview.

These early Bayesian systems suffered from a number of problems. Because they lacked any theoretical model of the conditions they were diagnosing, they were vulnerable to unrepresentative data occurring in situations for which only a small sample was available (de Dombal *et al.*, 1981). Even more fundamentally, because they lacked a concise formalism (such as the one to be described in Chapter 13) for representing and using conditional independence information, they depended on the acquisition, storage, and processing of enormous tables of probabilistic data. Because of these difficulties, probabilistic methods for coping with uncertainty fell out of favor in AI from the 1970s to the mid-1980s. Developments since the late 1980s are described in the next chapter.

The naive Bayes model for joint distributions has been studied extensively in the pattern recognition literature since the 1950s (Duda and Hart, 1973). It has also been used, often unwittingly, in information retrieval, beginning with the work of Maron (1961). The probabilistic foundations of this technique, described further in Exercise 12.BAYS, were elucidated by Robertson and Sparck Jones (1976). Domingos and Pazzani (1997) provide an explanation for the surprising success of naive Bayesian reasoning even in domains where the independence assumptions are clearly violated.

There are many good introductory textbooks on probability theory, including those by Bertsekas and Tsitsiklis (2008), Ross (2015), and Grinstead and Snell (1997). DeGroot and Schervish (2001) offer a combined introduction to probability and statistics from a Bayesian

standpoint, and Walpole *et al.* (2016) offer an introduction for scientists and engineers. Jaynes (2003) gives a very persuasive exposition of the Bayesian approach. Billingsley (2012) and Venkatesh (2012) provide more mathematical treatments, including all the complications with continuous variables that we have left out. Hacking (1975) and Hald (1990) cover the early history of the concept of probability, and Bernstein (1996) gives a popular account.

# CHAPTER 13

## PROBABILISTIC REASONING

*In which we explain how to build efficient network models to reason under uncertainty according to the laws of probability theory, and how to distinguish between correlation and causality.*

Chapter 12 introduced the basic elements of probability theory and noted the importance of independence and conditional independence relationships in simplifying probabilistic representations of the world. This chapter introduces a systematic way to represent such relationships explicitly in the form of **Bayesian networks**. We define the syntax and semantics of these networks and show how they can be used to capture uncertain knowledge in a natural and efficient way. We then show how probabilistic inference, although computationally intractable in the worst case, can be done efficiently in many practical situations. We also describe a variety of approximate inference algorithms that are often applicable when exact inference is infeasible. Chapter 18 extends the basic ideas of Bayesian networks to more expressive formal languages for defining probability models.

### 13.1 Representing Knowledge in an Uncertain Domain

In Chapter 12, we saw that the full joint probability distribution can answer any question about the domain, but can become intractably large as the number of variables grows. Furthermore, specifying probabilities for possible worlds one by one is unnatural and tedious.

We also saw that independence and conditional independence relationships among variables can greatly reduce the number of probabilities that need to be specified in order to define the full joint distribution. This section introduces a data structure called a **Bayesian network**<sup>1</sup> to represent the dependencies among variables. Bayesian networks can represent essentially *any* full joint probability distribution and in many cases can do so very concisely.

A Bayesian network is a directed graph in which each node is annotated with quantitative probability information. The full specification is as follows:

1. Each node corresponds to a random variable, which may be discrete or continuous.
2. Directed links or arrows connect pairs of nodes. If there is an arrow from node  $X$  to node  $Y$ ,  $X$  is said to be a *parent* of  $Y$ . The graph has no directed cycles and hence is a directed acyclic graph, or DAG.
3. Each node  $X_i$  has associated probability information  $\theta(X_i | \text{Parents}(X_i))$  that quantifies the effect of the parents on the node using a finite number of **parameters**.

Bayesian network

Parameter

<sup>1</sup> Bayesian networks, often abbreviated to “Bayes net,” were called **belief networks** in the 1980s and 1990s. A **causal network** is a Bayes net with additional constraints on the meaning of the arrows (see Section 13.5). The term **graphical model** refers to a broader class that includes Bayesian networks.

**Figure 13.1** A simple Bayesian network in which *Weather* is independent of the other three variables and *Toothache* and *Catch* are conditionally independent, given *Cavity*.

The topology of the network—the set of nodes and links—specifies the conditional independence relationships that hold in the domain, in a way that will be made precise shortly. The *intuitive* meaning of an arrow is typically that  $X$  has a *direct influence* on  $Y$ , which suggests that causes should be parents of effects. It is usually easy for a domain expert to decide what direct influences exist in the domain—much easier, in fact, than actually specifying the probabilities themselves. Once the topology of the Bayes net is laid out, we need only specify the local probability information for each variable, in the form of a conditional distribution given its parents. The full joint distribution for all the variables is defined by the topology and the local probability information.

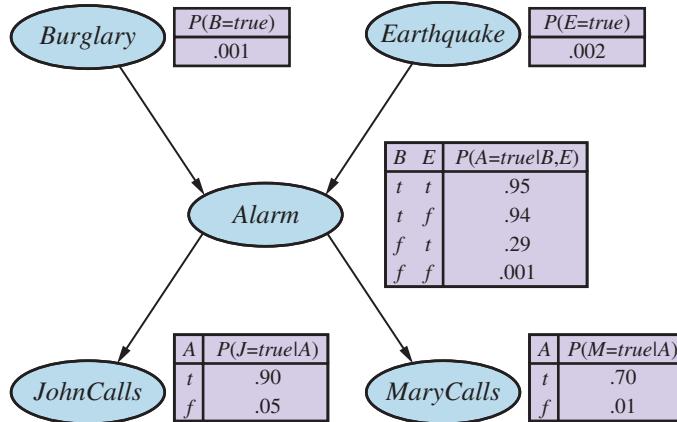

Recall the simple world described in Chapter 12, consisting of the variables *Toothache*, *Cavity*, *Catch*, and *Weather*. We argued that *Weather* is independent of the other variables; furthermore, we argued that *Toothache* and *Catch* are conditionally independent, given *Cavity*. These relationships are represented by the Bayes net structure shown in Figure 13.1. Formally, the conditional independence of *Toothache* and *Catch*, given *Cavity*, is indicated by the *absence* of a link between *Toothache* and *Catch*. Intuitively, the network represents the fact that *Cavity* is a direct cause of *Toothache* and *Catch*, whereas no direct causal relationship exists between *Toothache* and *Catch*.

Now consider the following example, which is just a little more complex. You have a new burglar alarm installed at home. It is fairly reliable at detecting a burglary, but is occasionally set off by minor earthquakes. (This example is due to Judea Pearl, a resident of earthquake-prone Los Angeles.) You also have two neighbors, John and Mary, who have promised to call you at work when they hear the alarm. John nearly always calls when he hears the alarm, but sometimes confuses the telephone ringing with the alarm and calls then, too. Mary, on the other hand, likes rather loud music and often misses the alarm altogether. Given the evidence of who has or has not called, we would like to estimate the probability of a burglary.

A Bayes net for this domain appears in Figure 13.2. The network structure shows that burglary and earthquakes directly affect the probability of the alarm’s going off, but whether John and Mary call depends only on the alarm. The network thus represents our assumptions that they do not perceive burglaries directly, they do not notice minor earthquakes, and they do not confer before calling.

The local probability information attached to each node in Figure 13.2 takes the form of a **conditional probability table (CPT)**. (CPTs can be used only for discrete variables; other representations, including those suitable for continuous variables, are described in Sec-

Conditional  
probability table  
(CPT)

**Figure 13.2** A typical Bayesian network, showing both the topology and the conditional probability tables (CPTs). In the CPTs, the letters *B*, *E*, *A*, *J*, and *M* stand for *Burglary*, *Earthquake*, *Alarm*, *JohnCalls*, and *MaryCalls*, respectively.

#### Conditioning case

tion 13.2.) Each row in a CPT contains the conditional probability of each node value for a **conditioning case**. A conditioning case is just a possible combination of values for the parent nodes—a miniature possible world, if you like. Each row must sum to 1, because the entries represent an exhaustive set of cases for the variable. For Boolean variables, once you know that the probability of a true value is  $p$ , the probability of false must be  $1 - p$ , so we often omit the second number, as in Figure 13.2. In general, a table for a Boolean variable with  $k$  Boolean parents contains  $2^k$  independently specifiable probabilities. A node with no parents has only one row, representing the prior probabilities of each possible value of the variable.

Notice that the network does not have nodes corresponding to Mary’s currently listening to loud music or to the telephone ringing and confusing John. These factors are summarized in the uncertainty associated with the links from *Alarm* to *JohnCalls* and *MaryCalls*. This shows both laziness and ignorance in operation, as explained on page 404: it would be a lot of work to find out why those factors would be more or less likely in any particular case, and we have no reasonable way to obtain the relevant information anyway.

The probabilities actually summarize a *potentially infinite* set of circumstances in which the alarm might fail to go off (high humidity, power failure, dead battery, cut wires, a dead mouse stuck inside the bell, etc.) or John or Mary might fail to call and report it (out to lunch, on vacation, temporarily deaf, passing helicopter, etc.). In this way, a small agent can cope with a very large world, at least approximately.

## 13.2 The Semantics of Bayesian Networks

The *syntax* of a Bayes net consists of a directed acyclic graph with some local probability information attached to each node. The *semantics* defines how the syntax corresponds to a joint distribution over the variables of the network.

Assume that the Bayes net contains  $n$  variables,  $X_1, \dots, X_n$ . A generic entry in the joint distribution is then  $P(X_1=x_1 \wedge \dots \wedge X_n=x_n)$ , or  $P(x_1, \dots, x_n)$  for short. The semantics of

Bayes nets defines each entry in the joint distribution as follows:

$$P(x_1, \dots, x_n) = \prod_{i=1}^n \theta(x_i | \text{parents}(X_i)), \quad (13.1)$$

where  $\text{parents}(X_i)$  denotes the values of  $\text{Parents}(X_i)$  that appear in  $x_1, \dots, x_n$ . Thus, each entry in the joint distribution is represented by the product of the appropriate elements of the local conditional distributions in the Bayes net.

To illustrate this, we can calculate the probability that the alarm has sounded, but neither a burglary nor an earthquake has occurred, and both John and Mary call. We simply multiply the relevant entries from the local conditional distributions (abbreviating the variable names):

$$\begin{aligned} P(j, m, a, \neg b, \neg e) &= P(j|a)P(m|a)P(a|\neg b \wedge \neg e)P(\neg b)P(\neg e) \\ &= 0.90 \times 0.70 \times 0.001 \times 0.999 \times 0.998 = 0.000628. \end{aligned}$$

Section 12.3 explained that the full joint distribution can be used to answer any query about the domain. If a Bayes net is a representation of the joint distribution, then it too can be used to answer any query, by summing all the relevant joint probability values, each calculated by multiplying probabilities from the local conditional distributions. Section 13.3 explains this in more detail, but also describes methods that are much more efficient.

So far, we have glossed over one important point: what is the meaning of the numbers that go into the local conditional distributions  $\theta(x_i | \text{parents}(X_i))$ ? It turns out that from Equation (13.1) we can prove that the parameters  $\theta(x_i | \text{parents}(X_i))$  are exactly the conditional probabilities  $P(x_i | \text{parents}(X_i))$  implied by the joint distribution. Remember that the conditional probabilities can be computed from the joint distribution as follows:

$$\begin{aligned} P(x_i | \text{parents}(X_i)) &\equiv \frac{P(x_i, \text{parents}(X_i))}{P(\text{parents}(X_i))} \\ &= \frac{\sum_{\mathbf{y}} P(x_i, \text{parents}(X_i), \mathbf{y})}{\sum_{x'_i, \mathbf{y}} P(x'_i, \text{parents}(X_i), \mathbf{y})} \end{aligned}$$

where  $\mathbf{y}$  represents the values of all variables other than  $X_i$  and its parents. From this last line one can prove that  $P(x_i | \text{parents}(X_i)) = \theta(x_i | \text{parents}(X_i))$  (Exercise [13.CPTE](#)). Hence, we can rewrite Equation (13.1) as

$$P(x_1, \dots, x_n) = \prod_{i=1}^n P(x_i | \text{parents}(X_i)). \quad (13.2)$$

This means that when one estimates values for the local conditional distributions, they need to be the actual conditional probabilities for the variable given its parents. So, for example, when we specify  $\theta(\text{JohnCalls}=\text{true} | \text{Alarm}=\text{true})=0.90$ , it should be the case that about 90% of the time when the alarm sounds, John calls. The fact that each parameter of the network has a precise meaning in terms of only a small set of variables is crucially important for robustness and ease of specification of the models.

### A method for constructing Bayesian networks

Equation (13.2) defines what a given Bayes net means. The next step is to explain how to *construct* a Bayesian network in such a way that the resulting joint distribution is a good representation of a given domain. We will now show that Equation (13.2) implies certain conditional independence relationships that can be used to guide the knowledge engineer in

constructing the topology of the network. First, we rewrite the entries in the joint distribution in terms of conditional probability, using the product rule (see page 408):

$$P(x_1, \dots, x_n) = P(x_n | x_{n-1}, \dots, x_1)P(x_{n-1}, \dots, x_1).$$

Then we repeat the process, reducing each joint probability to a conditional probability and a joint probability on a smaller set of variables. We end up with one big product:

$$\begin{aligned} P(x_1, \dots, x_n) &= P(x_n | x_{n-1}, \dots, x_1)P(x_{n-1} | x_{n-2}, \dots, x_1) \cdots P(x_2 | x_1)P(x_1) \\ &= \prod_{i=1}^n P(x_i | x_{i-1}, \dots, x_1). \end{aligned}$$

[Chain rule](#)

This identity is called the **chain rule**. It holds for any set of random variables. Comparing it with Equation (13.2), we see that the specification of the joint distribution is equivalent to the general assertion that, for every variable  $X_i$  in the network,

$$\mathbf{P}(X_i | X_{i-1}, \dots, X_1) = \mathbf{P}(X_i | \text{Parents}(X_i)), \quad (13.3)$$

[Topological ordering](#)

provided that  $\text{Parents}(X_i) \subseteq \{X_{i-1}, \dots, X_1\}$ . This last condition is satisfied by numbering the nodes in **topological order**—that is, in any order consistent with the directed graph structure. For example, the nodes in Figure 13.2 could be ordered  $B, E, A, J, M; E, B, A, M, J$ ; and so on.

What Equation (13.3) says is that the Bayesian network is a correct representation of the domain only if each node is conditionally independent of its other predecessors in the node ordering, given its parents. We can satisfy this condition with this methodology:

1. *Nodes*: First determine the set of variables that are required to model the domain. Now order them,  $\{X_1, \dots, X_n\}$ . Any order will work, but the resulting network will be more compact if the variables are ordered such that causes precede effects.
2. *Links*: For  $i = 1$  to  $n$  do:
  - Choose a minimal set of parents for  $X_i$  from  $X_1, \dots, X_{i-1}$ , such that Equation (13.3) is satisfied.
  - For each parent insert a link from the parent to  $X_i$ .
  - CPTs: Write down the conditional probability table,  $\mathbf{P}(X_i | \text{Parents}(X_i))$ .

► Intuitively, the parents of node  $X_i$  should contain all those nodes in  $X_1, \dots, X_{i-1}$  that *directly influence*  $X_i$ . For example, suppose we have completed the network in Figure 13.2 except for the choice of parents for *MaryCalls*. *MaryCalls* is certainly influenced by whether there is a *Burglary* or an *Earthquake*, but not *directly influenced*. Intuitively, our knowledge of the domain tells us that these events influence Mary's calling behavior only through their effect on the alarm. Also, given the state of the alarm, whether John calls has no influence on Mary's calling. Formally speaking, we believe that the following conditional independence statement holds:

$$\mathbf{P}(\text{MaryCalls} | \text{JohnCalls}, \text{Alarm}, \text{Earthquake}, \text{Burglary}) = \mathbf{P}(\text{MaryCalls} | \text{Alarm}).$$

Thus, *Alarm* will be the only parent node for *MaryCalls*.

Because each node is connected only to earlier nodes, this construction method guarantees that the network is acyclic. Another important property of Bayes nets is that they contain no redundant probability values. If there is no redundancy, then there is no chance for inconsistency: *it is impossible for the knowledge engineer or domain expert to create a Bayesian network that violates the axioms of probability*.

### Compactness and node ordering

As well as being a complete and nonredundant representation of the domain, a Bayes net can often be far more *compact* than the full joint distribution. This property is what makes it feasible to handle domains with many variables. The compactness of Bayesian networks is an example of a general property of **locally structured** (also called **sparse**) systems. In a locally structured system, each subcomponent interacts directly with only a bounded number of other components, regardless of the total number of components. Local structure is usually associated with linear rather than exponential growth in complexity.

Locally structured  
Sparse

In the case of Bayes nets, it is reasonable to suppose that in most domains each random variable is directly influenced by at most  $k$  others, for some constant  $k$ . If we assume  $n$  Boolean variables for simplicity, then the amount of information needed to specify each conditional probability table will be at most  $2^k$  numbers, and the complete network can be specified by  $2^k \cdot n$  numbers. In contrast, the joint distribution contains  $2^n$  numbers. To make this concrete, suppose we have  $n=30$  nodes, each with five parents ( $k=5$ ). Then the Bayesian network requires 960 numbers, but the full joint distribution requires over a billion.

Specifying the conditional probability tables for a fully connected network, in which each variable has all of its predecessors as parents, requires the same amount of information as specifying the joint distribution in tabular form. For this reason, we often leave out links even though a slight dependency exists, because the slight gain in accuracy is not worth the additional complexity in the network. For example, one might object to our burglary network on the grounds that if there is a large earthquake, then John and Mary would not call even if they heard the alarm, because they assume that the earthquake is the cause. Whether to add the link from *Earthquake* to *JohnCalls* and *MaryCalls* (and thus enlarge the tables) depends on the importance of getting more accurate probabilities compared with the cost of specifying the extra information.

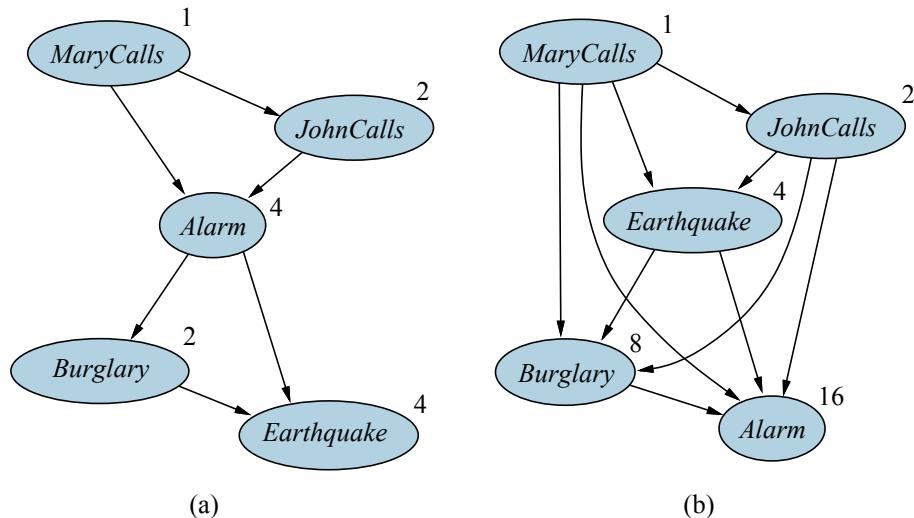

Even in a locally structured domain, we will get a compact Bayes net only if we choose the node ordering well. What happens if we happen to choose the wrong order? Consider the burglary example again. Suppose we decide to add the nodes in the order *MaryCalls*, *JohnCalls*, *Alarm*, *Burglary*, *Earthquake*. We then get the somewhat more complicated network shown in Figure 13.3(a). The process goes as follows:

- Adding *MaryCalls*: No parents.
- Adding *JohnCalls*: If Mary calls, that probably means the alarm has gone off, which makes it more likely that John calls. Therefore, *JohnCalls* needs *MaryCalls* as a parent.
- Adding *Alarm*: Clearly, if both call, it is more likely that the alarm has gone off than if just one or neither calls, so we need both *MaryCalls* and *JohnCalls* as parents.
- Adding *Burglary*: If we know the alarm state, then the call from John or Mary might give us information about our phone ringing or Mary's music, but not about burglary:

$$\mathbf{P}(\text{Burglary} | \text{Alarm}, \text{JohnCalls}, \text{MaryCalls}) = \mathbf{P}(\text{Burglary} | \text{Alarm}).$$

Hence we need just *Alarm* as parent.

- Adding *Earthquake*: If the alarm is on, it is more likely that there has been an earthquake. (The alarm is an earthquake detector of sorts.) But if we know that there has been a burglary, then that explains the alarm, and the probability of an earthquake would be only slightly above normal. Hence, we need both *Alarm* and *Burglary* as parents.

**Figure 13.3** Network structure and number of parameters depends on order of introduction. (a) The structure obtained with ordering  $M, J, A, B, E$ . (b) The structure obtained with  $M, J, E, B, A$ . Each node is annotated with the number of parameters required; 13 in all for (a) and 31 for (b). In Figure 13.2, only 10 parameters were required.

The resulting network has two more links than the original network in Figure 13.2 and requires 13 conditional probabilities rather than 10. What's worse, some of the links represent tenuous relationships that require difficult and unnatural probability judgments, such as assessing the probability of *Earthquake*, given *Burglary* and *Alarm*. This phenomenon is quite general and is related to the distinction between **causal** and **diagnostic** models introduced in Section 12.5.1 (see also Exercise 13.WUMD). *If we stick to a causal model, we end up having to specify fewer numbers, and the numbers will often be easier to come up with.* For example, in the domain of medicine, it has been shown by Tversky and Kahneman (1982) that expert physicians prefer to give probability judgments for causal rules rather than for diagnostic ones. Section 13.5 explores the idea of causal models in more depth.

Figure 13.3(b) shows a very bad node ordering: *MaryCalls*, *JohnCalls*, *Earthquake*, *Burglary*, *Alarm*. This network requires 31 distinct probabilities to be specified—exactly the same number as the full joint distribution. It is important to realize, however, that any of the three networks can represent *exactly the same joint distribution*. The two versions in Figure 13.3 simply fail to represent all the conditional independence relationships and hence end up specifying a lot of unnecessary numbers instead.

### 13.2.1 Conditional independence relations in Bayesian networks

From the semantics of Bayes nets as defined in Equation (13.2), we can derive a number of conditional independence properties. We have already seen the property that a variable is conditionally independent of its other predecessors, given its parents. It is also possible to prove the more general “non-descendants” property that:

*Each variable is conditionally independent of its non-descendants, given its parents.*

**Figure 13.4** (a) A node  $X$  is conditionally independent of its non-descendants (e.g., the  $Z_{ij}$ s) given its parents (the  $U_i$ s shown in the lavender area). (b) A node  $X$  is conditionally independent of all other nodes in the network given its Markov blanket (the lavender area).

For example, in Figure 13.2, the variable *JohnCalls* is independent of *Burglary*, *Earthquake*, and *MaryCalls* given the value of *Alarm*. The definition is illustrated in Figure 13.4(a).

It turns out that the non-descendants property combined with interpretation of the network parameters  $\theta(X_i | Parents(X_i))$  as conditional probabilities  $\mathbf{P}(X_i | Parents(X_i))$  suffices to reconstruct the full joint distribution given in Equation (13.2). In other words, one can view the semantics of Bayes nets in a different way: instead of defining the full joint distribution as the product of conditional distributions, the network defines a set of conditional independence properties. The full joint distribution can be derived from those properties.

Another important independence property is implied by the non-descendants property:

a variable is conditionally independent of all other nodes in the network, given its parents, children, and children’s parents—that is, given its **Markov blanket**.

Markov blanket

(Exercise 13.MARB asks you to prove this.) For example, the variable *Burglary* is independent of *JohnCalls* and *MaryCalls*, given *Alarm* and *Earthquake*. This property is illustrated in Figure 13.4(b). The Markov blanket property makes possible inference algorithms that use completely local and distributed stochastic sampling processes, as explained in Section 13.4.2.

The most general conditional independence question one might ask in a Bayes net is whether a set of nodes  $\mathbf{X}$  is conditionally independent of another set  $\mathbf{Y}$ , given a third set  $\mathbf{Z}$ . This can be determined efficiently by examining the Bayes net to see whether  $\mathbf{Z}$  **d-separates**  $\mathbf{X}$  and  $\mathbf{Y}$ . The process works as follows:

1. Consider just the **ancestral subgraph** consisting of  $\mathbf{X}$ ,  $\mathbf{Y}$ ,  $\mathbf{Z}$ , and their ancestors. Ancestral subgraph
2. Add links between any unlinked pair of nodes that share a common child; now we have the so-called **moral graph**. Moral graph
3. Replace all directed links by undirected links.
4. If  $\mathbf{Z}$  blocks all paths between  $\mathbf{X}$  and  $\mathbf{Y}$  in the resulting graph, then  $\mathbf{Z}$  d-separates  $\mathbf{X}$  and  $\mathbf{Y}$ . In that case,  $\mathbf{X}$  is conditionally independent of  $\mathbf{Y}$ , given  $\mathbf{Z}$ . Otherwise, the original Bayes net does not require conditional independence.

In brief, then, d-separation means separation in the undirected, moralized, ancestral subgraph. Applying the definition to the burglary network in Figure 13.2, we can deduce that *Burglary* and *Earthquake* are independent given the empty set (i.e., they are absolutely independent); that they are *not* necessarily conditionally independent given *Alarm*; and that *JohnCalls* and *MaryCalls* are conditionally independent given *Alarm*. Notice also that the Markov blanket property follows directly from the d-separation property, since a variable's Markov blanket d-separates it from all other variables.

### 13.2.2 Efficient Representation of Conditional Distributions

Even if the maximum number of parents  $k$  is smallish, filling in the CPT for a node requires up to  $O(2^k)$  numbers and perhaps a great deal of experience with all the possible conditioning cases. In fact, this is a worst-case scenario in which the relationship between the parents and the child is completely arbitrary. Usually, such relationships are describable by a **canonical distribution** that fits some standard pattern. In such cases, the complete table can be specified just by naming the pattern and perhaps supplying a few parameters.

Canonical distribution

Deterministic nodes

Context-specific independence

The simplest example is provided by **deterministic nodes**. A deterministic node has its value specified exactly by the values of its parents, with no uncertainty. The relationship can be a logical one: for example, the relationship between the parent nodes *Canadian*, *US*, *Mexican* and the child node *NorthAmerican* is simply that the child is the disjunction of the parents. The relationship can also be numerical: for example, the *BestPrice* for a car is the minimum of the prices at each dealer in the area; and the *WaterStored* in a reservoir at year's end is the sum of the original amount, plus the inflows (rivers, runoff, precipitation) and minus the outflows (releases, evaporation, seepage).

Many Bayes net systems allow the user to specify deterministic functions using a general-purpose programming language; this makes it possible to include complex elements such as global climate models or power-grid simulators within a probabilistic model.

Another important pattern that occurs often in practice is **context-specific independence** or CSI. A conditional distribution exhibits CSI if a variable is conditionally independent of some of its parents given *certain values* of others. For example, let's suppose that the *Damage* to your car occurring during a given period of time depends on the *Ruggedness* of your car and whether or not an *Accident* occurred in that period. Clearly, if *Accident* is false, then the *Damage*, if any, doesn't depend on the *Ruggedness* of your car. (There might be vandalism damage to the car's paintwork or windows, but we'll assume all cars are equally subject to such damage.) We say that *Damage* is context-specifically independent of *Ruggedness* given *Accident=false*. Bayes net systems often implement CSI using an if-then-else syntax for specifying conditional distributions; for example, one might write

$$\begin{aligned} \mathbf{P}(\text{Damage} | \text{Ruggedness}, \text{Accident}) = \\ \mathbf{if} (\text{Accident}=\text{false}) \mathbf{then} d_1 \mathbf{else} d_2(\text{Ruggedness}) \end{aligned}$$

where  $d_1$  and  $d_2$  represent arbitrary distributions. As with determinism, the presence of CSI in a network may facilitate efficient inference. All of the exact inference algorithms mentioned in Section 13.3 can be modified to take advantage of CSI to speed up computation.

Noisy-OR

Uncertain relationships can often be characterized by so-called **noisy** logical relationships. The standard example is the **noisy-OR** relation, which is a generalization of the logical OR. In propositional logic, we might say that *Fever* is true if and only if *Cold*, *Flu*, or *Malaria*

<i>Cold</i>	<i>Flu</i>	<i>Malaria</i>	$P(\text{fever}   \cdot)$	$P(\neg\text{fever}   \cdot)$
<i>f</i>	<i>f</i>	<i>f</i>	0.0	1.0
<i>f</i>	<i>f</i>	<i>t</i>	0.9	<b>0.1</b>
<i>f</i>	<i>t</i>	<i>f</i>	0.8	<b>0.2</b>
<i>f</i>	<i>t</i>	<i>t</i>	0.98	$0.02 = 0.2 \times 0.1$
<i>t</i>	<i>f</i>	<i>f</i>	0.4	<b>0.6</b>
<i>t</i>	<i>f</i>	<i>t</i>	0.94	$0.06 = 0.6 \times 0.1$
<i>t</i>	<i>t</i>	<i>f</i>	0.88	$0.12 = 0.6 \times 0.2$
<i>t</i>	<i>t</i>	<i>t</i>	0.988	$0.012 = 0.6 \times 0.2 \times 0.1$

**Figure 13.5** A complete conditional probability table for  $\mathbf{P}(\text{Fever} | \text{Cold}, \text{Flu}, \text{Malaria})$ , assuming a noisy-OR model with the three  $q$ -values shown in bold.

are true. The noisy-OR model allows for uncertainty about the ability of each parent to cause the child to be true—the causal relationship between parent and child may be *inhibited*, and so a patient could have a cold, but not exhibit a fever.

The model makes two assumptions. First, it assumes that all the possible causes are listed. (If some are missing, we can always add a so-called **leak node** that covers “miscellaneous causes.”) Second, it assumes that inhibition of each parent is independent of inhibition of any other parents: for example, whatever inhibits *Malaria* from causing a fever is independent of whatever inhibits *Flu* from causing a fever. Given these assumptions, *Fever* is *false* if and only if all its *true* parents are inhibited, and the probability of this is the product of the inhibition probabilities  $q_j$  for each parent. Let us suppose these individual inhibition probabilities are as follows:

$$\begin{aligned} q_{\text{cold}} &= P(\neg\text{fever} | \neg\text{cold}, \neg\text{flu}, \neg\text{malaria}) = 0.6, \\ q_{\text{flu}} &= P(\neg\text{fever} | \neg\text{cold}, \text{flu}, \neg\text{malaria}) = 0.2, \\ q_{\text{malaria}} &= P(\neg\text{fever} | \neg\text{cold}, \neg\text{flu}, \text{malaria}) = 0.1. \end{aligned}$$

Leak node

Then, from this information and the noisy-OR assumptions, the entire CPT can be built. The general rule is that

$$P(x_i | \text{parents}(X_i)) = 1 - \prod_{\{j: X_j = \text{true}\}} q_j,$$

where the product is taken over the parents that are set to true for that row of the CPT. Figure 13.5 illustrates this calculation.

In general, noisy logical relationships in which a variable depends on  $k$  parents can be described using  $O(k)$  parameters instead of  $O(2^k)$  for the full conditional probability table. This makes assessment and learning much easier. For example, the CPCS network (Pradhan *et al.*, 1994) uses noisy-OR and noisy-MAX distributions to model relationships among diseases and symptoms in internal medicine. With 448 nodes and 906 links, it requires only 8,254 parameters instead of 133,931,430 for a network with full CPTs.

Discretization

Nonparametric

Hybrid Bayesian network

Linear-Gaussian

### 13.2.3 Bayesian nets with continuous variables

Many real-world problems involve continuous quantities, such as height, mass, temperature, and money. By definition, continuous variables have an infinite number of possible values, so it is impossible to specify conditional probabilities explicitly for each value. One way to handle continuous variables is with **discretization**—that is, dividing up the possible values into a fixed set of intervals. For example, temperatures could be divided into three categories: ( $<0^{\circ}\text{C}$ ), ( $0^{\circ}\text{C} - 100^{\circ}\text{C}$ ), and ( $>100^{\circ}\text{C}$ ). In choosing the number of categories, there is a tradeoff between loss of accuracy and large CPTs which can lead to slow run times.

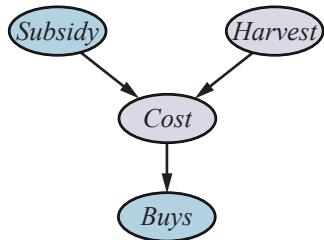

Another approach is to define a continuous variable using one of the standard families of probability density functions (see Appendix A). For example, a Gaussian (or normal) distribution  $\mathcal{N}(x; \mu, \sigma^2)$  is specified by just two parameters, the mean  $\mu$  and the variance  $\sigma^2$ . Yet another solution—sometimes called a **nonparametric** representation—is to define the conditional distribution implicitly with a collection of instances, each containing specific values of the parent and child variables. We explore this approach further in Chapter 19.

A network with both discrete and continuous variables is called a **hybrid Bayesian network**. To specify a hybrid network, we have to specify two new kinds of distributions: the conditional distribution for a continuous variable given discrete or continuous parents; and the conditional distribution for a discrete variable given continuous parents. Consider the simple example in Figure 13.6, in which a customer buys some fruit depending on its cost, which depends in turn on the size of the harvest and whether the government’s subsidy scheme is operating. The variable *Cost* is continuous and has continuous and discrete parents; the variable *Buys* is discrete and has a continuous parent.

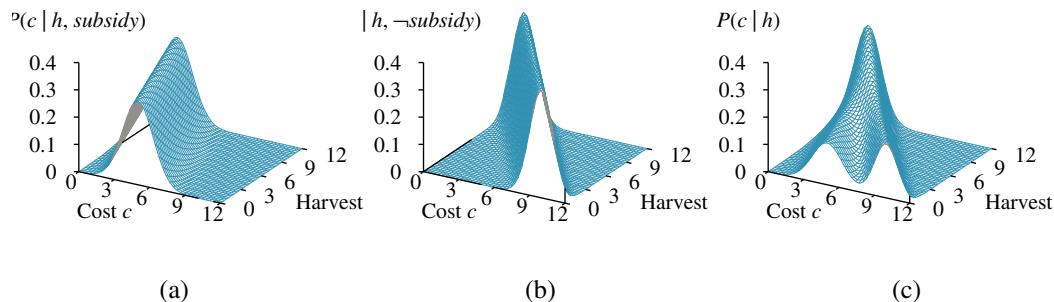

For the *Cost* variable, we need to specify  $\mathbf{P}(\text{Cost} | \text{Harvest}, \text{Subsidy})$ . The discrete parent is handled by enumeration—that is, by specifying both  $\mathbf{P}(\text{Cost} | \text{Harvest}, \text{subsidy})$  and  $\mathbf{P}(\text{Cost} | \text{Harvest}, \neg\text{subsidy})$ . To handle *Harvest*, we specify how the distribution over the cost  $c$  depends on the continuous value  $h$  of *Harvest*. In other words, we specify the *parameters* of the cost distribution as a function of  $h$ . The most common choice is the **linear-Gaussian** conditional distribution, in which the child has a Gaussian distribution whose mean  $\mu$  varies linearly with the value of the parent and whose standard deviation  $\sigma$  is fixed. We need two distributions, one for *subsidy* and one for  $\neg\text{subsidy}$ , with different parameters:

$$\begin{aligned} P(c|h, \text{subsidy}) &= \mathcal{N}(c; a_t h + b_t, \sigma_t^2) = \frac{1}{\sigma_t \sqrt{2\pi}} e^{-\frac{1}{2} \left( \frac{c - (a_t h + b_t)}{\sigma_t} \right)^2} \\ P(c|h, \neg\text{subsidy}) &= \mathcal{N}(c; a_f h + b_f, \sigma_f^2) = \frac{1}{\sigma_f \sqrt{2\pi}} e^{-\frac{1}{2} \left( \frac{c - (a_f h + b_f)}{\sigma_f} \right)^2}. \end{aligned}$$

For this example, then, the conditional distribution for *Cost* is specified by naming the linear-Gaussian distribution and providing the parameters  $a_t$ ,  $b_t$ ,  $\sigma_t$ ,  $a_f$ ,  $b_f$ , and  $\sigma_f$ . Figures 13.7(a) and (b) show these two relationships. Notice that in each case the slope of  $c$  versus  $h$  is negative, because cost decreases as the harvest size increases. (Of course, the assumption of linearity implies that the cost becomes negative at some point; the linear model is reasonable only if the harvest size is limited to a narrow range.) Figure 13.7(c) shows the distribution  $P(c|h)$ , averaging over the two possible values of *Subsidy* and assuming that each has prior probability 0.5. This shows that even with very simple models, quite interesting distributions can be represented.

**Figure 13.6** A simple network with discrete variables (*Subsidy* and *Buys*) and continuous variables (*Harvest* and *Cost*).

**Figure 13.7** The graphs in (a) and (b) show the probability distribution over *Cost* as a function of *Harvest* size, with *Subsidy* true and false, respectively. Graph (c) shows the distribution  $P(Cost|Harvest)$ , obtained by summing over the two subsidy cases.

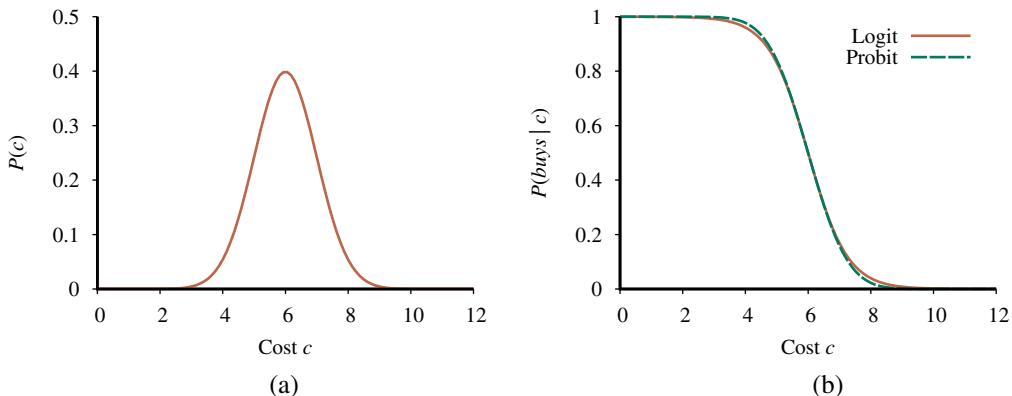

The linear–Gaussian conditional distribution has some special properties. A network containing only continuous variables with linear–Gaussian distributions has a joint distribution that is a multivariate Gaussian distribution (see Appendix A) over all the variables (Exercise 13.LGEX). Furthermore, the posterior distribution given any evidence also has this property.<sup>2</sup> When discrete variables are added as parents (not as children) of continuous variables, the network defines a **conditional Gaussian**, or CG, distribution: given any assignment to the discrete variables, the distribution over the continuous variables is a multivariate Gaussian.

Now we turn to the distributions for discrete variables with continuous parents. Consider, for example, the *Buys* node in Figure 13.6. It seems reasonable to assume that the customer will buy if the cost is low and will not buy if it is high and that the probability of buying varies smoothly in some intermediate region. In other words, the conditional distribution is like a “soft” threshold function. One way to make soft thresholds is to use the *integral* of the standard normal distribution:

$$\Phi(x) = \int_{-\infty}^x \mathcal{N}(s; 0, 1) ds.$$

Conditional Gaussian

<sup>2</sup> It follows that inference in linear–Gaussian networks takes only  $O(n^3)$  time in the worst case, regardless of the network topology. In Section 13.3, we see that inference for networks of discrete variables is NP-hard.

**Figure 13.8** (a) A normal (Gaussian) distribution for the cost threshold, centered on  $\mu = 6.0$  with standard deviation  $\sigma = 1.0$ . (b) Expit and probit models for the probability of *buys* given *cost*, for the parameters  $\mu = 6.0$  and  $\sigma = 1.0$ .

Probit

Expit

Inverse logit

Logistic function

$\Phi(x)$  is an increasing function of  $x$ , whereas the probability of buying decreases with cost, so here we flip the function around:

$$P(\text{buys} | \text{Cost} = c) = 1 - \Phi((c - \mu)/\sigma),$$

which means that the cost threshold occurs around  $\mu$ , the width of the threshold region is proportional to  $\sigma$ , and the probability of buying decreases as cost increases. This **probit** model (pronounced “pro-bit” and short for “probability unit”) is illustrated in Figure 13.8(a). The form can be justified by proposing that the underlying decision process has a hard threshold, but that the precise location of the threshold is subject to random Gaussian noise.

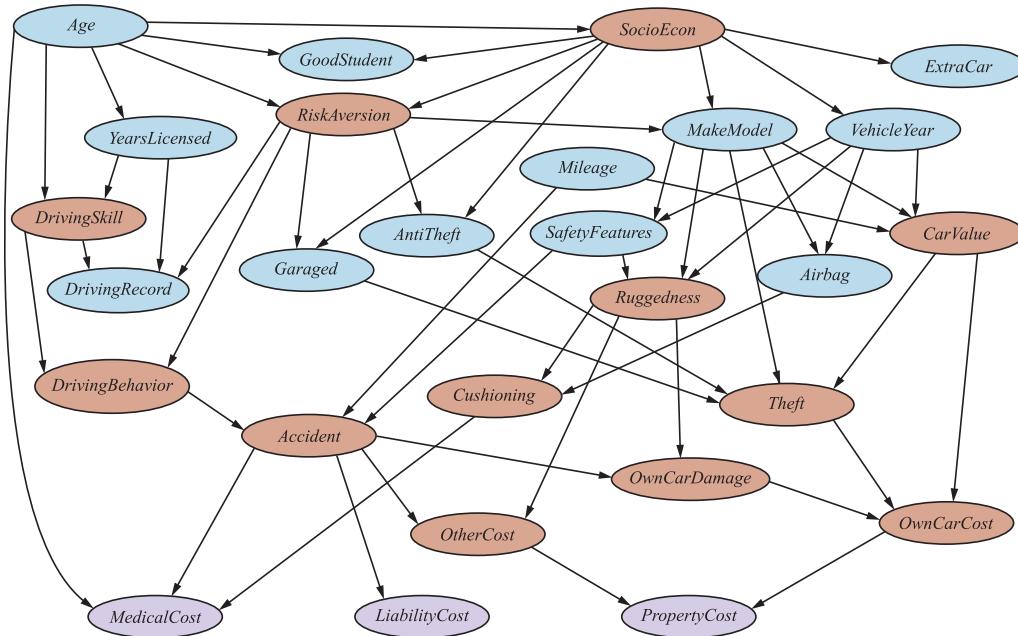

An alternative to the probit model is the **expit** or **inverse logit** model. It uses the **logistic function**  $1/(1 + e^{-x})$  to produce a soft threshold—it maps any  $x$  to a value between 0 and 1. Again, for our example, we flip it around to make a decreasing function; we also scale the exponent by  $4/\sqrt{2\pi}$  to match the probit’s slope at the mean:

$$P(\text{buys} | \text{Cost} = c) = 1 - \frac{1}{1 + \exp(-\frac{4}{\sqrt{2\pi}} \cdot \frac{c-\mu}{\sigma})}.$$

This is illustrated in Figure 13.8(b). The two distributions look similar, but the logit actually has much longer “tails.” The probit is often a better fit to real situations, but the logistic function is sometimes easier to deal with mathematically. It is used widely in machine learning. Both models can be generalized to handle multiple continuous parents by taking a linear combination of the parent values. This also works for discrete parents if their values are integers; for example, with  $k$  Boolean parents, each viewed as having values 0 or 1, the input to the expit or probit distribution would be a weighted linear combination with  $k$  parameters, yielding a model quite similar to the noisy-OR model discussed earlier.

### 13.2.4 Case study: Car insurance

A car insurance company receives an application from an individual to insure a specific vehicle and must decide on the appropriate annual premium to charge, based on the anticipated claims it will pay out for this applicant. The task is to build a Bayes net that captures the

**Figure 13.9** A Bayesian network for evaluating car insurance applications.

causal structure of the domain and gives an accurate, well-calibrated distribution over the output variables given the evidence available from the application form.<sup>3</sup> The Bayes net will include **hidden variables** that are neither input nor output variables, but are essential for structuring the network so that it is reasonably sparse with a manageable number of parameters. The hidden variables are shaded brown in Figure 13.9.

The claims to be paid out—shaded lavender in Figure 13.9—are of three kinds: the *MedicalCost* for any injuries sustained by the applicant; the *LiabilityCost* for lawsuits filed by other parties against the applicant and the company; and the *PropertyCost* for vehicle damage to either party and vehicle loss by theft. The application form asks for the following input information (the light blue nodes in Figure 13.9):

- About the applicant: *Age*; *YearsLicensed*—how long since a driving license was first obtained; *DrivingRecord*—some summary, perhaps based on “points,” of recent accidents and traffic violations; and (for students) a *GoodStudent* indicator for a grade-point average of 3.0 (B) on a 4-point scale.
- About the vehicle: the *MakeModel* and *VehicleYear*; whether it has an *Airbag*; and some summary of *SafetyFeatures* such as anti-lock braking and collision warning.
- About the driving situation: the annual *Mileage* driven and how securely the vehicle is *Garaged*, if at all.

Hidden variable

<sup>3</sup> The network shown in Figure 13.9 is not in actual use, but its structure has been vetted with insurance experts. In practice, the information requested on application forms varies by company and jurisdiction—for example, some ask for *Gender*—and the model could certainly be made more detailed and sophisticated.

Now we need to think about how to arrange these into a causal structure. The key hidden variables are whether or not a *Theft* or *Accident* will occur in the next time period. Obviously, one cannot ask the applicant to predict these; they have to be inferred from the available information and the insurer's previous experience.

What are the causal factors leading to *Theft*? The *MakeModel* is certainly important—some models are stolen much more often than others because there is an efficient resale market for vehicles and parts; the *CarValue* also matters, because an old, beat-up, or high-mileage vehicle has lower resale value. Moreover, a vehicle that is *Garaged* and has an *AntiTheft* device is harder to steal. The hidden variable *CarValue* depends in turn on the *MakeModel*, *VehicleYear*, and *Mileage*. *CarValue* also dictates the loss amount when a *Theft* occurs, so that is one of the contributors to *OwnCarCost* (the other being accidents, which we will get to shortly).

It is common in models of this type to introduce another hidden variable, *SocioEcon*, the socioeconomic category of the applicant. This is thought to influence a wide range of behaviors and characteristics. In our model, there is no *direct* evidence in the form of observed income and occupation variables;<sup>4</sup> but *SocioEcon* influences *MakeModel* and *VehicleYear*; it also affects *ExtraCar* and *GoodStudent*, and depends somewhat on *Age*.

For any insurance company, perhaps the most important hidden variable is *RiskAversion*: people who are risk-averse are good insurance risks! *Age* and *SocioEcon* affect *RiskAversion*, and its “symptoms” include the applicant’s choice of whether the vehicle is *Garaged* and has *AntiTheft* devices and *SafetyFeatures*.

In predicting future accidents, the key is the applicant’s future *DrivingBehavior*, which is influenced by both *RiskAversion* and *DrivingSkill*; the latter in turn depends on *Age* and *YearsLicensed*. The applicant’s past driving behavior is reflected in the *DrivingRecord*, which also depends on *RiskAversion* and *DrivingSkill* as well as on *YearsLicensed* (because someone who started driving only recently may not have had time to accumulate a litany of accidents and violations). In this way, *DrivingRecord* provides evidence about *RiskAversion* and *DrivingSkill*, which in turn help to predict future *DrivingBehavior*.

We can think of *DrivingBehavior* as a per-mile tendency to drive in an accident-prone way; whether an *Accident* actually occurs in a fixed time period depends also on the annual *Mileage* and on the *SafetyFeatures* of the vehicle. If an *Accident* occurs, there are three kinds of costs: the *MedicalCost* for the applicant depends on *Age* and *Cushioning*, which depends in turn on the *Ruggedness* of the car and whether it has an *Airbag*; the *LiabilityCost* (medical, pain and suffering, loss of income, etc.) for the other driver; and the *PropertyCost* for the applicant and the other driver, both of which depend (in different ways) on the car’s *Ruggedness* and on the applicant’s *CarValue*.

We have illustrated the kind of reasoning that goes into developing the topology and hidden variables in a Bayes net. We also need to specify the ranges and the conditional distributions for each variable. For the ranges, the primary decision is often whether to make the variable discrete or continuous. For example, the *Ruggedness* of the vehicle could be a continuous variable between 0 and 1, or a discrete variable with range *{TinCan, Normal, Tank}*.

---

<sup>4</sup> Some insurance companies also acquire the applicant’s credit history to help in assessing risk; this provides considerably more information about socioeconomic category. Whenever using hidden variables of this kind, one must be careful that they do not inadvertently become proxies for variables such as race that may not be used in insurance decisions. Techniques for avoiding biases of this kind are described in Chapter 19.

Continuous variables provide more precision, but they make exact inference impossible except in a few special cases. A discrete variable with many possible values can make it tedious to fill in the correspondingly large conditional probability tables and makes exact inference more expensive unless the variable's value is always observed. For example, *MakeModel* in a real system would have thousands of possible values, and this causes its child *CarValue* to have an enormous CPT that would have to be filled in from industry databases; but, because the *MakeModel* is always observed, this does not contribute to inference complexity: in fact, the observed values for the three parents pick out exactly one relevant row of the CPT for *CarValue*.

The conditional distributions in the model are given in the code repository for the book; we provide a version with only discrete variables, for which exact inference can be performed. In practice, many of the variables would be continuous and the conditional distributions would be learned from historical data on applicants and their insurance claims. We will see how to learn Bayes net models from data in Chapter 21.

The final question is, of course, how to do inference in the network to make predictions. We turn now to this question. For each inference method that we describe, we will evaluate the method on the insurance net to measure the time and space requirements of the method.

## 13.3 Exact Inference in Bayesian Networks

The basic task for any probabilistic inference system is to compute the posterior probability distribution for a set of **query variables**, given some observed **event**—usually, some assignment of values to a set of **evidence variables**.<sup>5</sup> To simplify the presentation, we will consider only one query variable at a time; the algorithms can easily be extended to queries with multiple variables. (For example, we can solve the query  $\mathbf{P}(U, V | \mathbf{e})$  by multiplying  $\mathbf{P}(V | \mathbf{e})$  and  $\mathbf{P}(U | V, \mathbf{e})$ .) We will use the notation from Chapter 12:  $X$  denotes the query variable;  $\mathbf{E}$  denotes the set of evidence variables  $E_1, \dots, E_m$ , and  $\mathbf{e}$  is a particular observed event;  $\mathbf{Y}$  denotes the hidden (nonevidence, nonquery) variables  $Y_1, \dots, Y_\ell$ . Thus, the complete set of variables is  $\{X\} \cup \mathbf{E} \cup \mathbf{Y}$ . A typical query asks for the posterior probability distribution  $\mathbf{P}(X | \mathbf{e})$ .

In the burglary network, we might observe the event in which  $JohnCalls = true$  and  $MaryCalls = true$ . We could then ask for, say, the probability that a burglary has occurred:

$$\mathbf{P}(\text{Burglary} | JohnCalls = true, MaryCalls = true) = \langle 0.284, 0.716 \rangle.$$

In this section we discuss exact algorithms for computing posterior probabilities as well as the complexity of this task. It turns out that the general case is intractable, so Section 13.4 covers methods for approximate inference.

### 13.3.1 Inference by enumeration

Chapter 12 explained that any conditional probability can be computed by summing terms from the full joint distribution. More specifically, a query  $\mathbf{P}(X | \mathbf{e})$  can be answered using Equation (12.9), which we repeat here for convenience:

$$\mathbf{P}(X | \mathbf{e}) = \alpha \mathbf{P}(X, \mathbf{e}) = \alpha \sum_{\mathbf{y}} \mathbf{P}(X, \mathbf{e}, \mathbf{y}).$$

<sup>5</sup> Another widely studied task is finding the **most probable explanation** for some observed evidence. This and other tasks are discussed in the notes at the end of the chapter.

Now, a Bayes net gives a complete representation of the full joint distribution. More specifically, Equation (13.2) on page 433 shows that the terms  $P(x, \mathbf{e}, \mathbf{y})$  in the joint distribution can be written as products of conditional probabilities from the network. Therefore, *a query can be answered using a Bayes net by computing sums of products of conditional probabilities from the network.*

Consider the query  $\mathbf{P}(\text{Burglary} | \text{JohnCalls} = \text{true}, \text{MaryCalls} = \text{true})$ . The hidden variables for this query are *Earthquake* and *Alarm*. From Equation (12.9), using initial letters for the variables to shorten the expressions, we have

$$\mathbf{P}(B | j, m) = \alpha \mathbf{P}(B, j, m) = \alpha \sum_e \sum_a \mathbf{P}(B, j, m, e, a).$$

The semantics of Bayes nets (Equation (13.2)) then gives us an expression in terms of CPT entries. For simplicity, we do this just for *Burglary* = *true*:

$$P(b | j, m) = \alpha \sum_e \sum_a P(b) P(e) P(a | b, e) P(j | a) P(m | a). \quad (13.4)$$

To compute this expression, we have to add four terms, each computed by multiplying five numbers. In the worst case, where we have to sum out almost all the variables, there will be  $O(2^n)$  terms in the sum, each a product of  $O(n)$  probability values. A naive implementation would therefore have complexity  $O(n2^n)$ .

This can be reduced to  $O(2^n)$  by taking advantage of the nested structure of the computation. In symbolic terms, this means moving the summations inwards as far as possible in expressions such as Equation (13.4). We can do this because not all the factors in the product of probabilities depend on all the variables. Thus we have

$$P(b | j, m) = \alpha P(b) \sum_e P(e) \sum_a P(a | b, e) P(j | a) P(m | a). \quad (13.5)$$

This expression can be evaluated by looping through the variables in order, multiplying CPT entries as we go. For each summation, we also need to loop over the variable's possible values. The structure of this computation is shown as a tree in Figure 13.10. Using the numbers from Figure 13.2, we obtain  $P(b | j, m) = \alpha \times 0.00059224$ . The corresponding computation for  $\neg b$  yields  $\alpha \times 0.0014919$ ; hence,

$$\mathbf{P}(B | j, m) = \alpha \langle 0.00059224, 0.0014919 \rangle \approx \langle 0.284, 0.716 \rangle.$$

That is, the chance of a burglary, given calls from both neighbors, is about 28%.

The ENUMERATION-ASK algorithm in Figure 13.11 evaluates these expression trees using depth-first, left-to-right recursion. The algorithm is very similar in structure to the backtracking algorithm for solving CSPs (Figure 5.5) and the DPLL algorithm for satisfiability (Figure 7.17). Its space complexity is only linear in the number of variables: the algorithm sums over the full joint distribution without ever constructing it explicitly. Unfortunately, its time complexity for a network with  $n$  Boolean variables (not counting the evidence variables) is always  $O(2^n)$ —better than the  $O(n2^n)$  for the simple approach described earlier, but still rather grim. For the insurance network in Figure 13.9, which is relatively small, exact inference using enumeration requires around 227 million arithmetic operations for a typical query on the cost variables.

If you look carefully at the tree in Figure 13.10, however, you will see that it contains *repeated subexpressions*. The products  $P(j | a)P(m | a)$  and  $P(j | \neg a)P(m | \neg a)$  are computed twice, once for each value of  $E$ . The key to efficient inference in Bayes nets is avoiding such wasted computations. The next section describes a general method for doing this.

**Figure 13.10** The structure of the expression shown in Equation (13.5). The evaluation proceeds top down, multiplying values along each path and summing at the “+” nodes. Notice the repetition of the paths for  $j$  and  $m$ .

```

function ENUMERATION-ASK( $X, \mathbf{e}, bn$ ) returns a distribution over  $X$ 
  inputs:  $X$ , the query variable
     $\mathbf{e}$ , observed values for variables  $\mathbf{E}$ 
     $bn$ , a Bayes net with variables  $vars$ 

   $\mathbf{Q}(X) \leftarrow$  a distribution over  $X$ , initially empty
  for each value  $x_i$  of  $X$  do
     $\mathbf{Q}(x_i) \leftarrow$  ENUMERATE-ALL( $vars, \mathbf{e}_{x_i}$ )
      where  $\mathbf{e}_{x_i}$  is  $\mathbf{e}$  extended with  $X = x_i$ 
  return NORMALIZE( $\mathbf{Q}(X)$ )

  else return  $\sum_v P(v | parents(V)) \times$  ENUMERATE-ALL( $REST(vars), \mathbf{e}_v$ )
    where  $\mathbf{e}_v$  is  $\mathbf{e}$  extended with  $V = v$ 

```

**Figure 13.11** The enumeration algorithm for exact inference in Bayes nets.

## Variable elimination

## 13.3.2 The variable elimination algorithm

The enumeration algorithm can be improved substantially by eliminating repeated calculations of the kind illustrated in Figure 13.10. The idea is simple: do the calculation once and save the results for later use. This is a form of dynamic programming. There are several versions of this approach; we present the **variable elimination** algorithm, which is the simplest. Variable elimination works by evaluating expressions such as Equation (13.5) in *right-to-left* order (that is, *bottom up* in Figure 13.10). Intermediate results are stored, and summations over each variable are done only for those portions of the expression that depend on the variable.

Let us illustrate this process for the burglary network. We evaluate the expression

$$\mathbf{P}(B|j,m) = \alpha \underbrace{\mathbf{P}(B)}_{\mathbf{f}_1(B)} \sum_e \underbrace{\mathbf{P}(e)}_{\mathbf{f}_2(E)} \sum_a \underbrace{\mathbf{P}(a|B,e)}_{\mathbf{f}_3(A,B,E)} \underbrace{\mathbf{P}(j|a)}_{\mathbf{f}_4(A)} \underbrace{\mathbf{P}(m|a)}_{\mathbf{f}_5(A)}.$$

## Factor

Notice that we have annotated each part of the expression with the name of the corresponding **factor**; each factor is a matrix indexed by the values of its argument variables. For example, the factors  $\mathbf{f}_4(A)$  and  $\mathbf{f}_5(A)$  corresponding to  $P(j|a)$  and  $P(m|a)$  depend just on  $A$  because  $J$  and  $M$  are fixed by the query. They are therefore two-element vectors:

$$\mathbf{f}_4(A) = \begin{pmatrix} P(j|a) \\ P(j|\neg a) \end{pmatrix} = \begin{pmatrix} 0.90 \\ 0.05 \end{pmatrix} \quad \mathbf{f}_5(A) = \begin{pmatrix} P(m|a) \\ P(m|\neg a) \end{pmatrix} = \begin{pmatrix} 0.70 \\ 0.01 \end{pmatrix}.$$

$\mathbf{f}_3(A,B,E)$  will be a  $2 \times 2 \times 2$  matrix, which is hard to show on the printed page. (The “first” element is given by  $P(a|b,e)=0.95$  and the “last” by  $P(\neg a|\neg b,\neg e)=0.999$ .) In terms of factors, the query expression is written as

$$\mathbf{P}(B|j,m) = \alpha \mathbf{f}_1(B) \times \sum_e \mathbf{f}_2(E) \times \sum_a \mathbf{f}_3(A,B,E) \times \mathbf{f}_4(A) \times \mathbf{f}_5(A).$$

## Pointwise product

Here the “ $\times$ ” operator is not ordinary matrix multiplication but instead the **pointwise product** operation, to be described shortly.

The evaluation process sums out variables (right to left) from pointwise products of factors to produce new factors, eventually yielding a factor that constitutes the solution—that is, the posterior distribution over the query variable. The steps are as follows:

- First, we sum out  $A$  from the product of  $\mathbf{f}_3$ ,  $\mathbf{f}_4$ , and  $\mathbf{f}_5$ . This gives us a new  $2 \times 2$  factor  $\mathbf{f}_6(B,E)$  whose indices range over just  $B$  and  $E$ :

$$\begin{aligned} \mathbf{f}_6(B,E) &= \sum_a \mathbf{f}_3(A,B,E) \times \mathbf{f}_4(A) \times \mathbf{f}_5(A) \\ &= (\mathbf{f}_3(a,B,E) \times \mathbf{f}_4(a) \times \mathbf{f}_5(a)) + (\mathbf{f}_3(\neg a,B,E) \times \mathbf{f}_4(\neg a) \times \mathbf{f}_5(\neg a)). \end{aligned}$$

Now we are left with the expression

$$\mathbf{P}(B|j,m) = \alpha \mathbf{f}_1(B) \times \sum_e \mathbf{f}_2(E) \times \mathbf{f}_6(B,E).$$

- Next, we sum out  $E$  from the product of  $\mathbf{f}_2$  and  $\mathbf{f}_6$ :

$$\begin{aligned} \mathbf{f}_7(B) &= \sum_e \mathbf{f}_2(E) \times \mathbf{f}_6(B,E) \\ &= \mathbf{f}_2(e) \times \mathbf{f}_6(B,e) + \mathbf{f}_2(\neg e) \times \mathbf{f}_6(B,\neg e). \end{aligned}$$

This leaves the expression

$$\mathbf{P}(B|j,m) = \alpha \mathbf{f}_1(B) \times \mathbf{f}_7(B)$$

which can be evaluated by taking the pointwise product and normalizing the result.

$X$	$Y$	$\mathbf{f}(X, Y)$	$Y$	$Z$	$\mathbf{g}(Y, Z)$	$X$	$Y$	$Z$	$\mathbf{h}(X, Y, Z)$
$t$	$t$	.3	$t$	$t$	.2	$t$	$t$	$t$	$.3 \times .2 = .06$
$t$	$f$	.7	$t$	$f$	.8	$t$	$t$	$f$	$.3 \times .8 = .24$
$f$	$t$	.9	$f$	$t$	.6	$t$	$f$	$t$	$.7 \times .6 = .42$
$f$	$f$	.1	$f$	$f$	.4	$t$	$f$	$f$	$.7 \times .4 = .28$
						$f$	$t$	$t$	$.9 \times .2 = .18$
						$f$	$t$	$f$	$.9 \times .8 = .72$
						$f$	$f$	$t$	$.1 \times .6 = .06$
						$f$	$f$	$f$	$.1 \times .4 = .04$

Figure 13.12 Illustrating pointwise multiplication:  $\mathbf{f}(X, Y) \times \mathbf{g}(Y, Z) = \mathbf{h}(X, Y, Z)$ .

Examining this sequence, we see that two basic computational operations are required: pointwise product of a pair of factors, and summing out a variable from a product of factors. The next section describes each of these operations.

### Operations on factors

The pointwise product of two factors  $\mathbf{f}$  and  $\mathbf{g}$  yields a new factor  $\mathbf{h}$  whose variables are the *union* of the variables in  $\mathbf{f}$  and  $\mathbf{g}$  and whose elements are given by the product of the corresponding elements in the two factors. Suppose the two factors have variables  $Y_1, \dots, Y_k$  in common. Then we have

$$\mathbf{f}(X_1 \dots X_j, Y_1 \dots Y_k) \times \mathbf{g}(Y_1 \dots Y_k, Z_1, \dots, Z_\ell) = \mathbf{h}(X_1 \dots X_j, Y_1 \dots Y_k, Z_1 \dots Z_\ell)$$

If all the variables are binary, then  $\mathbf{f}$  and  $\mathbf{g}$  have  $2^{j+k}$  and  $2^{k+\ell}$  entries, respectively, and the pointwise product has  $2^{j+k+\ell}$  entries. For example, given two factors  $\mathbf{f}(X, Y)$  and  $\mathbf{g}(Y, Z)$ , the pointwise product  $\mathbf{f} \times \mathbf{g} = \mathbf{h}(X, Y, Z)$  has  $2^{1+1+1} = 8$  entries, as illustrated in Figure 13.12. Notice that the factor resulting from a pointwise product can contain more variables than any of the factors being multiplied and that the size of a factor is exponential in the number of variables. This is where both space and time complexity arise in the variable elimination algorithm.

Summing out a variable from a product of factors is done by adding up the submatrices formed by fixing the variable to each of its values in turn. For example, to sum out  $X$  from  $\mathbf{h}(X, Y, Z)$ , we write

$$\begin{aligned} \mathbf{h}_2(Y, Z) &= \sum_x \mathbf{h}(X, Y, Z) = \mathbf{h}(x, Y, Z) + \mathbf{h}(\neg x, Y, Z) \\ &= \begin{pmatrix} .06 & .24 \\ .42 & .28 \end{pmatrix} + \begin{pmatrix} .18 & .72 \\ .06 & .04 \end{pmatrix} = \begin{pmatrix} .24 & .96 \\ .48 & .32 \end{pmatrix}. \end{aligned}$$

The only trick is to notice that any factor that does *not* depend on the variable to be summed out can be moved outside the summation. For example, to sum out  $X$  from the product of  $\mathbf{f}$  and  $\mathbf{g}$ , we can move  $\mathbf{g}$  outside the summation:

$$\sum_x \mathbf{f}(X, Y) \times \mathbf{g}(Y, Z) = \mathbf{g}(Y, Z) \times \sum_x \mathbf{f}(X, Y).$$

---

```

function ELIMINATION-ASK( $X, \mathbf{e}, bn$ ) returns a distribution over  $X$ 
  inputs:  $X$ , the query variable
     $\mathbf{e}$ , observed values for variables  $\mathbf{E}$ 
     $bn$ , a Bayesian network with variables  $vars$ 

   $factors \leftarrow []$ 
  for each  $V$  in ORDER( $vars$ ) do
     $factors \leftarrow [\text{MAKE-FACTOR}(V, \mathbf{e})] + factors$ 
    if  $V$  is a hidden variable then  $factors \leftarrow \text{SUM-OUT}(V, factors)$ 
  return NORMALIZE(POINTWISE-PRODUCT( $factors$ ))

```

**Figure 13.13** The variable elimination algorithm for exact inference in Bayes nets.

---

This is potentially much more efficient than computing the larger pointwise product  $\mathbf{h}$  first and then summing  $X$  out from that.

Notice that matrices are *not* multiplied until we need to sum out a variable from the accumulated product. At that point, we multiply just those matrices that include the variable to be summed out. Given functions for pointwise product and summing out, the variable elimination algorithm itself can be written quite simply, as shown in Figure 13.13.

### Variable ordering and variable relevance

The algorithm in Figure 13.13 includes an unspecified ORDER function to choose an ordering for the variables. Every choice of ordering yields a valid algorithm, but different orderings cause different intermediate factors to be generated during the calculation. For example, in the calculation shown previously, we eliminated  $A$  before  $E$ ; if we do it the other way, the calculation becomes

$$\mathbf{P}(B | j, m) = \alpha \mathbf{f}_1(B) \times \sum_a \mathbf{f}_4(A) \times \mathbf{f}_5(A) \times \sum_e \mathbf{f}_2(E) \times \mathbf{f}_3(A, B, E),$$

during which a new factor  $\mathbf{f}_6(A, B)$  will be generated.

In general, the time and space requirements of variable elimination are dominated by the size of the largest factor constructed during the operation of the algorithm. This in turn is determined by the order of elimination of variables and by the structure of the network. It turns out to be intractable to determine the optimal ordering, but several good heuristics are available. One fairly effective method is a greedy one: eliminate whichever variable minimizes the size of the next factor to be constructed.

Let us consider one more query:  $\mathbf{P}(\text{JohnCalls} | \text{Burglary} = \text{true})$ . As usual (see Equation (13.5)), the first step is to write out the nested summation:

$$\mathbf{P}(J | b) = \alpha P(b) \sum_e P(e) \sum_a P(a | b, e) \mathbf{P}(J | a) \sum_m P(m | a).$$

Evaluating this expression from right to left, we notice something interesting:  $\sum_m P(m | a)$  is equal to 1 by definition! Hence, there was no need to include it in the first place; the variable  $M$  is *irrelevant* to this query. Another way of saying this is that the result of the query  $P(\text{JohnCalls} | \text{Burglary} = \text{true})$  is unchanged if we remove  $\text{MaryCalls}$  from the network altogether. In general, we can remove any leaf node that is not a query variable or an evidence

variable. After its removal, there may be some more leaf nodes, and these too may be irrelevant. Continuing this process, we eventually find that *every variable that is not an ancestor of a query variable or evidence variable is irrelevant to the query*. A variable elimination algorithm can therefore remove all these variables before evaluating the query.

When applied to the insurance network shown in Figure 13.9, variable elimination shows considerable improvement over the naive enumeration algorithm. Using reverse topological order for the variables, exact inference using elimination is about 1,000 times faster than the enumeration algorithm.

### 13.3.3 The complexity of exact inference

The complexity of exact inference in Bayes nets depends strongly on the structure of the network. The burglary network of Figure 13.2 belongs to the family of networks in which there is at most one undirected path (i.e., ignoring the direction of the arrows) between any two nodes in the network. These are called **singly connected** networks or **polytrees**, and they have a particularly nice property: *The time and space complexity of exact inference in polytrees is linear in the size of the network*. Here, the size is defined as the number of CPT entries; if the number of parents of each node is bounded by a constant, then the complexity will also be linear in the number of nodes. These results hold for any ordering consistent with the topological ordering of the network (Exercise 13.VEXX).

Singly connected  
Polytree

For **multiply connected** networks, such as the insurance network in Figure 13.9, variable elimination can have exponential time and space complexity in the worst case, even when the number of parents per node is bounded. This is not surprising when one considers that *because it includes inference in propositional logic as a special case, inference in Bayes nets is NP-hard*. To prove this, we need to work out how to encode a propositional satisfiability problem as a Bayes net, such that running inference on this net tells us whether or not the original propositional sentences are satisfiable. (In the language of complexity theory, we **reduce** satisfiability problems to Bayes net inference problems.) This turns out to be quite straightforward. Figure 13.14 shows how to encode a particular 3-SAT problem. The propositional variables become the root variables of the network, each with prior probability 0.5. The next layer of nodes corresponds to the clauses, with each clause variable  $C_j$  connected to the appropriate variables as parents. The conditional distribution for a clause variable is a deterministic disjunction, with negation as needed, so that each clause variable is true if and only if the assignment to its parents satisfies that clause. Finally,  $S$  is the conjunction of the clause variables.

Multiply connected  
Reduction

To determine if the original sentence is satisfiable, we simply evaluate  $P(S=\text{true})$ . If the sentence is *satisfiable*, then there is some possible assignment to the logical variables that makes  $S$  true; in the Bayes net, this means that there is a possible world with nonzero probability in which the root variables have that assignment, the clause variables have value *true*, and  $S$  has value *true*. Therefore,  $P(S=\text{true}) > 0$  for a satisfiable sentence. Conversely,  $P(S=\text{true})=0$  for an unsatisfiable sentence: all worlds with  $S=\text{true}$  have probability 0. Hence, we can use Bayes net inference to solve 3-SAT problems; from this, we conclude that Bayes net inference is NP-hard.

We can, in fact, do more than this. Notice that the probability of each satisfying assignment is  $2^{-n}$  for a problem with  $n$  variables. Hence, the *number* of satisfying assignments is  $P(S=\text{true})/(2^{-n})$ . Because computing the *number* of satisfying assignments for a 3-SAT

**Figure 13.14** Bayes net encoding of the 3-CNF sentence

$$(W \vee X \vee Y) \wedge (\neg W \vee Y \vee Z) \wedge (X \vee Y \vee \neg Z).$$

problem is #P-complete (“number-P complete”), this means that Bayes net inference is #P-hard—that is, strictly harder than NP-complete problems.

There is a close connection between the complexity of Bayes net inference and the complexity of constraint satisfaction problems (CSPs). As we discussed in Chapter 5, the difficulty of solving a discrete CSP is related to how “treelike” its constraint graph is. Measures such as **tree width**, which bound the complexity of solving a CSP, can also be applied directly to Bayes nets. Moreover, the variable elimination algorithm can be generalized to solve CSPs as well as Bayes nets.

As well as reducing satisfiability problems to Bayes net inference, we can reduce Bayes net inference to satisfiability, which allows us to take advantage of the powerful machinery developed for SAT-solving (see Chapter 7). In this case, the reduction is to a particular form of SAT solving called **weighted model counting** (WMC). Regular model counting counts the number of satisfying assignments for a SAT expression; WMC sums the total weight of those satisfying assignments—where, in this application, the weight is essentially the product of the conditional probabilities for each variable assignment given its parents. (See Exercise 13.WMCX for details.) Partly because SAT-solving technology has been so well optimized for large-scale applications, Bayes net inference via WMC is competitive with and sometimes superior to other exact algorithms on networks with large tree width.

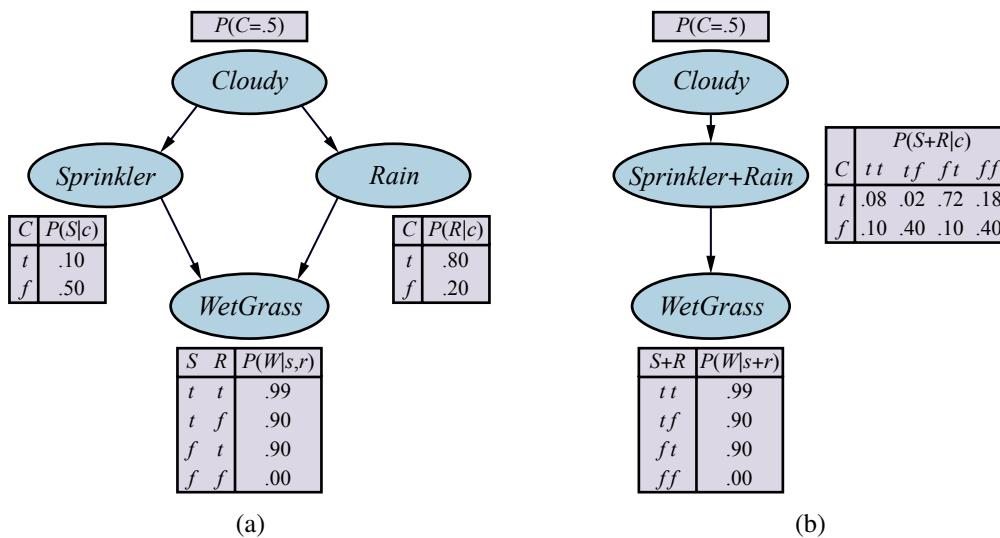

Weighted model  
counting

Clustering  
Join tree

### 13.3.4 Clustering algorithms

The variable elimination algorithm is simple and efficient for answering individual queries. If we want to compute posterior probabilities for all the variables in a network, however, it can be less efficient. For example, in a polytree network, one would need to issue  $O(n)$  queries costing  $O(n)$  each, for a total of  $O(n^2)$  time. Using **clustering** algorithms (also known as **join tree** algorithms), the time can be reduced to  $O(n)$ . For this reason, these algorithms are widely used in commercial Bayes net tools.

The basic idea of clustering is to join individual nodes of the network to form cluster nodes in such a way that the resulting network is a polytree. For example, the multiply connected network shown in Figure 13.15(a) can be converted into a polytree by combining the *Sprinkler* and *Rain* node into a cluster node called *Sprinkler+Rain*, as shown in Fig-

**Figure 13.15** (a) A multiply connected network describing Mary’s daily lawn routine: each morning, she checks the weather; if it’s cloudy, she usually doesn’t turn on the sprinkler; if the sprinkler is on, or if it rains during the day, the grass will be wet. Thus, *Cloudy* affects *WetGrass* via two different causal pathways. (b) A clustered equivalent of the multiply connected network.

ure 13.15(b). The two Boolean nodes are replaced by a **meganode** that takes on four possible values: *tt*, *tf*, *ft*, and *ff*. The meganode has only one parent, the Boolean variable *Cloudy*, so there are two conditioning cases. Although this example doesn’t show it, the process of clustering often produces meganodes that share some variables.

Once the network is in polytree form, a special-purpose inference algorithm is required, because ordinary inference methods cannot handle meganodes that share variables with each other. Essentially, the algorithm is a form of constraint propagation (see Chapter 5) where the constraints ensure that neighboring meganodes agree on the posterior probability of any variables that they have in common. With careful bookkeeping, this algorithm is able to compute posterior probabilities for all the nonevidence nodes in the network in time *linear* in the size of the clustered network. However, the NP-hardness of the problem has not disappeared: if a network requires exponential time and space with variable elimination, then the CPTs in the clustered network will necessarily be exponentially large.

## 13.4 Approximate Inference for Bayesian Networks

Given the intractability of exact inference in large networks, we will now consider approximate inference methods. This section describes randomized sampling algorithms, also called **Monte Carlo** algorithms, that provide approximate answers whose accuracy depends on the number of samples generated. They work by generating random events based on the probabilities in the Bayes net and counting up the different answers found in those random events. With enough samples, we can get arbitrarily close to recovering the true probability distribution—provided the Bayes net has no deterministic conditional distributions.

Monte Carlo algorithms, of which simulated annealing (page 133) is an example, are used in many branches of science to estimate quantities that are difficult to calculate exactly. In this section, we are interested in sampling applied to the computation of posterior probabilities in Bayes nets. We describe two families of algorithms: direct sampling and Markov chain sampling. Several other approaches for approximate inference are mentioned in the notes at the end of the chapter.

### 13.4.1 Direct sampling methods

The primitive element in any sampling algorithm is the generation of samples from a known probability distribution. For example, an unbiased coin can be thought of as a random variable *Coin* with values  $\langle \text{heads}, \text{tails} \rangle$  and a prior distribution  $\mathbf{P}(\text{Coin}) = \langle 0.5, 0.5 \rangle$ . Sampling from this distribution is exactly like flipping the coin: with probability 0.5 it will return *heads*, and with probability 0.5 it will return *tails*. Given a source of random numbers  $r$  uniformly distributed in the range  $[0, 1]$ , it is a simple matter to sample any distribution on a single variable, whether discrete or continuous. This is done by constructing the cumulative distribution for the variable and returning the first value whose cumulative probability exceeds  $r$  (see Exercise 13.PRSA).

We begin with a random sampling process for a Bayes net that has no evidence associated with it. The idea is to sample each variable in turn, in topological order. The probability distribution from which the value is sampled is conditioned on the values already assigned to the variable's parents. (Because we sample in topological order, the parents are guaranteed to have values already.) This algorithm is shown in Figure 13.16. Applying it to the network in Figure 13.15(a) with the ordering *Cloudy*, *Sprinkler*, *Rain*, *WetGrass*, we might produce a random event as follows:

1. Sample from  $\mathbf{P}(\text{Cloudy}) = \langle 0.5, 0.5 \rangle$ , value is *true*.
2. Sample from  $\mathbf{P}(\text{Sprinkler} | \text{Cloudy} = \text{true}) = \langle 0.1, 0.9 \rangle$ , value is *false*.
3. Sample from  $\mathbf{P}(\text{Rain} | \text{Cloudy} = \text{true}) = \langle 0.8, 0.2 \rangle$ , value is *true*.
4. Sample from  $\mathbf{P}(\text{WetGrass} | \text{Sprinkler} = \text{false}, \text{Rain} = \text{true}) = \langle 0.9, 0.1 \rangle$ , value is *true*.

In this case, PRIOR-SAMPLE returns the event  $[\text{true}, \text{false}, \text{true}, \text{true}]$ .

It is easy to see that PRIOR-SAMPLE generates samples from the prior joint distribution specified by the network. First, let  $S_{PS}(x_1, \dots, x_n)$  be the probability that a specific event is

---

```

function PRIOR-SAMPLE(bn) returns an event sampled from the prior specified by bn
inputs: bn, a Bayesian network specifying joint distribution  $\mathbf{P}(X_1, \dots, X_n)$ 

x  $\leftarrow$  an event with n elements
for each variable  $X_i$  in  $X_1, \dots, X_n$  do
    x[i]  $\leftarrow$  a random sample from  $\mathbf{P}(X_i | \text{parents}(X_i))$ 
return x

```

**Figure 13.16** A sampling algorithm that generates events from a Bayesian network. Each variable is sampled according to the conditional distribution given the values already sampled for the variable's parents.

generated by the PRIOR-SAMPLE algorithm. Just looking at the sampling process, we have

$$S_{PS}(x_1 \dots x_n) = \prod_{i=1}^n P(x_i | \text{parents}(X_i))$$

because each sampling step depends only on the parent values. This expression should look familiar, because it is also the probability of the event according to the Bayesian net's representation of the joint distribution, as stated in Equation (13.2). That is, we have

$$S_{PS}(x_1 \dots x_n) = P(x_1 \dots x_n).$$

This simple fact makes it easy to answer questions by using samples.

In any sampling algorithm, the answers are computed by counting the actual samples generated. Suppose there are  $N$  total samples produced by the PRIOR-SAMPLE algorithm, and let  $N_{PS}(x_1, \dots, x_n)$  be the number of times the specific event  $x_1, \dots, x_n$  occurs in the set of samples. We expect this number, as a fraction of the total, to converge in the limit to its expected value according to the sampling probability:

$$\lim_{N \rightarrow \infty} \frac{N_{PS}(x_1, \dots, x_n)}{N} = S_{PS}(x_1, \dots, x_n) = P(x_1, \dots, x_n). \quad (13.6)$$

For example, consider the event produced earlier: `[true, false, true, true]`. The sampling probability for this event is

$$S_{PS}(\text{true}, \text{false}, \text{true}, \text{true}) = 0.5 \times 0.9 \times 0.8 \times 0.9 = 0.324.$$

Hence, in the limit of large  $N$ , we expect 32.4% of the samples to be of this event.

Whenever we use an approximate equality (“ $\approx$ ”) in what follows, we mean it in exactly this sense—that the estimated probability becomes exact in the large-sample limit. Such an estimate is called **consistent**. For example, one can produce a consistent estimate of the probability of any partially specified event  $x_1, \dots, x_m$ , where  $m \leq n$ , as follows:

$$P(x_1, \dots, x_m) \approx N_{PS}(x_1, \dots, x_m)/N. \quad (13.7)$$

That is, the probability of the event can be estimated as the fraction of all complete events generated by the sampling process that match the partially specified event. We will use  $\hat{P}$  (pronounced “P-hat”) to mean an estimated probability. So, if we generate 1,000 samples from the sprinkler network, and 511 of them have *Rain = true*, then the estimated probability of rain is  $\hat{P}(\text{Rain} = \text{true}) = 0.511$ .

### Rejection sampling in Bayesian networks

**Rejection sampling** is a general method for producing samples from a hard-to-sample distribution given an easy-to-sample distribution. In its simplest form, it can be used to compute conditional probabilities—that is, to determine  $P(X | \mathbf{e})$ . The REJECTION-SAMPLING algorithm is shown in Figure 13.17. First, it generates samples from the prior distribution specified by the network. Then, it rejects all those that do not match the evidence. Finally, the estimate  $\hat{P}(X = x | \mathbf{e})$  is obtained by counting how often  $X = x$  occurs in the remaining samples.

Let  $\hat{\mathbf{P}}(X | \mathbf{e})$  be the estimated distribution that the algorithm returns; this distribution is computed by normalizing  $\mathbf{N}_{PS}(X, \mathbf{e})$ , the vector of sample counts for each value of  $X$  where the sample agrees with the evidence  $\mathbf{e}$ :

$$\hat{\mathbf{P}}(X | \mathbf{e}) = \alpha \mathbf{N}_{PS}(X, \mathbf{e}) = \frac{\mathbf{N}_{PS}(X, \mathbf{e})}{N_{PS}(\mathbf{e})}.$$

---

```

function REJECTION-SAMPLING( $X, \mathbf{e}, bn, N$ ) returns an estimate of  $\mathbf{P}(X | \mathbf{e})$ 
  inputs:  $X$ , the query variable
     $\mathbf{e}$ , observed values for variables  $\mathbf{E}$ 
     $bn$ , a Bayesian network
     $N$ , the total number of samples to be generated
  local variables:  $\mathbf{C}$ , a vector of counts for each value of  $X$ , initially zero

  for  $j = 1$  to  $N$  do
     $\mathbf{x} \leftarrow$  PRIOR-SAMPLE( $bn$ )
    if  $\mathbf{x}$  is consistent with  $\mathbf{e}$  then
       $\mathbf{C}[j] \leftarrow \mathbf{C}[j] + 1$  where  $x_j$  is the value of  $X$  in  $\mathbf{x}$ 
  return NORMALIZE( $\mathbf{C}$ )

```

**Figure 13.17** The rejection-sampling algorithm for answering queries given evidence in a Bayesian network.

---

From Equation (13.7), this becomes

$$\hat{\mathbf{P}}(X | \mathbf{e}) \approx \frac{\mathbf{P}(X, \mathbf{e})}{\mathbf{P}(\mathbf{e})} = \mathbf{P}(X | \mathbf{e}).$$

That is, rejection sampling produces a consistent estimate of the true probability.

Continuing with our example from Figure 13.15(a), let us assume that we wish to estimate  $\mathbf{P}(\text{Rain} | \text{Sprinkler} = \text{true})$ , using 100 samples. Of the 100 that we generate, suppose that 73 have  $\text{Sprinkler} = \text{false}$  and are rejected, while 27 have  $\text{Sprinkler} = \text{true}$ ; of the 27, 8 have  $\text{Rain} = \text{true}$  and 19 have  $\text{Rain} = \text{false}$ . Hence,

$$\mathbf{P}(\text{Rain} | \text{Sprinkler} = \text{true}) \approx \text{NORMALIZE}(\langle 8, 19 \rangle) = \langle 0.296, 0.704 \rangle.$$

The true answer is  $\langle 0.3, 0.7 \rangle$ . As more samples are collected, the estimate will converge to the true answer. The standard deviation of the error in each probability will be proportional to  $1/\sqrt{n}$ , where  $n$  is the number of samples used in the estimate.

Now we know that rejection sampling converges to the correct answer, the next question is, how fast does that happen? More precisely, how many samples are required before we know that the resulting estimates are close to the correct answers with high probability? Whereas the complexity of exact algorithms depends to a large extent on the topology of the network—trees are easy, densely connected networks are hard—the complexity of rejection sampling depends primarily on the fraction of samples that are accepted. This fraction is exactly equal to the prior probability of the evidence,  $P(\mathbf{e})$ . Unfortunately, for complex problems with many evidence variables, this fraction is vanishingly small. When applied to the discrete version of the car insurance network in Figure 13.9, the fraction of samples consistent with a typical evidence case sampled from the network itself is usually between one in a thousand and one in ten thousand. Convergence is extremely slow (see Figure 13.19 below).

We expect the fraction of samples consistent with the evidence  $\mathbf{e}$  to drop exponentially as the number of evidence variables grows, so the procedure is unusable for complex problems. It also has difficulties with continuous-valued evidence variables, because the probability of producing a sample consistent with such evidence is zero (if it is really continuous-valued) or infinitesimal (if it is merely a finite-precision floating-point number).

Notice that rejection sampling is very similar to the estimation of conditional probabilities in the real world. For example, to estimate the conditional probability that any humans survive after a 1km-diameter asteroid crashes into the Earth, one can simply count how often any humans survive after a 1km-diameter asteroid crashes into the Earth, ignoring all those days when no such event occurs. (Here, the universe itself plays the role of the sample-generation algorithm.) To get a decent estimate, one might need to wait for 100 such events to occur. Obviously, this could take a long time, and that is the weakness of rejection sampling.

### Importance sampling

The general statistical technique of **importance sampling** aims to emulate the effect of sampling from a distribution  $P$  using samples from another distribution  $Q$ . We ensure that the answers are correct in the limit by applying a correction factor  $P(\mathbf{x})/Q(\mathbf{x})$ , also known as a **weight**, to each sample  $\mathbf{x}$  when counting up the samples.

The reason for using importance sampling in Bayes nets is simple: we would like to sample from the true posterior distribution conditioned on all the evidence, but usually this is too hard;<sup>6</sup> so instead, we sample from an easy distribution and apply the necessary corrections. The reason why importance sampling works is also simple. Let the nonevidence variables be  $\mathbf{Z}$ . If we could sample directly from  $P(\mathbf{z}|\mathbf{e})$ , we could construct estimates like this:

$$\hat{P}(\mathbf{z}|\mathbf{e}) = \frac{N_P(\mathbf{z})}{N} \approx P(\mathbf{z}|\mathbf{e})$$

where  $N_P(\mathbf{z})$  is the number of samples with  $\mathbf{Z}=\mathbf{z}$  when sampling from  $P$ . Now suppose instead that we sample from  $Q(\mathbf{z})$ . The estimate in this case includes the correction factors:

$$\hat{P}(\mathbf{z}|\mathbf{e}) = \frac{N_Q(\mathbf{z})}{N} \frac{P(\mathbf{z}|\mathbf{e})}{Q(\mathbf{z})} \approx Q(\mathbf{z}) \frac{P(\mathbf{z}|\mathbf{e})}{Q(\mathbf{z})} = P(\mathbf{z}|\mathbf{e}).$$

Thus, the estimate converges to the correct value *regardless of which sampling distribution  $Q$  is used*. (The only technical requirement is that  $Q(\mathbf{z})$  should not be zero for any  $\mathbf{z}$  where  $P(\mathbf{z}|\mathbf{e})$  is nonzero.) Intuitively, the correction factor compensates for oversampling or undersampling. For example, if  $Q(\mathbf{z})$  is much bigger than  $P(\mathbf{z}|\mathbf{e})$  for some  $\mathbf{z}$ , then there will be many more samples of that  $\mathbf{z}$  than there should be, but each will have a small weight, so it works out just as if there were the right number.

As for which  $Q$  to use, we want one that is easy to sample from and as close as possible to the true posterior  $P(\mathbf{z}|\mathbf{e})$ . The most common approach is called **likelihood weighting** (for reasons we will see shortly). As shown in the WEIGHTED-SAMPLE function in Figure 13.18, the algorithm fixes the values for the evidence variables  $\mathbf{E}$  and samples all the nonevidence variables in topological order, each conditioned on its parents. This guarantees that each event generated is consistent with the evidence.

Let's call the sampling distribution produced by this algorithm  $Q_{WS}$ . If the nonevidence variables are  $\mathbf{Z}=\{Z_1, \dots, Z_l\}$ , then we have

$$Q_{WS}(\mathbf{z}) = \prod_{i=1}^l P(z_i | \text{parents}(Z_i)) \tag{13.8}$$

<sup>6</sup> If it was easy, then we could approximate the desired probability to arbitrary accuracy with a polynomial number of samples. It can be shown that no such polynomial-time approximation scheme can exist.

Importance sampling

Likelihood weighting

---

```

function LIKELIHOOD-WEIGHTING( $X, \mathbf{e}, bn, N$ ) returns an estimate of  $\mathbf{P}(X | \mathbf{e})$ 
  inputs:  $X$ , the query variable
     $\mathbf{e}$ , observed values for variables  $\mathbf{E}$ 
     $bn$ , a Bayesian network specifying joint distribution  $\mathbf{P}(X_1, \dots, X_n)$ 
     $N$ , the total number of samples to be generated
  local variables:  $\mathbf{W}$ , a vector of weighted counts for each value of  $X$ , initially zero

  for  $j = 1$  to  $N$  do
     $\mathbf{x}, w \leftarrow$  WEIGHTED-SAMPLE( $bn, \mathbf{e}$ )
     $\mathbf{W}[j] \leftarrow \mathbf{W}[j] + w$  where  $x_j$  is the value of  $X$  in  $\mathbf{x}$ 
  return NORMALIZE( $\mathbf{W}$ )

function WEIGHTED-SAMPLE( $bn, \mathbf{e}$ ) returns an event and a weight
   $w \leftarrow 1$ ;  $\mathbf{x} \leftarrow$  an event with  $n$  elements, with values fixed from  $\mathbf{e}$ 
  for  $i = 1$  to  $n$  do
    if  $X_i$  is an evidence variable with value  $x_{ij}$  in  $\mathbf{e}$ 
      then  $w \leftarrow w \times P(X_i = x_{ij} | parents(X_i))$ 
      else  $\mathbf{x}[i] \leftarrow$  a random sample from  $\mathbf{P}(X_i | parents(X_i))$ 
  return  $\mathbf{x}, w$ 

```

**Figure 13.18** The likelihood-weighting algorithm for inference in Bayesian networks. In WEIGHTED-SAMPLE, each nonevidence variable is sampled according to the conditional distribution given the values already sampled for the variable's parents, while a weight is accumulated based on the likelihood for each evidence variable.

---

because each variable is sampled conditioned on its parents. In order to complete the algorithm, we need to know how to compute the weight for each sample generated from  $Q_{ws}$ . According to the general scheme for importance sampling, the weight should be

$$w(\mathbf{z}) = P(\mathbf{z} | \mathbf{e}) / Q_{ws}(\mathbf{z}) = \alpha P(\mathbf{z}, \mathbf{e}) / Q_{ws}(\mathbf{z})$$

where the normalizing factor  $\alpha = 1/P(\mathbf{e})$  is the same for all samples. Now  $\mathbf{z}$  and  $\mathbf{e}$  together cover all the variables in the Bayes net, so  $P(\mathbf{z}, \mathbf{e})$  is just the product of all the conditional probabilities (Equation (13.2) page 433); and we can write this as the product of the conditional probabilities for the nonevidence variables times the product of the conditional probabilities for the evidence variables:

$$\begin{aligned} w(\mathbf{z}) &= \alpha \frac{P(\mathbf{z}, \mathbf{e})}{Q_{ws}(\mathbf{z})} = \alpha \frac{\prod_{i=1}^l P(z_i | parents(Z_i)) \prod_{i=1}^m P(e_i | parents(E_i))}{\prod_{i=1}^l P(z_i | parents(Z_i))} \\ &= \alpha \prod_{i=1}^m P(e_i | parents(E_i)). \end{aligned} \tag{13.9}$$

Thus the weight is the product of the conditional probabilities for the evidence variables given their parents. (Probabilities of evidence are generally called **likelihoods**, hence the name.) The weight calculation is implemented incrementally in WEIGHTED-SAMPLE, multiplying by the conditional probability each time an evidence variable is encountered. The normalization is done at the end before the query result is returned.

Let us apply the algorithm to the network shown in Figure 13.15(a), with the query  $\mathbf{P}(Rain | Cloudy=true, WetGrass=true)$  and the ordering *Cloudy, Sprinkler, Rain, WetGrass*.

(Any topological ordering will do.) The process goes as follows: First, the weight  $w$  is set to 1.0. Then an event is generated:

1. *Cloudy* is an evidence variable with value *true*. Therefore, we set

$$w \leftarrow w \times P(\text{Cloudy} = \text{true}) = 0.5.$$

2. *Sprinkler* is not an evidence variable, so sample from  $\mathbf{P}(\text{Sprinkler} | \text{Cloudy} = \text{true}) = \langle 0.1, 0.9 \rangle$ ; suppose this returns *false*.
3. *Rain* is not an evidence variable, so sample from  $\mathbf{P}(\text{Rain} | \text{Cloudy} = \text{true}) = \langle 0.8, 0.2 \rangle$ ; suppose this returns *true*.

4. *WetGrass* is an evidence variable with value *true*. Therefore, we set

$$\begin{aligned} w &\leftarrow w \times P(\text{WetGrass} = \text{true} | \text{Sprinkler} = \text{false}, \text{Rain} = \text{true}) \\ &= 0.5 \times 0.9 = 0.45. \end{aligned}$$

Here WEIGHTED-SAMPLE returns the event  $[\text{true}, \text{false}, \text{true}, \text{true}]$  with weight 0.45, and this is tallied under *Rain = true*.

Notice that  $\text{Parents}(Z_i)$  can include both nonevidence variables and evidence variables. Unlike the prior distribution  $P(\mathbf{z})$ , the distribution  $Q_{WS}$  pays some attention to the evidence: the sampled values for each  $Z_i$  will be influenced by evidence among  $Z_i$ 's ancestors. For example, when sampling *Sprinkler* the algorithm pays attention to the evidence *Cloudy = true* in its parent variable. On the other hand,  $Q_{WS}$  pays less attention to the evidence than does the true posterior distribution  $P(\mathbf{z} | \mathbf{e})$ , because the sampled values for each  $Z_i$  ignore evidence among  $Z_i$ 's non-ancestors. For example, when sampling *Sprinkler* and *Rain* the algorithm ignores the evidence in the child variable *WetGrass = true*; this means it will generate many samples with *Sprinkler = false* and *Rain = false* despite the fact that the evidence actually rules out this case. Those samples will have zero weight.

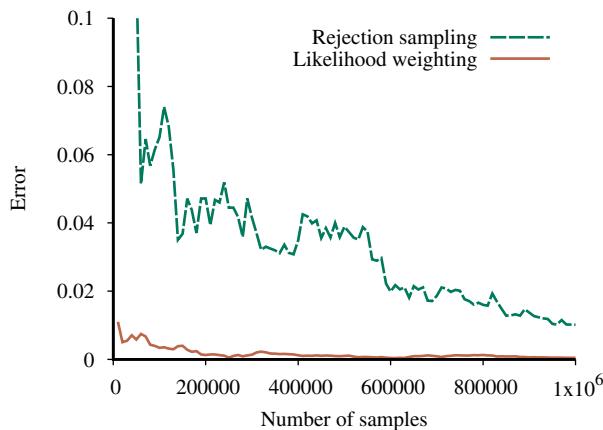

Because likelihood weighting uses all the samples generated, it can be much more efficient than rejection sampling. It will, however, suffer a degradation in performance as the number of evidence variables increases. This is because most samples will have very low weights and hence the weighted estimate will be dominated by the tiny fraction of samples that accord more than an infinitesimal likelihood to the evidence. The problem is exacerbated if the evidence variables occur “downstream”—that is, late in the variable ordering—because then the nonevidence variables will have no evidence in their parents and ancestors to guide the generation of samples. This means the samples will be mere hallucinations—simulations that bear little resemblance to the reality suggested by the evidence.

When applied to the discrete version of the car insurance network in Figure 13.9, likelihood weighting is considerably more efficient than rejection sampling (see Figure 13.19). The insurance network is a relatively benign case for likelihood weighting because much of the evidence is “upstream” and the query variables are leaf nodes of the network.

### 13.4.2 Inference by Markov chain simulation

**Markov chain Monte Carlo** (MCMC) algorithms work differently from rejection sampling and likelihood weighting. Instead of generating each sample from scratch, MCMC algorithms generate a sample by making a random change to the preceding sample. Think of an MCMC algorithm as being in a particular *current state* that specifies a value for every variable and generating a *next state* by making random changes to the current state.

Markov chain Monte Carlo

**Figure 13.19** Performance of rejection sampling and likelihood weighting on the insurance network. The x-axis shows the number of samples generated and the y-axis shows the maximum absolute error in any of the probability values for a query on *PropertyCost*.

Markov chain

Gibbs sampling

Metropolis–Hastings

The term **Markov chain** refers to a random process that generates a sequence of states. (Markov chains also figure prominently in Chapters 14 and 16; the simulated annealing algorithm in Chapter 4 and the WALKSAT algorithm in Chapter 7 are also members of the MCMC family.) We begin by describing a particular form of MCMC called **Gibbs sampling**, which is especially well suited for Bayes nets. We then describe the more general **Metropolis–Hastings** algorithm, which allows much greater flexibility in generating samples.

### Gibbs sampling in Bayesian networks

The Gibbs sampling algorithm for Bayesian networks starts with an arbitrary state (with the evidence variables fixed at their observed values) and generates a next state by randomly sampling a value for one of the nonevidence variables  $X_i$ . Recall from page 437 that  $X_i$  is independent of all other variables given its Markov blanket (its parents, children, and children’s other parents); therefore, Gibbs sampling for  $X_i$  means sampling *conditioned on the current values of the variables in its Markov blanket*. The algorithm wanders randomly around the state space—the space of possible complete assignments—flipping one variable at a time, but keeping the evidence variables fixed. The complete algorithm is shown in Figure 13.20.

Consider the query  $\mathbf{P}(\text{Rain} \mid \text{Sprinkler} = \text{true}, \text{WetGrass} = \text{true})$  for the network in Figure 13.15(a). The evidence variables *Sprinkler* and *WetGrass* are fixed to their observed values (both *true*), and the nonevidence variables *Cloudy* and *Rain* are initialized randomly to, say, *true* and *false* respectively. Thus, the initial state is **[true, true, false, true]**, where we have marked the fixed evidence values in bold. Now the nonevidence variables  $Z_i$  are sampled repeatedly in some random order according to a probability distribution  $\rho(i)$  for choosing variables. For example:

1. *Cloudy* is chosen and then sampled, given the current values of its Markov blanket: in this case, we sample from  $\mathbf{P}(\text{Cloudy} \mid \text{Sprinkler} = \text{true}, \text{Rain} = \text{false})$ . Suppose the result is *Cloudy* = *false*. Then the new current state is **[false, true, false, true]**.

---

```

function GIBBS-ASK( $X, \mathbf{e}, bn, N$ ) returns an estimate of  $\mathbf{P}(X | \mathbf{e})$ 
  local variables:  $\mathbf{C}$ , a vector of counts for each value of  $X$ , initially zero
     $\mathbf{Z}$ , the nonevidence variables in  $bn$ 
     $\mathbf{x}$ , the current state of the network, initialized from  $\mathbf{e}$ 

  initialize  $\mathbf{x}$  with random values for the variables in  $\mathbf{Z}$ 
  for  $k = 1$  to  $N$  do
    choose any variable  $Z_i$  from  $\mathbf{Z}$  according to any distribution  $\rho(i)$ 
    set the value of  $Z_i$  in  $\mathbf{x}$  by sampling from  $\mathbf{P}(Z_i | mb(Z_i))$ 
     $\mathbf{C}[j] \leftarrow \mathbf{C}[j] + 1$  where  $x_j$  is the value of  $X$  in  $\mathbf{x}$ 
  return NORMALIZE( $\mathbf{C}$ )

```

**Figure 13.20** The Gibbs sampling algorithm for approximate inference in Bayes nets; this version chooses variables at random, but cycling through the variables but also works.

---

2. *Rain* is chosen and then sampled, given the current values of its Markov blanket: in this case, we sample from  $\mathbf{P}(\text{Rain} | \text{Cloudy}=\text{false}, \text{Sprinkler}=\text{true}, \text{WetGrass}=\text{true})$ . Suppose this yields  $\text{Rain}=\text{true}$ . The new current state is  $[\text{false}, \text{true}, \text{true}, \text{true}]$ .

The one remaining detail concerns the method of calculating the Markov blanket distribution  $\mathbf{P}(X_i | mb(X_i))$ , where  $mb(X_i)$  denotes the values of the variables in  $X_i$ 's Markov blanket,  $MB(X_i)$ . Fortunately, this does not involve any complex inference. As shown in Exercise 13.MARB, the distribution is given by

$$P(x_i | mb(X_i)) = \alpha P(x_i | parents(X_i)) \prod_{Y_j \in Children(X_i)} P(y_j | parents(Y_j)). \quad (13.10)$$

In other words, for each value  $x_i$ , the probability is given by multiplying probabilities from the CPTs of  $X_i$  and its children. For example, in the first sampling step shown above, we sampled from  $\mathbf{P}(\text{Cloudy} | \text{Sprinkler}=\text{true}, \text{Rain}=\text{false})$ . By Equation (13.10), and abbreviating the variable names, we have

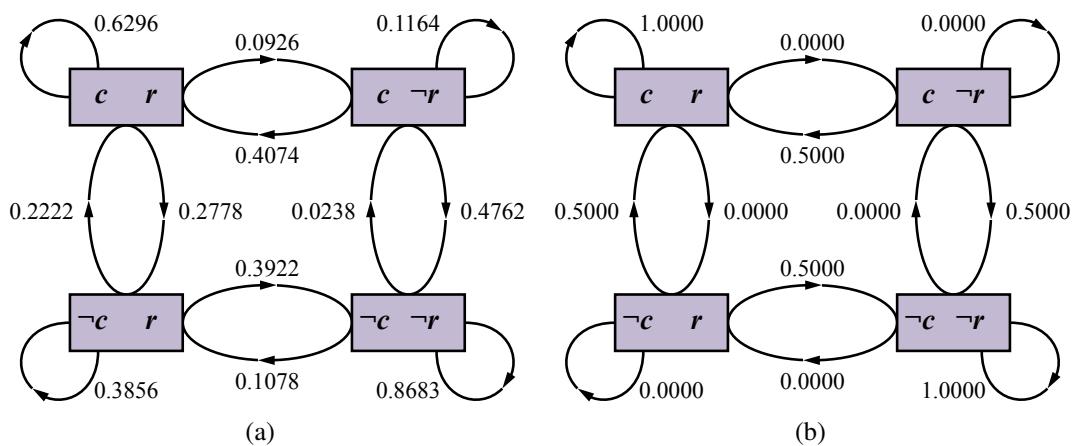

$$\begin{aligned} P(c | s, \neg r) &= \alpha P(c)P(s | c)P(\neg r | c) = \alpha 0.5 \cdot 0.1 \cdot 0.2 \\ P(\neg c | s, \neg r) &= \alpha P(\neg c)P(s | \neg c)P(\neg r | \neg c) = \alpha 0.5 \cdot 0.5 \cdot 0.8, \end{aligned}$$

so the sampling distribution is  $\alpha \langle 0.001, 0.020 \rangle \approx \langle 0.048, 0.952 \rangle$ .

Figure 13.21(a) shows the complete Markov chain for the case where variables are chosen uniformly, i.e.,  $\rho(\text{Cloudy})=\rho(\text{Rain})=0.5$ . The algorithm is simply wandering around in this graph, following links with the stated probabilities. Each state visited during this process is a sample that contributes to the estimate for the query variable *Rain*. If the process visits 20 states where *Rain* is true and 60 states where *Rain* is false, then the answer to the query is  $\text{NORMALIZE}(\langle 20, 60 \rangle) = \langle 0.25, 0.75 \rangle$ .

### Analysis of Markov chains

We have said that Gibbs sampling works by wandering randomly around the state space to generate samples. To explain why Gibbs sampling works *correctly*—that is, why its estimates converge to correct values in the limit—we will need some careful analysis. (This section is somewhat mathematical and can be skipped on first reading.)

**Figure 13.21** (a) The states and transition probabilities of the Markov chain for the query  $\mathbf{P}(\text{Rain} \mid \text{Sprinkler} = \text{true}, \text{WetGrass} = \text{true})$ . Note the self-loops: the state stays the same when either variable is chosen and then resamples the same value it already has. (b) The transition probabilities when the CPT for Rain constrains it to have the same value as Cloudy.

## Transition kernel

We begin with some of the basic concepts for analyzing Markov chains in general. Any such chain is defined by its initial state and its **transition kernel**  $k(\mathbf{x} \rightarrow \mathbf{x}')$ —the probability of a transition to state  $\mathbf{x}'$  starting from state  $\mathbf{x}$ . Now suppose that we run the Markov chain for  $t$  steps, and let  $\pi_t(\mathbf{x})$  be the probability that the system is in state  $\mathbf{x}$  at time  $t$ . Similarly, let  $\pi_{t+1}(\mathbf{x}')$  be the probability of being in state  $\mathbf{x}'$  at time  $t+1$ . Given  $\pi_t(\mathbf{x})$ , we can calculate  $\pi_{t+1}(\mathbf{x}')$  by summing, for all states  $\mathbf{x}$  the system could be in at time  $t$ , the probability of being in  $\mathbf{x}$  times the probability of making the transition to  $\mathbf{x}'$ :

$$\pi_{t+1}(\mathbf{x}') = \sum_{\mathbf{x}} \pi_t(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}').$$

## Stationary distribution

We say that the chain has reached its **stationary distribution** if  $\pi_t = \pi_{t+1}$ . Let us call this stationary distribution  $\pi$ ; its defining equation is therefore

$$\pi(\mathbf{x}') = \sum_{\mathbf{x}} \pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}') \quad \text{for all } \mathbf{x}'. \quad (13.11)$$

## Ergodic

Provided the transition kernel  $k$  is **ergodic**—that is, every state is reachable from every other and there are no strictly periodic cycles—there is exactly one distribution  $\pi$  satisfying this equation for any given  $k$ .

Equation (13.11) can be read as saying that the expected “outflow” from each state (i.e., its current “population”) is equal to the expected “inflow” from all the states. One obvious way to satisfy this relationship is if the expected flow between any pair of states is the same in both directions; that is,

$$\pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}') = \pi(\mathbf{x}') k(\mathbf{x}' \rightarrow \mathbf{x}) \quad \text{for all } \mathbf{x}, \mathbf{x}'. \quad (13.12)$$

## Detailed balance

When these equations hold, we say that  $k(\mathbf{x} \rightarrow \mathbf{x}')$  is in **detailed balance** with  $\pi(\mathbf{x})$ . One special case is the self-loop  $\mathbf{x} = \mathbf{x}'$ , i.e., a transition from a state to itself. In that case, the detailed balance condition becomes  $\pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}) = \pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x})$  which is of course trivially true for any stationary distribution  $\pi$  and any transition kernel  $k$ .

We can show that detailed balance implies stationarity simply by summing over  $\mathbf{x}$  in Equation (13.12). We have

$$\sum_{\mathbf{x}} \pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}') = \sum_{\mathbf{x}} \pi(\mathbf{x}') k(\mathbf{x}' \rightarrow \mathbf{x}) = \pi(\mathbf{x}') \sum_{\mathbf{x}} k(\mathbf{x}' \rightarrow \mathbf{x}) = \pi(\mathbf{x}')$$

where the last step follows because a transition from  $\mathbf{x}'$  is guaranteed to occur.

### Why Gibbs sampling works

We will now show that Gibbs sampling returns consistent estimates for posterior probabilities. The basic claim is straightforward: *the stationary distribution of the Gibbs sampling process is exactly the posterior distribution for the nonevidence variables conditioned on the evidence*. This remarkable property follows from the specific way in which the Gibbs sampling process moves from state to state. 

The general definition of Gibbs sampling is that a variable  $X_i$  is chosen and then sampled conditionally on the current values of *all* the other variables. (When applied specifically to Bayes nets, we simply use the additional fact that sampling conditionally on all variables is equivalent to sampling conditionally on the variable's Markov blanket, as shown on page 437.) We will use the notation  $\bar{\mathbf{X}}_i$  to refer to these other variables (except the evidence variables); their values in the current state are  $\bar{\mathbf{x}}_i$ .

To write down the transition kernel  $k(\mathbf{x} \rightarrow \mathbf{x}')$  for Gibbs sampling, there are three cases to consider:

1. The states  $\mathbf{x}$  and  $\mathbf{x}'$  differ in two or more variables. In that case,  $k(\mathbf{x} \rightarrow \mathbf{x}') = 0$  because Gibbs sampling changes only a single variable.
2. The states differ in exactly one variable  $X_i$  that changes its value from  $x_i$  to  $x'_i$ . The probability of such an occurrence is

$$k(\mathbf{x} \rightarrow \mathbf{x}') = k((x_i, \bar{\mathbf{x}}_i) \rightarrow (x'_i, \bar{\mathbf{x}}_i)) = \rho(i) P(x'_i | \bar{\mathbf{x}}_i). \quad (13.13)$$

3. The states are the same:  $\mathbf{x} = \mathbf{x}'$ . In that case, *any* variable could be chosen but then the sampling process produces the same value the variable already has. The probability of such an occurrence is

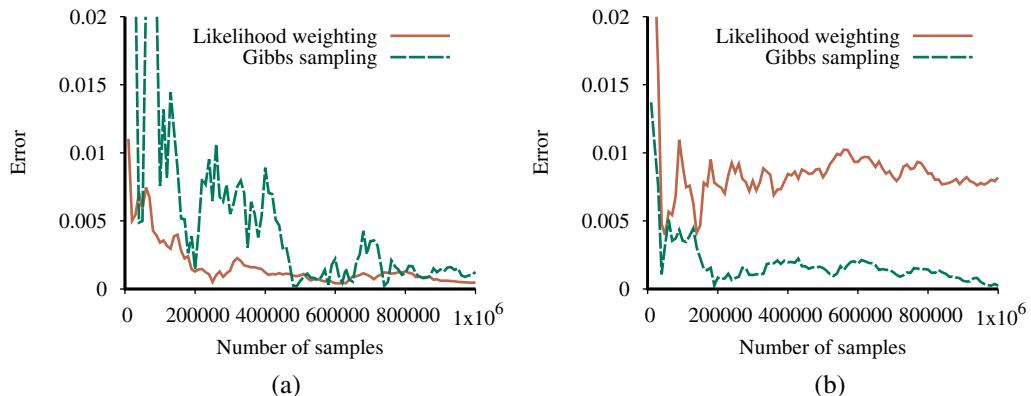

$$k(\mathbf{x} \rightarrow \mathbf{x}) = \sum_i \rho(i) k((x_i, \bar{\mathbf{x}}_i) \rightarrow (x_i, \bar{\mathbf{x}}_i)) = \sum_i \rho(i) P(x_i | \bar{\mathbf{x}}_i).$$

Now we show that this general definition of Gibbs sampling satisfies the detailed balance equation with a stationary distribution equal to  $P(\mathbf{x} | \mathbf{e})$ , the true posterior distribution on the nonevidence variables. That is, we show that  $\pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}') = \pi(\mathbf{x}') k(\mathbf{x}' \rightarrow \mathbf{x})$  where  $\pi(\mathbf{x}) = P(\mathbf{x} | \mathbf{e})$ , for all states  $\mathbf{x}$  and  $\mathbf{x}'$ .

For the first and third cases given above, detailed balance is *always* satisfied: if two states differ in two or more variables, the transition probability in both directions is zero. If  $\mathbf{x} \neq \mathbf{x}'$  then from Equation (13.13), we have

$$\begin{aligned} \pi(\mathbf{x}) k(\mathbf{x} \rightarrow \mathbf{x}') &= P(\mathbf{x} | \mathbf{e}) \rho(i) P(x'_i | \bar{\mathbf{x}}_i, \mathbf{e}) = \rho(i) P(x_i, \bar{\mathbf{x}}_i | \mathbf{e}) P(x'_i | \bar{\mathbf{x}}_i, \mathbf{e}) \\ &= \rho(i) P(x_i | \bar{\mathbf{x}}_i, \mathbf{e}) P(\bar{\mathbf{x}}_i | \mathbf{e}) P(x'_i | \bar{\mathbf{x}}_i, \mathbf{e}) \quad (\text{using the chain rule on the first term}) \\ &= \rho(i) P(x_i | \bar{\mathbf{x}}_i, \mathbf{e}) P(x'_i, \bar{\mathbf{x}}_i | \mathbf{e}) \quad (\text{reverse chain rule on last two terms}) \\ &= \pi(\mathbf{x}') k(\mathbf{x}' \rightarrow \mathbf{x}). \end{aligned}$$

The final piece of the puzzle is the ergodicity of the chain—that is, every state must be reachable from every other and there are no periodic cycles. Both conditions are satisfied provided

**Figure 13.22** Performance of Gibbs sampling compared to likelihood weighting on the car insurance network: (a) for the standard query on *PropertyCost*, and (b) for the case where the output variables are observed and *Age* is the query variable.

the CPTs do not contain probabilities of 0 or 1. Reachability comes from the fact that we can convert one state into another by changing one variable at a time, and the absence of periodic cycles comes from the fact that every state has a self-loop with nonzero probability. Hence, under the stated conditions,  $k$  is ergodic, which means that the samples generated by Gibbs sampling will eventually be drawn from the true posterior distribution.

### Complexity of Gibbs sampling

First, the good news: each Gibbs sampling step involves calculating the Markov blanket distribution for the chosen variable  $X_i$ , which requires a number of multiplications proportional to the number of  $X_i$ 's children and the size of  $X_i$ 's range. This is important because it means that *the work required to generate each sample is independent of the size of the network*.

Now, the not necessarily bad news: the complexity of Gibbs sampling is much harder to analyze than that of rejection sampling and likelihood weighting. The first thing to notice is that Gibbs sampling, unlike likelihood weighting, *does* pay attention to downstream evidence. Information propagates from evidence nodes in all directions: first, any neighbors of the evidence nodes sample values that reflect the evidence in those nodes; then *their* neighbors, and so on. Thus, we expect Gibbs sampling to outperform likelihood weighting when evidence is mostly downstream; and indeed, this is borne out in Figure 13.22.

#### Mixing rate

The rate of convergence for Gibbs sampling—the **mixing rate** of the Markov chain defined by the algorithm—depends strongly on the quantitative properties of the conditional distributions in the network. To see this, consider what happens in Figure 13.15(a) as the CPT for *Rain* becomes deterministic: it rains *if and only if* it is cloudy. In that case, the true posterior distribution for the query  $\mathbf{P}(\text{Rain} \mid \text{sprinkler}, \text{wetGrass})$  is roughly  $\langle 0.18, 0.82 \rangle$  but Gibbs sampling will never reach this value. The problem is that the only two joint states for *Cloudy* and *Rain* that have non-zero probability are  $[\text{true}, \text{true}]$  and  $[\text{false}, \text{false}]$ . Starting in  $[\text{true}, \text{true}]$ , the chain can never reach  $[\text{false}, \text{false}]$  because transitions to the intermediate states have probability zero (see Figure 13.21(b)). So, if the process starts in  $[\text{true}, \text{true}]$  it

always reports a posterior probability for the query of  $\langle 1.0, 0.0 \rangle$ ; if it starts in  $[false, false]$  it always reports a posterior probability for the query of  $\langle 0.0, 1.0 \rangle$ .

Gibbs sampling fails in this case because the deterministic relationship between *Cloudy* and *Rain* breaks the property of ergodicity that is required for convergence. If, however, we make the relationship *nearly* deterministic, then convergence is restored, but happens arbitrarily slowly. There are several fixes that help MCMC algorithms mix more quickly. One is **block sampling**: sampling multiple variables simultaneously. In this case, we could sample *Cloudy* and *Rain* jointly, conditioned on their combined Markov blanket. Another is to generate next states more intelligently, as we will see in the next section.

Block sampling

## Metropolis–Hastings sampling

The Metropolis–Hastings or MH sampling method is perhaps the most broadly applicable MCMC algorithm. Like Gibbs sampling, MH is designed to generate samples  $\mathbf{x}$  (eventually) according to target probabilities  $\pi(\mathbf{x})$ ; in the case of inference in Bayesian networks, we want  $\pi(\mathbf{x}) = P(\mathbf{x} | \mathbf{e})$ . Like simulated annealing (page 133), MH has two stages in each iteration of the sampling process:

1. Sample a new state  $\mathbf{x}'$  from a **proposal distribution**  $q(\mathbf{x}' | \mathbf{x})$ , given the current state  $\mathbf{x}$ .
2. Probabilistically accept or reject  $\mathbf{x}'$  according to the **acceptance probability**

Proposal distribution  
Acceptance probability

$$a(\mathbf{x}' | \mathbf{x}) = \min \left( 1, \frac{\pi(\mathbf{x}') q(\mathbf{x} | \mathbf{x}')}{\pi(\mathbf{x}) q(\mathbf{x}' | \mathbf{x})} \right).$$

If the proposal is rejected, the state remains at  $\mathbf{x}$ .

The transition kernel for MH consists of this two-step process. Note that if the proposal is rejected, the chain stays in the same state.

The proposal distribution is responsible, as its name suggests, for proposing a next state  $\mathbf{x}'$ . For example,  $q(\mathbf{x}' | \mathbf{x})$  could be defined as follows:

- With probability 0.95, perform a Gibbs sampling step to generate  $\mathbf{x}'$ .
- Otherwise, generate  $\mathbf{x}'$  by running the WEIGHTED-SAMPLE algorithm from page 458.

This proposal distribution causes MH to do about 20 steps of Gibbs sampling then “restarts” the process from a new state (assuming it is accepted) that is generated from scratch. By this stratagem, it gets around the problem of Gibbs sampling getting stuck in one part of the state space and being unable to reach the other parts.

You might ask how on Earth we know that MH with such a weird proposal actually converges to the right answer. The remarkable thing about MH is that *convergence to the correct stationary distribution is guaranteed for any proposal distribution*, provided the resulting transition kernel is ergodic.

This property follows from the way the acceptance probability is defined. As with Gibbs sampling, the self-loop with  $\mathbf{x} = \mathbf{x}'$  automatically satisfies detailed balance, so we focus on the case where  $\mathbf{x} \neq \mathbf{x}'$ . This can occur only if the proposal is accepted. The probability of such a transition occurring is

$$k(\mathbf{x} \rightarrow \mathbf{x}') = q(\mathbf{x}' | \mathbf{x})a(\mathbf{x}' | \mathbf{x}).$$

As with Gibbs sampling, proving detailed balance means showing that the flow from  $\mathbf{x}$  to  $\mathbf{x}'$ ,  $\pi(\mathbf{x})k(\mathbf{x} \rightarrow \mathbf{x}')$ , matches the flow from  $\mathbf{x}'$  to  $\mathbf{x}$ ,  $\pi(\mathbf{x}')k(\mathbf{x}' \rightarrow \mathbf{x})$ . After plugging in the

expression above for  $k(\mathbf{x} \rightarrow \mathbf{x}')$ , the proof is quite straightforward:

$$\begin{aligned}\pi(\mathbf{x})q(\mathbf{x}'|\mathbf{x})a(\mathbf{x}'|\mathbf{x}) &= \pi(\mathbf{x})q(\mathbf{x}'|\mathbf{x})\min\left(1, \frac{\pi(\mathbf{x}')q(\mathbf{x}|\mathbf{x}')}{\pi(\mathbf{x})q(\mathbf{x}'|\mathbf{x})}\right) \quad (\text{definition of } a(\cdot|\cdot)) \\ &= \min(\pi(\mathbf{x})q(\mathbf{x}'|\mathbf{x}), \pi(\mathbf{x}')q(\mathbf{x}|\mathbf{x}')) \quad (\text{multiplying in}) \\ &= \pi(\mathbf{x}')q(\mathbf{x}|\mathbf{x}')\min\left(\frac{\pi(\mathbf{x})q(\mathbf{x}'|\mathbf{x})}{\pi(\mathbf{x}')q(\mathbf{x}|\mathbf{x}')}, 1\right) \quad (\text{dividing out}) \\ &= \pi(\mathbf{x}')q(\mathbf{x}|\mathbf{x}')a(\mathbf{x}|\mathbf{x}').\end{aligned}$$

Mathematical properties aside, the important part of MH to focus on is the ratio  $\pi(\mathbf{x}')/\pi(\mathbf{x})$  in the acceptance probability. This says that if a next state is proposed that is *more* likely than the current state, it will definitely be accepted. (We are overlooking, for now, the term  $q(\mathbf{x}|\mathbf{x}')/q(\mathbf{x}'|\mathbf{x})$ , which is there to ensure detailed balance and is, in many state spaces, equal to 1 because of symmetry.) If the proposed state is *less* likely than the current state, its probability of being accepted drops proportionally.

Thus, one guideline for designing proposal distributions is to make sure the new states being proposed are reasonably likely. Gibbs sampling does this automatically: it proposes from the Gibbs distribution  $P(X_i|\bar{\mathbf{x}}_i)$ , which means that the probability of generating any particular new value for  $X_i$  is directly proportional to its probability. (Exercise 13.GIBM asks you to show that Gibbs is a special case of MH with an acceptance probability of 1.)

Another guideline is to make sure that the chain mixes well, which means sometimes proposing large moves to distant parts of the state space. In the example given above, the occasional use of WEIGHTED-SAMPLE to restart the chain in a new state serves this purpose.

Besides near-complete freedom in designing proposal distributions, MH has two additional properties that make it practical. First, the posterior probability  $\pi(\mathbf{x}) = P(\mathbf{x}|\mathbf{e})$  appears in the acceptance calculation only in the form of a ratio  $\pi(\mathbf{x}')/\pi(\mathbf{x})$ , which is very fortunate. Computing  $P(\mathbf{x}|\mathbf{e})$  directly is the very computation we're trying to approximate using MH, so it wouldn't make sense to do it for each sample! Instead, we use the following trick:

$$\frac{\pi(\mathbf{x}')}{\pi(\mathbf{x})} = \frac{P(\mathbf{x}'|\mathbf{e})}{P(\mathbf{x}|\mathbf{e})} = \frac{P(\mathbf{x}', \mathbf{e})}{P(\mathbf{e})} \frac{P(\mathbf{e})}{P(\mathbf{x}, \mathbf{e})} = \frac{P(\mathbf{x}', \mathbf{e})}{P(\mathbf{x}, \mathbf{e})}.$$

The terms in this ratio are full joint probabilities, i.e., products of conditional probabilities in the Bayes net. The second useful property of this ratio is that as long as the proposal distribution makes only local changes in  $\mathbf{x}$  to produce  $\mathbf{x}'$ , only a small number of terms in the product of conditional probabilities will be different. All of the conditional probabilities involving variables whose values are unchanged will cancel out in the ratio. So, as with Gibbs sampling, the work required to generate each sample is independent of the size of the network as long as the state changes are local.

### 13.4.3 Compiling approximate inference

The sampling algorithms in Figures 13.17, 13.18, and 13.20 share a common property: they operate on a Bayes net represented as a data structure. This seems quite natural: after all, a Bayes net is a directed acyclic graph, so how else could it be represented? The problem with this approach is that the operations required to access the data structure—for example to find a node's parents—are repeated thousands or millions of times as the sampling algorithm runs, and *all of these computations are completely unnecessary*.

The network's structure and conditional probabilities remain fixed throughout the computation, so there is an opportunity to *compile* the network into model-specific inference code that carries out just the inference computations needed for that specific network. (In case this sounds familiar, it is the same idea used in the compilation of logic programs in Chapter 9.) For example, suppose we want to Gibbs-sample the *Earthquake* variable in the burglary network of Figure 13.2. According to the GIBBS-ASK algorithm in Figure 13.20, we need to perform the following computation:

set the value of *Earthquake* in  $\mathbf{x}$  by sampling from  $\mathbf{P}(\text{Earthquake} | mb(\text{Earthquake}))$

where the latter distribution is computed according to Equation (13.10), repeated here:

$$P(x_i | mb(X_i)) = \alpha P(x_i | \text{parents}(X_i)) \prod_{Y_j \in \text{Children}(X_i)} P(y_j | \text{parents}(Y_j)).$$

This computation, in turn, requires looking up the parents and children of *Earthquake* in the Bayes net structure; looking up their current values; using those values to index into the corresponding CPTs (which also have to be found from the Bayes net); and multiplying together all the appropriate rows from those CPTs to form a new distribution from which to sample. Finally, as noted on page 454, the sampling step itself has to construct the cumulative version of the discrete distribution and then find the value therein that corresponds to a random number sampled from  $[0, 1]$ .

If, instead, we compile the network, we obtain model-specific sampling code for the *Earthquake* variable that looks like this:

```
r ← a uniform random sample from [0, 1]
if Alarm = true
  then if Burglary = true
    then return [r < 0.0020212]
    else return [r < 0.36755]
  else if Burglary = true
    then return [r < 0.0016672]
  else return [r < 0.0014222]
```

Here, Bayes net variables *Alarm*, *Burglary*, and so on become ordinary program variables with values that comprise the current state of the Markov chain. The numerical threshold expressions evaluate to *true* or *false* and represent the precomputed Gibbs distributions for each combination of values in the Markov blanket of *Earthquake*. The code is not especially pretty—typically, it will be roughly as large as the Bayes net itself—but it is incredibly efficient. Compared to GIBBS-ASK, the compiled code will typically be 2–3 orders of magnitude faster. It can perform tens of millions of sampling steps per second on an ordinary laptop, and its speed is limited largely by the cost of generating random numbers.

## 13.5 Causal Networks

---

We have discussed several advantages of keeping node ordering in Bayes nets compatible with the direction of causation. In particular, we noted the ease with which conditional probabilities can be assessed if such ordering is maintained, as well as the compactness of the resultant network structure. We noted however that, in principle, any node ordering permits

a consistent construction of the network to represent the joint distribution function. This was demonstrated in Figure 13.3, where changing the node ordering produced networks that were bushier and a lot less natural than the original network in Figure 13.2 but enabled us, nevertheless, to represent the same distribution on all variables.

#### Causal network

This section describes **causal networks**, a restricted class of Bayesian networks that forbids all but causally compatible orderings. We will explore how to construct such networks, what is gained by such construction, and how to leverage this gain in decision-making tasks.

Consider the simplest Bayesian network imaginable, a single arrow,  $\text{Fire} \rightarrow \text{Smoke}$ . It tells us that variables  $\text{Fire}$  and  $\text{Smoke}$  may be dependent, so one needs to specify the prior  $P(\text{Fire})$  and the conditional probability  $P(\text{Smoke}|\text{Fire})$  in order to specify the joint distribution  $P(\text{Fire}, \text{Smoke})$ . However, this distribution can be represented equally well by the reverse arrow  $\text{Fire} \leftarrow \text{Smoke}$ , using the appropriate  $P(\text{Smoke})$  and  $P(\text{Fire}|\text{Smoke})$  computed from Bayes' rule. The idea that these two networks are equivalent, hence convey the same information, evokes discomfort and even resistance in most people. How could they convey the same information when we know that  $\text{Fire}$  causes  $\text{Smoke}$  and not the other way around?

In other words, we know from our experience and scientific understanding that clearing the smoke would not stop the fire and extinguishing the fire will stop the smoke. We expect therefore to represent this asymmetry through the directionality of the arrow between them. But if arrow reversal only makes things equivalent, how can we hope to represent this important information formally?

Causal Bayesian networks, sometimes called Causal Diagrams, were devised to permit us to represent causal asymmetries and to leverage the asymmetries towards reasoning with causal information. The idea is to decide on arrow directionality by considerations that go beyond probabilistic dependence and invoke a totally different type of judgment. Instead of asking an expert whether  $\text{Smoke}$  and  $\text{Fire}$  are probabilistically dependent, as we do in ordinary Bayesian networks, we now ask which responds to which,  $\text{Smoke}$  to  $\text{Fire}$  or  $\text{Fire}$  to  $\text{Smoke}$ ?

This may sound a bit mystical, but it can be made precise through the notion of “assignment,” similar to the assignment operator in programming languages. If nature assigns a value to  $\text{Smoke}$  on the basis of what nature learns about  $\text{Fire}$ , we draw an arrow from  $\text{Fire}$  to  $\text{Smoke}$ . More importantly, if we judge that nature assigns  $\text{Fire}$  a truth value that depends on other variables, not  $\text{Smoke}$ , we refrain from drawing the arrow  $\text{Fire} \leftarrow \text{Smoke}$ . In other words, the value  $x_i$  of each variable  $X_i$  is determined by an equation  $x_i = f_i(\text{OtherVariables})$ , and an arrow  $X_j \rightarrow X_i$  is drawn if and only if  $X_j$  is one of the arguments of  $f_i$ .

#### Structural equation

The equation  $x_i = f_i(\cdot)$  is called a **structural equation**, because it describes a stable mechanism in nature which, unlike the probabilities that quantify a Bayesian network, remains invariant to measurements and local changes in the environment.

To appreciate this stability to local changes, consider Figure 13.23(a), which depicts a slightly modified version of the lawn sprinkler story of Figure 13.15. To represent a disabled sprinkler, for example, we simply delete from the network all links incident to the *Sprinkler* node. To represent a lawn covered by a tent, we simply delete the arrow  $\text{Rain} \rightarrow \text{WetGrass}$ . Any local reconfiguration of the mechanisms in the environment can thus be translated, with only minor modification, into an isomorphic reconfiguration of the network topology. A much more elaborate transformation would be required had the network been constructed contrary to causal ordering. This local stability is particularly important for representing actions or interventions, our next topic of discussion.

**Figure 13.23** (a) A causal Bayesian network representing cause–effect relations among five variables. (b) The network after performing the action “turn *Sprinkler* on.”

### 13.5.1 Representing actions: The *do*-operator

Consider again the *Sprinkler* story of Figure 13.23(a). According to the standard semantics of Bayes nets, the joint distribution of the five variables is given by a product of five conditional distributions:

$$P(c, r, s, w, g) = P(c) P(r|c) P(s|c) P(w|r, s) P(g|w) \quad (13.14)$$

where we have abbreviated each variable name by its first letter. As a system of structural equations, the model looks like this:

$$\begin{aligned} C &= f_C(U_C) \\ R &= f_R(C, U_R) \\ S &= f_S(C, U_S) \\ W &= f_W(R, S, U_W) \\ G &= f_G(W, U_G) \end{aligned} \tag{13.15}$$

where, without loss of generality,  $f_C$  can be the identity function. The  $U$ -variables in these equations represent **unmodeled variables**, also called **error terms** or **disturbances**, that perturb the functional relationship between each variable and its parents. For example,  $U_W$  may represent another potential source of wetness, in addition to *Sprinkler* and *Rain*—perhaps *MorningDew* or *FirefightingHelicopter*.

### Unmodeled variable

If all the  $U$ -variables are mutually independent random variables with suitably chosen priors, the joint distribution in Equation (13.14) can be represented exactly by the structural equations in Equation (13.15). Thus, a system of stochastic relationships can be captured by a system of deterministic relationships, each of which is affected by an exogenous disturbance. However, the system of structural equations gives us more than that: it allows us to predict how *interventions* will affect the operation of the system and hence the observable consequences of those interventions. This is not possible given just the joint distribution.

## Chapter 13 Probabilistic Reasoning

For example, suppose we *turn the sprinkler on*—that is, if we (who are, by definition, not part of the causal processes described by the model) *intervene* to impose the condition  $\text{Sprinkler} = \text{true}$ . In the notation of the **do-calculus**, which is a key part of the theory of causal networks, this is written as  $\text{do}(\text{Sprinkler} = \text{true})$ . Once done, this means that the sprinkler variable is no longer dependent on whether it's a cloudy day. We therefore delete the equation  $S = f_S(C, U_S)$  from the system of structural equations and replace it with  $S = \text{true}$ , giving us

$$\begin{aligned} C &= f_C(U_C) \\ R &= f_R(C, U_R) \\ S &= \text{true} \\ W &= f_W(R, S, U_W) \\ G &= f_G(W, U_G). \end{aligned} \tag{13.16}$$

From these equations, we obtain the new joint distribution for the remaining variables conditioned on  $\text{do}(\text{Sprinkler} = \text{true})$ :

$$P(c, r, w, g | \text{do}(S = \text{true})) = P(c) P(r | c) P(w | r, s = \text{true}) P(g | w) \tag{13.17}$$

This corresponds to the “mutilated” network in Figure 13.23(b). From Equation (13.17), we see that the only variables whose probabilities change are *WetGrass* and *GreenerGrass*, that is, the descendants of the manipulated variable *Sprinkler*.

Note the difference between conditioning on the *action*  $\text{do}(\text{Sprinkler} = \text{true})$  in the original network and conditioning on the *observation*  $\text{Sprinkler} = \text{true}$ . The original network tells us that the sprinkler is less likely to be on when the weather is cloudy, so if we *observe* the sprinkler to be on, that reduces the probability that the weather is cloudy. But common sense tells us that if we (operating from outside the world, so to speak) reach in and turn on the sprinkler, that doesn't affect the weather or provide new information about what the weather is like that day. As shown in Figure 13.23(b), intervening breaks the normal causal link between the weather and the sprinkler. This prevents any influence flowing backward from *Sprinkler* to *Cloudy*. Thus, conditioning on  $\text{do}(\text{Sprinkler} = \text{true})$  in the original graph is equivalent to conditioning on  $\text{Sprinkler} = \text{true}$  in the mutilated graph.

A similar approach can be taken to analyze the effect of  $\text{do}(X_j = x_{jk})$  in a general causal network with variables  $X_1, \dots, X_n$ . The network corresponds to a joint distribution defined in the usual way (see Equation (13.2)):

$$P(x_1, \dots, x_n) = \prod_{i=1}^n P(x_i | \text{parents}(X_i)). \tag{13.18}$$

After applying  $\text{do}(X_j = x_{jk})$ , the new joint distribution  $P_{x_{jk}}$  simply omits the factor for  $X_j$ :

$$P_{x_{jk}}(x_1, \dots, x_n) = \begin{cases} \prod_{i \neq j} P(x_i | \text{parents}(X_i)) = \frac{P(x_1, \dots, x_n)}{P(x_j | \text{parents}(X_j))} & \text{if } x_j = x_{jk} \\ 0 & \text{if } x_j \neq x_{jk} \end{cases} \tag{13.19}$$

This follows from the fact that setting  $X_j$  to a particular value  $x_{jk}$  corresponds to deleting the equation  $X_j = f_j(\text{Parents}(X_j), U_j)$  from the system of structural equations and replacing it with  $X_j = x_{jk}$ . With a bit more algebraic manipulation, one can derive a formula for the effect of setting variable  $X_j$  on any other variable  $X_i$ :

$$\begin{aligned} P(X_i = x_i | \text{do}(X_j = x_{jk})) &= P_{x_{jk}}(X_i = x_i) \\ &= \sum_{\text{parents}(X_j)} P(x_i | x_{jk}, \text{parents}(X_j)) P(\text{parents}(X_j)). \end{aligned} \tag{13.20}$$

The probability terms in the sum are obtained by computation on the original network, by any of the standard inference algorithms. This equation is known as an **adjustment formula**; it is a probability-weighted average of the influence of  $X_j$  and its parents on  $X_i$ , where the weights are the priors on the parent values. The effects of intervening on multiple variables can be computed by imagining that the individual interventions happen in sequence, each one in turn deleting the causal influences on a variable and yielding a new, mutilated model.

Adjustment formula

### 13.5.2 The back-door criterion

The ability to predict the effect of any intervention is a remarkable result, but it does require accurate knowledge of the necessary conditional distributions in the model, particularly  $P(x_j | \text{parents}(X_j))$ . In many real-world settings, however, this is too much to ask. For example, we know that “genetic factors” play a role in obesity, but we do not know which genes play a role or the precise nature of their effects. Even in the simple story of Mary’s sprinkler decisions (Figure 13.15, which also applies in Figure 13.23(a)), we might know that she checks the weather before deciding whether to turn on the sprinkler, but we might not know how she makes her decision.

The specific reason this is problematic in this instance is that we would like to predict the effect of turning on the sprinkler on a downstream variable such as *GreenerGrass*, but the adjustment formula (Equation (13.20)) must take into account not only the direct route from *Sprinkler*, but also the “back door” route via *Cloudy* and *Rain*. If we knew the value of *Rain*, this back-door path would be blocked—which suggests that there might be a way to write an adjustment formula that conditions on *Rain* instead of *Cloudy*. And indeed this is possible:

$$P(g | \text{do}(S = \text{true})) = \sum_r P(g | S = \text{true}, r) P(r) \quad (13.21)$$

In general, if we wish to find the effect of  $\text{do}(X_j = x_{jk})$  on a variable  $X_i$ , the **back-door criterion** allows us to write an adjustment formula that conditions on any set of variables  $Z$  that closes the back door, so to speak. In more technical language, we want a set  $Z$  such that  $X_i$  is conditionally independent of  $\text{Parents}(X_j)$  given  $X_j$  and  $Z$ . This is a straightforward application of d-separation (see page 437).

Back-door criterion

The back-door criterion is a basic building block for a theory of causal reasoning that has emerged in the past two decades. It provides a way to argue against a century of statistical dogma asserting that only a **randomized controlled trial** can provide causal information. The theory has provided conceptual tools and algorithms for causal analysis in a wide range of non-experimental and quasi-experimental settings; for computing probabilities on counterfactual statements (“if this had happened instead, what would the probability have been?”); for determining when findings in one population can be transferred to another; and for handling all forms of missing data when learning probability models.

Randomized controlled trial

## Summary

---

This chapter has described **Bayesian networks**, a well-developed representation for uncertain knowledge. Bayesian networks play a role roughly analogous to that of propositional logic for definite knowledge.

- A Bayesian network is a directed acyclic graph whose nodes correspond to random variables; each node has a conditional distribution for the node, given its parents.
- Bayesian networks provide a concise way to represent **conditional independence** relationships in the domain.
- A Bayesian network specifies a joint probability distribution over its variables. The probability of any given assignment to all the variables is defined as the product of the corresponding entries in the local conditional distributions. A Bayesian network is often exponentially smaller than an explicitly enumerated joint distribution.
- Many conditional distributions can be represented compactly by canonical families of distributions. **Hybrid Bayesian networks**, which include both discrete and continuous variables, use a variety of canonical distributions.
- Inference in Bayesian networks means computing the probability distribution of a set of query variables, given a set of evidence variables. Exact inference algorithms, such as **variable elimination**, evaluate sums of products of conditional probabilities as efficiently as possible.
- In **polytrees** (singly connected networks), exact inference takes time linear in the size of the network. In the general case, the problem is intractable.
- Random sampling techniques such as **likelihood weighting** and **Markov chain Monte Carlo** can give reasonable estimates of the true posterior probabilities in a network and can cope with much larger networks than can exact algorithms.
- Whereas Bayes nets capture probabilistic influences, **causal networks** capture causal relationships and allow prediction of the effects of interventions as well as observations.

## Bibliographical and Historical Notes

---

The use of networks to represent probabilistic information began early in the 20th century, with the work of Sewall Wright on the probabilistic analysis of genetic inheritance and animal growth factors (Wright, 1921, 1934). I. J. Good (1961), in collaboration with Alan Turing, developed probabilistic representations and Bayesian inference methods that could be regarded as a forerunner of modern Bayesian networks—although the paper is not often cited in this context.<sup>7</sup> The same paper is the original source for the noisy-OR model.

The **influence diagram** representation for decision problems, which incorporated a DAG representation for random variables, was used in decision analysis in the late 1970s (see Chapter 15), but only enumeration was used for evaluation. Judea Pearl developed the message-passing method for inference in tree networks (Pearl, 1982a) and polytree networks (Kim and Pearl, 1983) and explained the importance of causal rather than diagnostic probability models. The first expert system using Bayesian networks was CONVINCE (Kim, 1983).

As chronicled in Chapter 1, the mid-1980s saw a boom in rule-based expert systems, which incorporated ad hoc methods for handling uncertainty. Probability was considered both impractical and “cognitively implausible” as a basis for reasoning. Peter Cheeseman’s (1985)

<sup>7</sup> I. J. Good was chief statistician for Turing’s code-breaking team in World War II. In *2001: A Space Odyssey* (Clarke, 1968), Good and Minsky are credited with making the breakthrough that led to the development of the HAL 9000 computer.

pugnacious “In Defense of Probability” and his later article “An Inquiry into Computer Understanding” (Cheeseman, 1988, with commentaries) helped to turn the tables.

The resurgence of probability depended mainly, however, on Pearl’s development of Bayesian networks and the broad development of a probabilistic approach to AI as outlined in his book, *Probabilistic Reasoning in Intelligent Systems* (Pearl, 1988). The book covered both representational issues, including conditional independence relationships and the d-separation criterion, and algorithmic approaches. Geiger *et al.* (1990a) and Tian *et al.* (1998) presented key computational results on efficient detection of d-separation.

Eugene Charniak helped present Pearl’s ideas to AI researchers with a popular article, “Bayesian networks without tears”<sup>8</sup> (1991), and book (1993). The book by Dean and Wellman (1991) also helped introduce Bayesian networks to AI researchers. Shachter (1998) presented a simplified way to determine d-separation called the “Bayes-ball” algorithm.

As applications of Bayes nets were developed, researchers found it necessary to go beyond the basic model of discrete variables with CPTs. For example, the CPCS system (Pradhan *et al.*, 1994), a Bayesian network for internal medicine with 448 nodes and 906 links, made extensive use of the noisy logical operators proposed by Good (1961). Boutilier *et al.* (1996) analyzed the algorithmic benefits of context-specific independence. The inclusion of continuous random variables in Bayesian networks was considered by Pearl (1988) and Shachter and Kenley (1989); these papers discussed networks containing only continuous variables with linear Gaussian distributions.

Hybrid networks with both discrete and continuous variables were investigated by Lauritzen and Wermuth (1989) and implemented in the cHUGIN system (Olesen, 1993). Further analysis of linear–Gaussian models, with connections to many other models used in statistics, appears in Roweis and Ghahramani (1999); Lerner (2002) provides a very thorough discussion of their use in hybrid Bayes nets. The probit distribution is usually attributed to Gaddum (1933) and Bliss (1934), although it had been discovered several times in the 19th century. Bliss’s work was expanded considerably by Finney (1947). The probit has been used widely for modeling discrete choice phenomena and can be extended to handle more than two choices (Daganzo, 1979). The expit (inverse logit) model was introduced by Berkson (1944); initially much derided, it eventually became more popular than the probit model. Bishop (1995) gives a simple justification for its use.

Early applications of Bayes nets in medicine included the MUNIN system for diagnosing neuromuscular disorders (Andersen *et al.*, 1989) and the PATHFINDER system for pathology (Heckerman, 1991). Applications in engineering include the Electric Power Research Institute’s work on monitoring power generators (Morjaria *et al.*, 1995), NASA’s work on displaying time-critical information at Mission Control in Houston (Horvitz and Barry, 1995), and the general field of **network tomography**, which aims to infer unobserved local properties of nodes and links in the Internet from observations of end-to-end message performance (Castro *et al.*, 2004). Perhaps the most widely used Bayesian network systems have been the diagnosis-and-repair modules (e.g., the Printer Wizard) in Microsoft Windows (Breese and Heckerman, 1996) and the Office Assistant in Microsoft Office (Horvitz *et al.*, 1998).

Another important application area is biology: the mathematical models used to analyze genetic inheritance in family trees (so-called **pedigree analysis**) are in fact a special form

Pedigree analysis

<sup>8</sup> The title of the original version of the article was “Pearl for swine.”

of Bayesian networks. Exact inference algorithms for pedigree analysis, resembling variable elimination, were developed in the 1970s (Cannings *et al.*, 1978). Bayesian networks have been used for identifying human genes by reference to mouse genes (Zhang *et al.*, 2003), inferring cellular networks (Friedman, 2004), genetic linkage analysis to locate disease-related genes (Silberstein *et al.*, 2013), and many other tasks in bioinformatics. We could go on, but instead we'll refer you to Pourret *et al.* (2008), a 400-page guide to applications of Bayesian networks. Published applications over the last decade run into the tens of thousands, ranging from dentistry to global climate models.

Judea Pearl (1985), in the first paper to use the term “Bayesian networks,” briefly described an inference algorithm for general networks based on the cutset conditioning idea introduced in Chapter 5. Independently, Ross Shachter (1986), working in the influence diagram community, developed a complete algorithm based on goal-directed reduction of the network using posterior-preserving transformations.

Pearl (1986) developed a clustering algorithm for exact inference in general Bayesian networks, utilizing a conversion to a directed polytree of clusters in which message passing was used to achieve consistency over variables shared between clusters. A similar approach, developed by the statisticians David Spiegelhalter and Steffen Lauritzen (Lauritzen and Spiegelhalter, 1988), is based on conversion to an undirected form of graphical model called a **Markov network**. This approach is implemented in the HUGIN system, an efficient and widely used tool for uncertain reasoning (Andersen *et al.*, 1989).

The basic idea of variable elimination—that repeated computations within the overall sum-of-products expression can be avoided by caching—appeared in the symbolic probabilistic inference (SPI) algorithm (Shachter *et al.*, 1990). The elimination algorithm we describe is closest to that developed by Zhang and Poole (1994). Criteria for pruning irrelevant variables were developed by Geiger *et al.* (1990b) and by Lauritzen *et al.* (1990); the criterion we give is a simple special case of these. Dechter (1999) shows how the variable elimination idea is essentially identical to **nonserial dynamic programming** (Bertele and Brioschi, 1972).

This connects Bayesian network algorithms to related methods for solving CSPs and gives a direct measure of the complexity of exact inference in terms of the tree width of the network. Preventing the exponential growth in the size of factors in variable elimination can be done by dropping variables from large factors (Dechter and Rish, 2003); it is also possible to bound the error introduced thereby (Wexler and Meek, 2009). Alternatively, factors can be compressed by representing them using algebraic decision diagrams instead of tables (Gogate and Domingos, 2011).

Exact methods based on recursive enumeration (see Figure 13.11) combined with caching include the recursive conditioning algorithm (Darwiche, 2001), the value elimination algorithm (Bacchus *et al.*, 2003), and AND–OR search (Dechter and Mateescu, 2007). The method of weighted model counting (Sang *et al.*, 2005; Chavira and Darwiche, 2008) is usually based on a DPLL-style SAT solver (see Figure 7.17 on page 252). As such, it is also performing a recursive enumeration of variable assignments with caching, so the approach is in fact quite similar. All three of these algorithms can implement a complete range of space/time tradeoffs. Because they consider variable assignments, the algorithms can easily take advantage of determinism and context-specific independence in the model. They can also be modified to use an efficient linear-time algorithm whenever the partial assignment makes the remaining network a polytree. (This is a version of the method of **cutset conditioning**, which was described

for CSPs in Chapter 5.) For exact inference in large models, where the space requirements of clustering and variable elimination become enormous, these recursive algorithms are often the most practical approach.

There are other important inference tasks in Bayes nets besides computing marginal probabilities. The **most probable explanation** or MPE is the most likely assignment to the nonevidence variables given the evidence. (MPE is a special case of MAP—maximum a posteriori—inference, which asks for the most likely assignment to a *subset* of nonevidence variables given the evidence.) For such problems, many different algorithms have been developed, some related to shortest-path or AND–OR search algorithms; for a summary, see Marinescu and Dechter (2009).

The first result on the complexity of inference in Bayes nets is due to Cooper (1990), who showed that the general problem of computing marginals in Bayesian networks is NP-hard; as noted in the chapter, this can be strengthened to #P-hardness through a reduction from counting satisfying assignments (Roth, 1996). This also implies the NP-hardness of approximate inference (Dagum and Luby, 1993); however, for the case where probabilities can be bounded away from 0 and 1, a form of likelihood weighting converges in (randomized) polynomial time (Dagum and Luby, 1997). Shimony (1994) showed that finding the most probable explanation is NP-complete—intractable, but somewhat easier than computing marginals—while Park and Darwiche (2004) provide a thorough complexity analysis of MAP computation, showing that it falls into the class of NP<sup>PP</sup>-complete problems—that is, somewhat harder than computing marginals.

The development of fast approximation algorithms for Bayesian network inference is a very active area, with contributions from statistics, computer science, and physics. The rejection sampling method is a general technique dating back at least to Buffon’s needle (1777); it was first applied to Bayesian networks by Max Henrion (1988), who called it **logic sampling**. Importance sampling was invented originally for applications in physics (Kahn, 1950a, 1950b) and applied to Bayes net inference by Fung and Chang (1989) (who called the algorithm “evidence weighting”) and by Shachter and Peot (1989).

In statistics, **adaptive sampling** has been applied to all sorts of Monte Carlo algorithms to speed up convergence. The basic idea is to adapt the distribution from which samples are generated, based on the outcome from previous samples. Gilks and Wild (1992) developed adaptive rejection sampling, while adaptive importance sampling appears to have originated independently in physics (Lepage, 1978), civil engineering (Karamchandani *et al.*, 1989), statistics (Oh and Berger, 1992), and computer graphics (Veach and Guibas, 1995). Cheng and Druzdzel (2000) describe an adaptive version of importance sampling applied to Bayes net inference. More recently, Le *et al.* (2017) have demonstrated the use of deep learning systems to produce proposal distributions that speed up importance sampling by many orders of magnitude.

Markov chain Monte Carlo (MCMC) algorithms began with the Metropolis algorithm, due to Metropolis *et al.* (1953), which was also the source of the simulated annealing algorithm described in Chapter 4. Hastings (1970) introduced the accept/reject step that is an integral part of what we now call the Metropolis–Hastings algorithm. The Gibbs sampler was devised by Geman and Geman (1984) for inference in undirected Markov networks. The application of Gibbs sampling to Bayesian networks is due to Pearl (1987). The papers collected by Gilks *et al.* (1996) cover both theory and applications of MCMC.

Most probable explanation

Since the mid-1990s, MCMC has become the workhorse of Bayesian statistics and statistical computation in many other disciplines including physics and biology. The *Handbook of Markov Chain Monte Carlo* (Brooks *et al.*, 2011) covers many aspects of this literature. The BUGS package (Gilks *et al.*, 1994) was an early and influential system for Bayes net modeling and inference using Gibbs sampling. STAN (named after Stanislaw Ulam, an originator of Monte Carlo methods in physics) is a more recent system that uses Hamiltonian Monte Carlo inference (Carpenter *et al.*, 2017).

There are two very important families of approximation methods that we did not cover in the chapter. The first is the family of **variational approximation** methods, which can be used to simplify complex calculations of all kinds. The basic idea is to propose a reduced version of the original problem that is simple to work with, but that resembles the original problem as closely as possible. The reduced problem is described by some **variational parameters**  $\lambda$  that are adjusted to minimize a distance function  $D$  between the original and the reduced problem, often by solving the system of equations  $\partial D / \partial \lambda = 0$ . In many cases, strict upper and lower bounds can be obtained. Variational methods have long been used in statistics (Rustagi, 1976). In statistical physics, the **mean-field** method is a particular variational approximation in which the individual variables making up the model are assumed to be completely independent.

This idea was applied to solve large undirected Markov networks (Peterson and Anderson, 1987; Parisi, 1988). Saul *et al.* (1996) developed the mathematical foundations for applying variational methods to Bayesian networks and obtained accurate lower-bound approximations for sigmoid networks with the use of mean-field methods. Jaakkola and Jordan (1996) extended the methodology to obtain both lower and upper bounds. Since these early papers, variational methods have been applied to many specific families of models. The remarkable paper by Wainwright and Jordan (2008) provides a unifying theoretical analysis of the literature on variational methods.

A second important family of approximation algorithms is based on Pearl’s polytree message-passing algorithm (1982a). This algorithm can be applied to general “loopy” networks, as suggested by Pearl (1988). The results might be incorrect, or the algorithm might fail to terminate, but in many cases, the values obtained are close to the true values. Little attention was paid to this so-called **loopy belief propagation** approach until McEliece *et al.* (1998) observed that it is exactly the computation performed by the **turbo decoding** algorithm (Berrou *et al.*, 1993), which provided a major breakthrough in the design of efficient error-correcting codes.

The implication of these observations is if loopy BP is both fast and accurate on the very large and very highly connected networks used for decoding, it might therefore be useful more generally. Theoretical support for these findings, including convergence proofs for some special cases, was provided by Weiss (2000b), Weiss and Freeman (2001), and Yedidia *et al.* (2005), drawing on connections to ideas from statistical physics.

Theories of causal inference going beyond randomized controlled trials were proposed by Rubin (1974) and Robins (1986), but these ideas remained both obscure and controversial until Judea Pearl developed and presented a fully articulated theory of causality based on causal networks (Pearl, 2000). Peters *et al.* (2017) further develop the theory, with an emphasis on learning. A more recent work, *The Book of Why* (Pearl and McKenzie, 2018), provides a less mathematical but more readable and wide-ranging introduction.

Loopy belief  
propagation  
Turbo decoding

Uncertain reasoning in AI has not always been based on probability theory. As noted in Chapter 12, early probabilistic systems fell out of favor in the early 1970s, leaving a partial vacuum to be filled by alternative methods. These included rule-based expert systems, Dempster–Shafer theory, and (to some extent) fuzzy logic.<sup>9</sup>

Rule-based approaches to uncertainty hoped to build on the success of logical rule-based systems, but add a sort of “fudge factor”—more politely called a **certainty factor**—to each rule to accommodate uncertainty. The first such system was MYCIN (Shortliffe, 1976), a medical expert system for bacterial infections. The collection *Rule-Based Expert Systems* (Buchanan and Shortliffe, 1984) provides a complete overview of MYCIN and its descendants (see also Stefik, 1995).

David Heckerman (1986) showed that a slightly modified version of certainty factor calculations gives correct probabilistic results in some cases, but results in serious overcounting of evidence in other cases. As rule sets became larger, undesirable interactions between rules became more common, and practitioners found that the certainty factors of many other rules had to be “tweaked” when new rules were added. The basic mathematical properties that allow *chains* of reasoning in logic simply do not hold for probability.

Dempster–Shafer theory originates with a paper by Arthur Dempster (1968) proposing a generalization of probability to interval values and a combination rule for using them. Such an approach might alleviate the difficulty of specifying probabilities exactly. Later work by Glenn Shafer (1976) led to the Dempster–Shafer theory’s being viewed as a competing approach to probability. Pearl (1988) and Ruspini *et al.* (1992) analyze the relationship between the Dempster–Shafer theory and standard probability theory. In many cases, probability theory does not require probabilities to be specified exactly: we can express uncertainty about probability values as (second-order) probability distributions, as explained in Chapter 21.

**Fuzzy sets** were developed by Lotfi Zadeh (1965) in response to the perceived difficulty of providing exact inputs to intelligent systems. A fuzzy set is one in which membership is a matter of degree. **Fuzzy logic** is a method for reasoning with logical expressions describing membership in fuzzy sets. **Fuzzy control** is a methodology for constructing control systems in which the mapping between real-valued input and output parameters is represented by fuzzy rules. Fuzzy control has been very successful in commercial products such as automatic transmissions, video cameras, and electric shavers. The text by Zimmermann (2001) provides a thorough introduction to fuzzy set theory; papers on fuzzy applications are collected in Zimmermann (1999).

Fuzzy logic has often been perceived incorrectly as a direct competitor to probability theory, whereas in fact it addresses a different set of issues: rather than considering uncertainty about the truth of well-defined propositions, fuzzy logic handles **vagueness** in the mapping from terms in a symbolic theory to an actual world. Vagueness is a real issue in any application of logic, probability, or indeed standard mathematical models to reality. Even a variable as impeccable as the mass of the Earth turns out, on inspection, to vary with time as meteorites and molecules come and go. It is also imprecise—does it include the atmosphere? If so, to what height? In some cases, further elaboration of the model can reduce vagueness, but fuzzy logic takes vagueness as a given and develops a theory around it.

<sup>9</sup> A fourth approach, **default reasoning**, treats conclusions not as “believed to a certain degree,” but as “believed until a better reason is found to believe something else.” It is covered in Chapter 10.

[Possibility theory](#)

**Possibility theory** (Zadeh, 1978) was introduced to handle uncertainty in fuzzy systems and has much in common with probability (Dubois and Prade, 1994).

Many AI researchers in the 1970s rejected probability because the numerical calculations that probability theory was thought to require were not apparent to introspection and presumed an unrealistic level of precision in our uncertain knowledge. The development of **qualitative probabilistic networks** (Wellman, 1990a) provided a purely qualitative abstraction of Bayesian networks, using the notion of positive and negative influences between variables. Wellman shows that in many cases such information is sufficient for optimal decision making without the need for the precise specification of probability values. Goldszmidt and Pearl (1996) take a similar approach. Work by Darwiche and Ginsberg (1992) extracts the basic properties of conditioning and evidence combination from probability theory and shows that they can also be applied in logical and default reasoning.

Several excellent texts (Jensen, 2007; Darwiche, 2009; Koller and Friedman, 2009; Korb and Nicholson, 2010; Dechter, 2019) provide thorough treatments of the topics we have covered in this chapter. New research on probabilistic reasoning appears both in mainstream AI journals, such as *Artificial Intelligence* and the *Journal of AI Research*, and in more specialized journals, such as the *International Journal of Approximate Reasoning*. Many papers on graphical models, which include Bayesian networks, appear in statistical journals. The proceedings of the conferences on Uncertainty in Artificial Intelligence (UAI), Neural Information Processing Systems (NeurIPS), and Artificial Intelligence and Statistics (AISTATS) are good sources for current research.

# CHAPTER 14

## PROBABILISTIC REASONING OVER TIME

*In which we try to interpret the present, understand the past, and perhaps predict the future, even when very little is crystal clear.*

Agents in partially observable environments must be able to keep track of the current state, to the extent that their sensors allow. In Section 4.4 we showed a methodology for doing that: an agent maintains a **belief state** that represents which states of the world are currently possible. From the belief state and a **transition model**, the agent can predict how the world might evolve in the next time step. From the percepts observed and a **sensor model**, the agent can update the belief state. This is a pervasive idea: in Chapter 4 belief states were represented by explicitly enumerated sets of states, whereas in Chapters 7 and 11 they were represented by logical formulas. Those approaches defined belief states in terms of which world states were *possible*, but could say nothing about which states were *likely* or *unlikely*. In this chapter, we use probability theory to quantify the degree of belief in elements of the belief state.

As we show in Section 14.1, time itself is handled in the same way as in Chapter 7: a changing world is modeled using a variable for each aspect of the world state *at each point in time*. The transition and sensor models may be uncertain: the transition model describes the probability distribution of the variables at time  $t$ , given the state of the world at past times, while the sensor model describes the probability of each percept at time  $t$ , given the current state of the world. Section 14.2 defines the basic inference tasks and describes the general structure of inference algorithms for temporal models. Then we describe three specific kinds of models: **hidden Markov models**, **Kalman filters**, and **dynamic Bayesian networks** (which include hidden Markov models and Kalman filters as special cases).

### 14.1 Time and Uncertainty

---

We have developed our techniques for probabilistic reasoning in the context of *static* worlds, in which each random variable has a single fixed value. For example, when repairing a car, we assume that whatever is broken remains broken during the process of diagnosis; our job is to infer the state of the car from observed evidence, which also remains fixed.

Now consider a slightly different problem: treating a diabetic patient. As in the case of car repair, we have evidence such as recent insulin doses, food intake, blood sugar measurements, and other physical signs. The task is to assess the current state of the patient, including the actual blood sugar level and insulin level. Given this information, we can make a decision about the patient's food intake and insulin dose. Unlike the case of car repair, here the

*dynamic* aspects of the problem are essential. Blood sugar levels and measurements thereof can change rapidly over time, depending on recent food intake and insulin doses, metabolic activity, the time of day, and so on. To assess the current state from the history of evidence and to predict the outcomes of treatment actions, we must model these changes.

The same considerations arise in many other contexts, such as tracking the location of a robot, tracking the economic activity of a nation, and making sense of a spoken or written sequence of words. How can dynamic situations like these be modeled?

### 14.1.1 States and observations

Discrete time

Time slice

This chapter discusses **discrete-time** models, in which the world is viewed as a series of snapshots or **time slices**.<sup>1</sup> We'll just number the time slices 0, 1, 2, and so on, rather than assigning specific times to them. Typically, the time interval  $\Delta$  between slices is assumed to be the same for every interval. For any particular application, a specific value of  $\Delta$  has to be chosen. Sometimes this is dictated by the sensor; for example, a video camera might supply images at intervals of 1/30 of a second. In other cases, the interval is dictated by the typical rates of change of the relevant variables; for example, in the case of blood glucose monitoring, things can change significantly in the course of ten minutes, so a one-minute interval might be appropriate. On the other hand, in modeling continental drift over geological time, an interval of a million years might be fine.

Each time slice in a discrete-time probability model contains a set of random variables, some observable and some not. For simplicity, we will assume that the same subset of variables is observable in each time slice (although this is not strictly necessary in anything that follows). We will use  $\mathbf{X}_t$  to denote the set of state variables at time  $t$ , which are assumed to be unobservable, and  $\mathbf{E}_t$  to denote the set of observable evidence variables. The observation at time  $t$  is  $\mathbf{E}_t = \mathbf{e}_t$  for some set of values  $\mathbf{e}_t$ .

Consider the following example: You are the security guard stationed at a secret underground installation. You want to know whether it's raining today, but your only access to the outside world occurs each morning when you see the director coming in with, or without, an umbrella. For each day  $t$ , the set  $\mathbf{E}_t$  thus contains a single evidence variable  $\text{Umbrella}_t$  or  $U_t$  for short (whether the umbrella appears), and the set  $\mathbf{X}_t$  contains a single state variable  $\text{Rain}_t$  or  $R_t$  for short (whether it is raining). Other problems can involve larger sets of variables. In the diabetes example, the evidence variables might be  $\text{MeasuredBloodSugar}_t$  and  $\text{PulseRate}_t$ , while the state variables might include  $\text{BloodSugar}_t$  and  $\text{StomachContents}_t$ . (Notice that  $\text{BloodSugar}_t$  and  $\text{MeasuredBloodSugar}_t$  are not the same variable; this is how we deal with noisy measurements of actual quantities.)

We will assume that the state sequence starts at  $t=0$  and evidence starts arriving at  $t=1$ . Hence, our umbrella world is represented by state variables  $R_0, R_1, R_2, \dots$  and evidence variables  $U_1, U_2, \dots$ . We will use the notation  $a:b$  to denote the sequence of integers from  $a$  to  $b$  inclusive and the notation  $\mathbf{X}_{a:b}$  to denote the set of variables from  $\mathbf{X}_a$  to  $\mathbf{X}_b$  inclusive. For example,  $U_{1:3}$  corresponds to  $U_1, U_2, U_3$ . (Note that this is different from the notation used in programming languages such as Python and Go, where  $U[1:3]$  would *not* include  $U[3]$ .)

---

<sup>1</sup> Uncertainty over *continuous* time can be modeled by **stochastic differential equations** (SDEs). The models studied in this chapter can be viewed as discrete-time approximations to SDEs.

**Figure 14.1** (a) Bayesian network structure corresponding to a first-order Markov process with state defined by the variables  $\mathbf{X}_t$ . (b) A second-order Markov process.

### 14.1.2 Transition and sensor models

With the set of state and evidence variables for a given problem decided on, the next step is to specify how the world evolves (the transition model) and how the evidence variables get their values (the sensor model).

The transition model specifies the probability distribution over the latest state variables, given the previous values, that is,  $\mathbf{P}(\mathbf{X}_t | \mathbf{X}_{0:t-1})$ . Now we face a problem: the set  $\mathbf{X}_{0:t-1}$  is unbounded in size as  $t$  increases. We solve the problem by making a **Markov assumption**—that the current state depends on only a *finite fixed number* of previous states. Processes satisfying this assumption were first studied in depth by the statistician Andrei Markov (1856–1922) and are called **Markov processes** or **Markov chains**. They come in various flavors; the simplest is the **first-order Markov process**, in which the current state depends only on the previous state and not on any earlier states. In other words, a state provides enough information to make the future conditionally independent of the past, and we have

$$\mathbf{P}(\mathbf{X}_t | \mathbf{X}_{0:t-1}) = \mathbf{P}(\mathbf{X}_t | \mathbf{X}_{t-1}). \quad (14.1)$$

Hence, in a first-order Markov process, the transition model is the conditional distribution  $\mathbf{P}(\mathbf{X}_t | \mathbf{X}_{t-1})$ . The transition model for a second-order Markov process is the conditional distribution  $\mathbf{P}(\mathbf{X}_t | \mathbf{X}_{t-2}, \mathbf{X}_{t-1})$ . Figure 14.1 shows the Bayesian network structures corresponding to first-order and second-order Markov processes.

Even with the Markov assumption there is still a problem: there are infinitely many possible values of  $t$ . Do we need to specify a different distribution for each time step? We avoid this problem by assuming that changes in the world state are caused by a **time-homogeneous** process—that is, a process of change that is governed by laws that do not themselves change over time. In the umbrella world, then, the conditional probability of rain,  $\mathbf{P}(R_t | R_{t-1})$ , is the same for all  $t$ , and we need specify only one conditional probability table.

Now for the sensor model. The evidence variables  $\mathbf{E}_t$  could depend on previous variables as well as the current state variables, but any state that's worth its salt should suffice to generate the current sensor values. Thus, we make a **sensor Markov assumption** as follows:

$$\mathbf{P}(\mathbf{E}_t | \mathbf{X}_{0:t}, \mathbf{E}_{1:t-1}) = \mathbf{P}(\mathbf{E}_t | \mathbf{X}_t). \quad (14.2)$$

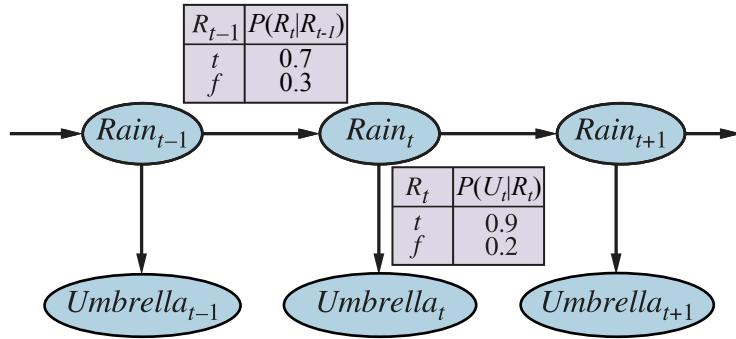

Thus,  $\mathbf{P}(\mathbf{E}_t | \mathbf{X}_t)$  is our sensor model (sometimes called the **observation model**). Figure 14.2 shows both the transition model and the sensor model for the umbrella example. Notice the direction of the dependence between state and sensors: the arrows go from the actual state of the world to sensor values because the state of the world *causes* the sensors to take on particular values: the rain *causes* the umbrella to appear. (The inference process, of course,

Markov assumption

Markov process  
First-order Markov process

Time-homogeneous

Sensor Markov assumption

**Figure 14.2** Bayesian network structure and conditional distributions describing the umbrella world. The transition model is  $\mathbf{P}(Rain_t | Rain_{t-1})$  and the sensor model is  $\mathbf{P}(Umbrella_t | Rain_t)$ .

goes in the other direction; the distinction between the direction of modeled dependencies and the direction of inference is one of the principal advantages of Bayesian networks.)

In addition to specifying the transition and sensor models, we need to say how everything gets started—the prior probability distribution at time 0,  $\mathbf{P}(\mathbf{X}_0)$ . With that, we have a specification of the complete joint distribution over all the variables, using Equation (13.2). For any time step  $t$ ,

$$\mathbf{P}(\mathbf{X}_{0:t}, \mathbf{E}_{1:t}) = \mathbf{P}(\mathbf{X}_0) \prod_{i=1}^t \mathbf{P}(\mathbf{X}_i | \mathbf{X}_{i-1}) \mathbf{P}(\mathbf{E}_i | \mathbf{X}_i). \quad (14.3)$$

The three terms on the right-hand side are the initial state model  $\mathbf{P}(\mathbf{X}_0)$ , the transition model  $\mathbf{P}(\mathbf{X}_i | \mathbf{X}_{i-1})$ , and the sensor model  $\mathbf{P}(\mathbf{E}_i | \mathbf{X}_i)$ . This equation defines the semantics of the family of temporal models represented by the three terms. Notice that standard Bayesian networks cannot represent such models because they require a finite set of variables. The ability to handle an infinite set of variables comes from two things: first, defining the infinite set using integer indices; and second, the use of implicit universal quantification (see Section 8.2) to define the sensor and transition models for every time step.

The structure in Figure 14.2 is a first-order Markov process—the probability of rain is assumed to depend only on whether it rained the previous day. Whether such an assumption is reasonable depends on the domain itself. The first-order Markov assumption says that the state variables contain *all* the information needed to characterize the probability distribution for the next time slice. Sometimes the assumption is exactly true—for example, if a particle is executing a random walk along the  $x$ -axis, changing its position by  $\pm 1$  at each time step, then using the  $x$ -coordinate as the state gives a first-order Markov process. Sometimes the assumption is only approximate, as in the case of predicting rain only on the basis of whether it rained the previous day. There are two ways to improve the accuracy of the approximation:

1. Increasing the order of the Markov process model. For example, we could make a second-order model by adding  $Rain_{t-2}$  as a parent of  $Rain_t$ , which might give slightly more accurate predictions. For example, in Palo Alto, California, it very rarely rains more than two days in a row.

- Increasing the set of state variables. For example, we could add  $Season_t$ , to allow us to incorporate historical records of rainy seasons, or we could add  $Temperature_t$ ,  $Humidity_t$ , and  $Pressure_t$  (perhaps at a range of locations) to allow us to use a physical model of rainy conditions.

Exercise 14.AUGM asks you to show that the first solution—increasing the order—can always be reformulated as an increase in the set of state variables, keeping the order fixed. Notice that adding state variables might improve the system’s predictive power but also increases the prediction *requirements*: we now have to predict the new variables as well. Thus, we are looking for a “self-sufficient” set of variables, which really means that we have to understand the “physics” of the process being modeled. The requirement for accurate modeling of the process is obviously lessened if we can add new sensors (e.g., measurements of temperature and pressure) that provide information directly about the new state variables.

Consider, for example, the problem of tracking a robot wandering randomly on the X–Y plane. One might propose that the position and velocity are a sufficient set of state variables: one can simply use Newton’s laws to calculate the new position, and the velocity may change unpredictably. If the robot is battery-powered, however, then battery exhaustion would tend to have a systematic effect on the change in velocity. Because this in turn depends on how much power was used by all previous maneuvers, the Markov property is violated.

We can restore the Markov property by including the charge level  $Battery_t$  as one of the state variables that make up  $\mathbf{X}_t$ . This helps in predicting the motion of the robot, but in turn requires a model for predicting  $Battery_t$  from  $Battery_{t-1}$  and the velocity. In some cases, that can be done reliably, but more often we find that error accumulates over time. In that case, accuracy can be improved by *adding a new sensor* for the battery level. We will return to the battery example in Section 14.5.

## 14.2 Inference in Temporal Models

Having set up the structure of a generic temporal model, we can formulate the basic inference tasks that must be solved:

- **Filtering**<sup>2</sup> or **state estimation** is the task of computing the **belief state**  $\mathbf{P}(\mathbf{X}_t | \mathbf{e}_{1:t})$ —the posterior distribution over the most recent state given all evidence to date. In the umbrella example, this would mean computing the probability of rain today, given all the umbrella observations made so far. Filtering is what a rational agent does to keep track of the current state so that rational decisions can be made. It turns out that an almost identical calculation provides the likelihood of the evidence sequence,  $P(\mathbf{e}_{1:t})$ . Filtering
- **Prediction**: This is the task of computing the posterior distribution over the *future* state, given all evidence to date. That is, we wish to compute  $\mathbf{P}(\mathbf{X}_{t+k} | \mathbf{e}_{1:t})$  for some  $k > 0$ . In the umbrella example, this might mean computing the probability of rain three days from now, given all the observations to date. Prediction is useful for evaluating possible courses of action based on their expected outcomes. Prediction
- **Smoothing**: This is the task of computing the posterior distribution over a *past* state, given all evidence up to the present. That is, we wish to compute  $\mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:t})$  for some  $k$ . Smoothing

<sup>2</sup> The term “filtering” refers to the roots of this problem in early work on signal processing, where the problem is to filter out the noise in a signal by estimating its underlying properties.

such that  $0 \leq k < t$ . In the umbrella example, it might mean computing the probability that it rained last Wednesday, given all the observations of the umbrella carrier made up to today. Smoothing provides a better estimate of the state at time  $k$  than was available at that time, because it incorporates more evidence.<sup>3</sup>

- **Most likely explanation:** Given a sequence of observations, we might wish to find the sequence of states that is most likely to have generated those observations. That is, we wish to compute  $\operatorname{argmax}_{\mathbf{x}_{1:t}} P(\mathbf{x}_{1:t} | \mathbf{e}_{1:t})$ . For example, if the umbrella appears on each of the first three days and is absent on the fourth, then the most likely explanation is that it rained on the first three days and did not rain on the fourth. Algorithms for this task are useful in many applications, including speech recognition—where the aim is to find the most likely sequence of words, given a series of sounds—and the reconstruction of bit strings transmitted over a noisy channel.

In addition to these inference tasks, we also have

- **Learning:** The transition and sensor models, if not yet known, can be learned from observations. Just as with static Bayesian networks, dynamic Bayes net learning can be done as a by-product of inference. Inference provides an estimate of what transitions actually occurred and of what states generated the sensor readings, and these estimates can be used to learn the models. The learning process can operate via an iterative update algorithm called expectation–maximization or EM, or it can result from Bayesian updating of the model parameters given the evidence. See Chapter 21 for more details.

The remainder of this section describes generic algorithms for the four inference tasks, independent of the particular kind of model employed. Improvements specific to each model are described in subsequent sections.

### 14.2.1 Filtering and prediction

As we pointed out in Section 7.7.3, a useful filtering algorithm needs to maintain a current state estimate and update it, rather than going back over the entire history of percepts for each update. (Otherwise, the cost of each update increases as time goes by.) In other words, given the result of filtering up to time  $t$ , the agent needs to compute the result for  $t + 1$  from the new evidence  $\mathbf{e}_{t+1}$ . So we have

$$\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t+1}) = f(\mathbf{e}_{t+1}, \mathbf{P}(\mathbf{X}_t | \mathbf{e}_{1:t}))$$

for some function  $f$ . This process is called **recursive estimation**. (See also Sections 4.4 and 7.7.3.) We can view the calculation as being composed of two parts: first, the current state distribution is projected forward from  $t$  to  $t + 1$ ; then it is updated using the new evidence  $\mathbf{e}_{t+1}$ . This two-part process emerges quite simply when the formula is rearranged:

$$\begin{aligned} \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t+1}) &= \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t}, \mathbf{e}_{t+1}) \quad (\text{dividing up the evidence}) \\ &= \alpha \mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1}, \mathbf{e}_{1:t}) \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t}) \quad (\text{using Bayes' rule, given } \mathbf{e}_{1:t}) \\ &= \alpha \underbrace{\mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1})}_{\text{update}} \underbrace{\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t})}_{\text{prediction}} \quad (\text{by the sensor Markov assumption}). \end{aligned} \tag{14.4}$$

Here and throughout this chapter,  $\alpha$  is a normalizing constant used to make probabilities sum up to 1. Now we plug in an expression for the one-step prediction  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t})$ , obtained by

---

<sup>3</sup> In particular, when tracking a moving object with inaccurate position observations, smoothing gives a smoother estimated trajectory than filtering—hence the name.

conditioning on the current state  $\mathbf{X}_t$ . The resulting equation for the new state estimate is the central result in this chapter:

$$\begin{aligned} \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t+1}) &= \alpha \mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1}) \sum_{\mathbf{x}_t} \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{x}_t, \mathbf{e}_{1:t}) P(\mathbf{x}_t | \mathbf{e}_{1:t}) \\ &= \alpha \underbrace{\mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1})}_{\text{sensor model}} \sum_{\mathbf{x}_t} \underbrace{\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{x}_t)}_{\text{transition model}} \underbrace{P(\mathbf{x}_t | \mathbf{e}_{1:t})}_{\text{recursion}} \quad (\text{Markov assumption}). \end{aligned} \quad (14.5)$$

In this expression, all the terms come either from the model or from the previous state estimate. Hence, we have the desired recursive formulation. We can think of the filtered estimate  $\mathbf{P}(\mathbf{X}_t | \mathbf{e}_{1:t})$  as a “message”  $\mathbf{f}_{1:t}$  that is propagated forward along the sequence, modified by each transition and updated by each new observation. The process is given by

$$\mathbf{f}_{1:t+1} = \text{FORWARD}(\mathbf{f}_{1:t}, \mathbf{e}_{t+1}),$$

where FORWARD implements the update described in Equation (14.5) and the process begins with  $\mathbf{f}_{1:0} = \mathbf{P}(\mathbf{X}_0)$ . When all the state variables are discrete, the time for each update is constant (i.e., independent of  $t$ ), and the space required is also constant. (The constants depend, of course, on the size of the state space and the specific type of the temporal model in question.) *The time and space requirements for updating must be constant if a finite agent is to keep track of the current state distribution indefinitely.*

Let us illustrate the filtering process for two steps in the basic umbrella example (Figure 14.2). That is, we will compute  $\mathbf{P}(R_2 | u_{1:2})$  as follows:

- On day 0, we have no observations, only the security guard’s prior beliefs; let’s assume that consists of  $\mathbf{P}(R_0) = \langle 0.5, 0.5 \rangle$ .
- On day 1, the umbrella appears, so  $U_1 = \text{true}$ . The prediction from  $t=0$  to  $t=1$  is

$$\begin{aligned} \mathbf{P}(R_1) &= \sum_{r_0} \mathbf{P}(R_1 | r_0) P(r_0) \\ &= \langle 0.7, 0.3 \rangle \times 0.5 + \langle 0.3, 0.7 \rangle \times 0.5 = \langle 0.5, 0.5 \rangle. \end{aligned}$$

Then the update step simply multiplies by the probability of the evidence for  $t=1$  and normalizes, as shown in Equation (14.4):

$$\begin{aligned} \mathbf{P}(R_1 | u_1) &= \alpha \mathbf{P}(u_1 | R_1) \mathbf{P}(R_1) = \alpha \langle 0.9, 0.2 \rangle \langle 0.5, 0.5 \rangle \\ &= \alpha \langle 0.45, 0.1 \rangle \approx \langle 0.818, 0.182 \rangle. \end{aligned}$$

- On day 2, the umbrella appears, so  $U_2 = \text{true}$ . The prediction from  $t=1$  to  $t=2$  is

$$\begin{aligned} \mathbf{P}(R_2 | u_1) &= \sum_{r_1} \mathbf{P}(R_2 | r_1) P(r_1 | u_1) \\ &= \langle 0.7, 0.3 \rangle \times 0.818 + \langle 0.3, 0.7 \rangle \times 0.182 \approx \langle 0.627, 0.373 \rangle, \end{aligned}$$

and updating it with the evidence for  $t=2$  gives

$$\begin{aligned} \mathbf{P}(R_2 | u_1, u_2) &= \alpha \mathbf{P}(u_2 | R_2) \mathbf{P}(R_2 | u_1) = \alpha \langle 0.9, 0.2 \rangle \langle 0.627, 0.373 \rangle \\ &= \alpha \langle 0.565, 0.075 \rangle \approx \langle 0.883, 0.117 \rangle. \end{aligned}$$

Intuitively, the probability of rain increases from day 1 to day 2 because rain persists. Exercise 14.CONV(a) asks you to investigate this tendency further.

The task of **prediction** can be seen simply as filtering without the addition of new evidence. In fact, the filtering process already incorporates a one-step prediction, and it is easy

to derive the following recursive computation for predicting the state at  $t+k+1$  from a prediction for  $t+k$ :

$$\mathbf{P}(\mathbf{X}_{t+k+1} | \mathbf{e}_{1:t}) = \sum_{\mathbf{x}_{t+k}} \underbrace{\mathbf{P}(\mathbf{X}_{t+k+1} | \mathbf{x}_{t+k})}_{\text{transition model}} \underbrace{P(\mathbf{x}_{t+k} | \mathbf{e}_{1:t})}_{\text{recursion}}. \quad (14.6)$$

Naturally, this computation involves only the transition model and not the sensor model.

Mixing time

It is interesting to consider what happens as we try to predict further and further into the future. As Exercise 14.CONV(b) shows, the predicted distribution for rain converges to a fixed point  $\langle 0.5, 0.5 \rangle$ , after which it remains constant for all time.<sup>4</sup> This is the **stationary distribution** of the Markov process defined by the transition model. (See also page 462.) A great deal is known about the properties of such distributions and about the **mixing time**—roughly, the time taken to reach the fixed point. In practical terms, this dooms to failure any attempt to predict the *actual* state for a number of steps that is more than a small fraction of the mixing time, unless the stationary distribution itself is strongly peaked in a small area of the state space. The more uncertainty there is in the transition model, the shorter will be the mixing time and the more the future is obscured.

In addition to filtering and prediction, we can use a forward recursion to compute the **likelihood** of the evidence sequence,  $P(\mathbf{e}_{1:t})$ . This is a useful quantity if we want to compare different temporal models that might have produced the same evidence sequence (e.g., two different models for the persistence of rain). For this recursion, we use a likelihood message  $\ell_{1:t}(\mathbf{X}_t) = \mathbf{P}(\mathbf{X}_t, \mathbf{e}_{1:t})$ . It is easy to show (Exercise 14.LIKL) that the message calculation is identical to that for filtering:

$$\ell_{1:t+1} = \text{FORWARD}(\ell_{1:t}, \mathbf{e}_{t+1}).$$

Having computed  $\ell_{1:t}$ , we obtain the actual likelihood by summing out  $\mathbf{X}_t$ :

$$L_{1:t} = P(\mathbf{e}_{1:t}) = \sum_{\mathbf{x}_t} \ell_{1:t}(\mathbf{x}_t). \quad (14.7)$$

Notice that the likelihood message represents the probabilities of longer and longer evidence sequences as time goes by and so becomes numerically smaller and smaller, leading to underflow problems with floating-point arithmetic. This is an important problem in practice, but we shall not go into solutions here.

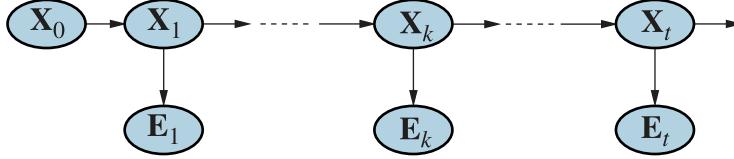

### 14.2.2 Smoothing

As we said earlier, smoothing is the process of computing the distribution over past states given evidence up to the present—that is,  $\mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:t})$  for  $0 \leq k < t$ . (See Figure 14.3.) In anticipation of another recursive message-passing approach, we can split the computation into two parts—the evidence up to  $k$  and the evidence from  $k+1$  to  $t$ ,

$$\begin{aligned} \mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:t}) &= \mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:k}, \mathbf{e}_{k+1:t}) \\ &= \alpha \mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:k}) \mathbf{P}(\mathbf{e}_{k+1:t} | \mathbf{X}_k, \mathbf{e}_{1:k}) \quad (\text{using Bayes' rule, given } \mathbf{e}_{1:k}) \\ &= \alpha \mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:k}) \mathbf{P}(\mathbf{e}_{k+1:t} | \mathbf{X}_k) \quad (\text{using conditional independence}) \\ &= \alpha \mathbf{f}_{1:k} \times \mathbf{b}_{k+1:t}. \end{aligned} \quad (14.8)$$

where “ $\times$ ” represents pointwise multiplication of vectors. Here we have defined a “back-

<sup>4</sup> If one picks an arbitrary day to be  $t=0$ , then it makes sense to choose the prior  $\mathbf{P}(\text{Rain}_0)$  to match the stationary distribution, which is why we picked  $\langle 0.5, 0.5 \rangle$  as the prior. Had we picked a different prior, the stationary distribution would still have worked out to  $\langle 0.5, 0.5 \rangle$ .

**Figure 14.3** Smoothing computes  $\mathbf{P}(\mathbf{X}_k | \mathbf{e}_{1:t})$ , the posterior distribution of the state at some past time  $k$  given a complete sequence of observations from 1 to  $t$ .

ward” message  $\mathbf{b}_{k+1:t} = \mathbf{P}(\mathbf{e}_{k+1:t} | \mathbf{X}_k)$ , analogous to the forward message  $\mathbf{f}_{1:k}$ . The forward message  $\mathbf{f}_{1:k}$  can be computed by filtering forward from 1 to  $k$ , as given by Equation (14.5). It turns out that the backward message  $\mathbf{b}_{k+1:t}$  can be computed by a recursive process that runs *backward* from  $t$ :

$$\begin{aligned}
 \mathbf{P}(\mathbf{e}_{k+1:t} | \mathbf{X}_k) &= \sum_{\mathbf{x}_{k+1}} \mathbf{P}(\mathbf{e}_{k+1:t} | \mathbf{X}_k, \mathbf{x}_{k+1}) \mathbf{P}(\mathbf{x}_{k+1} | \mathbf{X}_k) \quad (\text{conditioning on } \mathbf{X}_{k+1}) \\
 &= \sum_{\mathbf{x}_{k+1}} P(\mathbf{e}_{k+1:t} | \mathbf{x}_{k+1}) \mathbf{P}(\mathbf{x}_{k+1} | \mathbf{X}_k) \quad (\text{by conditional independence}) \\
 &= \sum_{\mathbf{x}_{k+1}} P(\mathbf{e}_{k+1}, \mathbf{e}_{k+2:t} | \mathbf{x}_{k+1}) \mathbf{P}(\mathbf{x}_{k+1} | \mathbf{X}_k) \\
 &= \sum_{\mathbf{x}_{k+1}} \underbrace{P(\mathbf{e}_{k+1} | \mathbf{x}_{k+1})}_{\text{sensor model}} \underbrace{P(\mathbf{e}_{k+2:t} | \mathbf{x}_{k+1})}_{\text{recursion}} \underbrace{\mathbf{P}(\mathbf{x}_{k+1} | \mathbf{X}_k)}_{\text{transition model}}, \tag{14.9}
 \end{aligned}$$

where the last step follows by the conditional independence of  $\mathbf{e}_{k+1}$  and  $\mathbf{e}_{k+2:t}$ , given  $\mathbf{x}_{k+1}$ . In this expression, all the terms come either from the model or from the previous backward message. Hence, we have the desired recursive formulation. In message form, we have

$$\mathbf{b}_{k+1:t} = \text{BACKWARD}(\mathbf{b}_{k+2:t}, \mathbf{e}_{k+1}),$$

where BACKWARD implements the update described in Equation (14.9). As with the forward recursion, the time and space needed for each update are constant and thus independent of  $t$ .

We can now see that the two terms in Equation (14.8) can both be computed by recursions through time, one running forward from 1 to  $k$  and using the filtering equation (14.5) and the other running backward from  $t$  to  $k+1$  and using Equation (14.9).

For the initialization of the backward phase, we have  $\mathbf{b}_{t+1:t} = \mathbf{P}(\mathbf{e}_{t+1:t} | \mathbf{X}_t) = \mathbf{P}(\cdot | \mathbf{X}_t) = \mathbf{1}$ , where  $\mathbf{1}$  is a vector of 1s. The reason for this is that  $\mathbf{e}_{t+1:t}$  is an empty sequence, so the probability of observing it is 1.

Let us now apply this algorithm to the umbrella example, computing the smoothed estimate for the probability of rain at time  $k=1$ , given the umbrella observations on days 1 and 2. From Equation (14.8), this is given by

$$\mathbf{P}(R_1 | u_1, u_2) = \alpha \mathbf{P}(R_1 | u_1) \mathbf{P}(u_2 | R_1). \tag{14.10}$$

The first term we already know to be  $\langle .818, .182 \rangle$ , from the forward filtering process described earlier. The second term can be computed by applying the backward recursion in Equation (14.9):

$$\begin{aligned}
 \mathbf{P}(u_2 | R_1) &= \sum_{r_2} P(u_2 | r_2) P(\cdot | r_2) \mathbf{P}(r_2 | R_1) \\
 &= (0.9 \times 1 \times \langle 0.7, 0.3 \rangle) + (0.2 \times 1 \times \langle 0.3, 0.7 \rangle) = \langle 0.69, 0.41 \rangle.
 \end{aligned}$$

---

```

function FORWARD-BACKWARD(ev, prior) returns a vector of probability distributions
  inputs: ev, a vector of evidence values for steps 1, ..., t
          prior, the prior distribution on the initial state,  $\mathbf{P}(\mathbf{X}_0)$ 
  local variables: fv, a vector of forward messages for steps 0, ..., t
                    b, a representation of the backward message, initially all 1s
                    sv, a vector of smoothed estimates for steps 1, ..., t

  fv[0]  $\leftarrow$  prior
  for i = 1 to t do
    fv[i]  $\leftarrow$  FORWARD(fv[i - 1], ev[i])
  for i = t down to 1 do
    sv[i]  $\leftarrow$  NORMALIZE(fv[i]  $\times$  b)
    b  $\leftarrow$  BACKWARD(b, ev[i])
  return sv

```

**Figure 14.4** The forward–backward algorithm for smoothing: computing posterior probabilities of a sequence of states given a sequence of observations. The FORWARD and BACKWARD operators are defined by Equations (14.5) and (14.9), respectively.

---

Plugging this into Equation (14.10), we find that the smoothed estimate for rain on day 1 is

$$\mathbf{P}(R_1 | u_1, u_2) = \alpha \langle 0.818, 0.182 \rangle \times \langle 0.69, 0.41 \rangle \approx \langle 0.883, 0.117 \rangle.$$

Thus, the smoothed estimate for rain on day 1 is *higher* than the filtered estimate (0.818) in this case. This is because the umbrella on day 2 makes it more likely to have rained on day 2; in turn, because rain tends to persist, that makes it more likely to have rained on day 1.

Both the forward and backward recursions take a constant amount of time per step; hence, the time complexity of smoothing with respect to evidence  $\mathbf{e}_{1:t}$  is  $O(t)$ . This is the complexity for smoothing at a particular time step *k*. If we want to smooth the whole sequence, one obvious method is simply to run the whole smoothing process once for each time step to be smoothed. This results in a time complexity of  $O(t^2)$ .

A better approach uses a simple application of dynamic programming to reduce the complexity to  $O(t)$ . A clue appears in the preceding analysis of the umbrella example, where we were able to reuse the results of the forward-filtering phase. The key to the linear-time algorithm is to *record the results* of forward filtering over the whole sequence. Then we run the backward recursion from *t* down to 1, computing the smoothed estimate at each step *k* from the computed backward message  $\mathbf{b}_{k+1:t}$  and the stored forward message  $\mathbf{f}_{1:k}$ . The algorithm, aptly called the **forward–backward algorithm**, is shown in Figure 14.4.

Forward–backward algorithm

The alert reader will have spotted that the Bayesian network structure shown in Figure 14.3 is a *polytree* as defined on page 451. This means that a straightforward application of the clustering algorithm also yields a linear-time algorithm that computes smoothed estimates for the entire sequence. It is now understood that the forward–backward algorithm is in fact a special case of the polytree propagation algorithm used with clustering methods (although the two were developed independently).

The forward–backward algorithm forms the computational backbone for many applications that deal with sequences of noisy observations. As described so far, it has two practical drawbacks. The first is that its space complexity can be too high when the state space is large

and the sequences are long. It uses  $O(|\mathbf{f}|t)$  space where  $|\mathbf{f}|$  is the size of the representation of the forward message. The space requirement can be reduced to  $O(|\mathbf{f}|\log t)$  with a concomitant increase in the time complexity by a factor of  $\log t$ , as shown in Exercise 14.ISLE. In some cases (see Section 14.3), a constant-space algorithm can be used.

The second drawback of the basic algorithm is that it needs to be modified to work in an *online* setting where smoothed estimates must be computed for earlier time slices as new observations are continuously added to the end of the sequence. The most common requirement is for **fixed-lag smoothing**, which requires computing the smoothed estimate  $\mathbf{P}(\mathbf{X}_{t-d} | \mathbf{e}_{1:t})$  for fixed  $d$ . That is, smoothing is done for the time slice  $d$  steps behind the current time  $t$ ; as  $t$  increases, the smoothing has to keep up. Obviously, we can run the forward–backward algorithm over the  $d$ -step “window” as each new observation is added, but this seems inefficient. In Section 14.3, we will see that fixed-lag smoothing can, in some cases, be done in constant time per update, independent of the lag  $d$ .

Fixed-lag smoothing

### 14.2.3 Finding the most likely sequence

Suppose that  $[true, true, false, true, true]$  is the observed umbrella sequence for the security guard’s first five days on the job. What weather sequence is most likely to explain this? Does the absence of the umbrella on day 3 mean that it wasn’t raining, or did the director forget to bring it? If it didn’t rain on day 3, perhaps (because weather tends to persist) it didn’t rain on day 4 either, but the director brought the umbrella just in case. In all, there are  $2^5$  possible weather sequences we could pick. Is there a way to find the most likely one, short of enumerating all of them and calculating their likelihoods?

We could try this linear-time procedure: use smoothing to find the posterior distribution for the weather at each time step; then construct the sequence, using at each step the weather that is most likely according to the posterior. Such an approach should set off alarm bells in the reader’s head, because the posterior distributions computed by smoothing are distributions over *single* time steps, whereas to find the most likely *sequence* we must consider *joint* probabilities over all the time steps. The results can in fact be quite different. (See Exercise 14.VITE.)

There is a linear-time algorithm for finding the most likely sequence, but it requires more thought. It relies on the same Markov property that yielded efficient algorithms for filtering and smoothing. The idea is to view each sequence as a *path* through a graph whose nodes are the possible *states* at each time step. Such a graph is shown for the umbrella world in Figure 14.5(a). Now consider the task of finding the most likely path through this graph, where the likelihood of any path is the product of the transition probabilities along the path and the probabilities of the given observations at each state.

Let’s focus in particular on paths that reach the state  $Rain_5 = true$ . Because of the Markov property, it follows that the most likely path to the state  $Rain_5 = true$  consists of the most likely path to *some* state at time 4 followed by a transition to  $Rain_5 = true$ ; and the state at time 4 that will become part of the path to  $Rain_5 = true$  is whichever maximizes the likelihood of that path. In other words, *there is a recursive relationship between most likely paths to each state  $\mathbf{x}_{t+1}$  and most likely paths to each state  $\mathbf{x}_t$* .

We can use this property directly to construct a recursive algorithm for computing the most likely path given the evidence. We will use a recursively computed message  $m_{1:t}$ , like

**Figure 14.5** (a) Possible state sequences for  $Rain_t$  can be viewed as paths through a graph of the possible states at each time step. (States are shown as rectangles to avoid confusion with nodes in a Bayes net.) (b) Operation of the Viterbi algorithm for the umbrella observation sequence  $[true, true, false, true, true]$ , where the evidence starts at time 1. For each  $t$ , we have shown the values of the message  $\mathbf{m}_{1:t}$ , which gives the probability of the best sequence reaching each state at time  $t$ . Also, for each state, the bold arrow leading into it indicates its best predecessor as measured by the product of the preceding sequence probability and the transition probability. Following the bold arrows back from the most likely state in  $\mathbf{m}_{1:5}$  gives the most likely sequence, shown by the bold outlines and darker shading.

the forward message  $\mathbf{f}_{1:t}$  in the filtering algorithm. The message is defined as follows:<sup>5</sup>

$$\mathbf{m}_{1:t} = \max_{\mathbf{x}_{1:t-1}} \mathbf{P}(\mathbf{x}_{1:t-1}, \mathbf{X}_t, \mathbf{e}_{1:t}).$$

To obtain the recursive relationship between  $\mathbf{m}_{1:t+1}$  and  $\mathbf{m}_{1:t}$ , we can repeat more or less the same steps that we used for Equation (14.5):

$$\begin{aligned} \mathbf{m}_{1:t+1} &= \max_{\mathbf{x}_{1:t}} \mathbf{P}(\mathbf{x}_{1:t}, \mathbf{X}_{t+1}, \mathbf{e}_{1:t+1}) = \max_{\mathbf{x}_{1:t}} \mathbf{P}(\mathbf{x}_{1:t}, \mathbf{X}_{t+1}, \mathbf{e}_{1:t}, e_{t+1}) \\ &= \max_{\mathbf{x}_{1:t}} \mathbf{P}(e_{t+1} | \mathbf{x}_{1:t}, \mathbf{X}_{t+1}, \mathbf{e}_{1:t}) \mathbf{P}(\mathbf{x}_{1:t}, \mathbf{X}_{t+1}, \mathbf{e}_{1:t}) \\ &= \mathbf{P}(e_{t+1} | \mathbf{X}_{t+1}) \max_{\mathbf{x}_{1:t}} \mathbf{P}(\mathbf{X}_{t+1}, | \mathbf{x}_t) \mathbf{P}(\mathbf{x}_{1:t}, \mathbf{e}_{1:t}) \\ &= \mathbf{P}(e_{t+1} | \mathbf{X}_{t+1}) \max_{\mathbf{x}_t} \mathbf{P}(\mathbf{X}_{t+1}, | \mathbf{x}_t) \max_{\mathbf{x}_{1:t-1}} \mathbf{P}(\mathbf{x}_{1:t-1}, \mathbf{x}_t, \mathbf{e}_{1:t}) \end{aligned} \quad (14.11)$$

where the final term  $\max_{\mathbf{x}_{1:t-1}} \mathbf{P}(\mathbf{x}_{1:t-1}, \mathbf{x}_t, \mathbf{e}_{1:t})$  is exactly the entry for the particular state  $\mathbf{x}_t$  in the message vector  $\mathbf{m}_{1:t}$ . Equation (14.11) is essentially identical to the filtering equation (14.5) except that the summation over  $\mathbf{x}_t$  in Equation (14.5) is replaced by the maximization over  $\mathbf{x}_t$  in Equation (14.11), and there is no normalization constant  $\alpha$  in Equation (14.11). Thus, the algorithm for computing the most likely sequence is similar to filtering: it starts at time 0 with the prior  $\mathbf{m}_{1:0} = \mathbf{P}(\mathbf{X}_0)$  and then runs forward along the sequence, computing the

<sup>5</sup> Notice that these are not quite the probabilities of the most likely paths to reach the states  $\mathbf{X}_t$  given the evidence, which would be the conditional probabilities  $\max_{\mathbf{x}_{1:t-1}} \mathbf{P}(\mathbf{x}_{1:t-1}, \mathbf{X}_t | \mathbf{e}_{1:t})$ ; but the two vectors are related by a constant factor  $P(\mathbf{e}_{1:t})$ . The difference is immaterial because the max operator doesn't care about constant factors. We get a slightly simpler recursion with  $\mathbf{m}_{1:t}$  defined this way.

$\mathbf{m}$  message at each time step using Equation (14.11). The progress of this computation is shown in Figure 14.5(b).

At the end of the observation sequence,  $\mathbf{m}_{1:t}$  will contain the probability for the most likely sequence reaching *each* of the final states. One can thus easily select the final state of the most likely sequence overall (the state outlined in bold at step 5). In order to identify the actual sequence, as opposed to just computing its probability, the algorithm will also need to record, for each state, the best state that leads to it; these are indicated by the bold arrows in Figure 14.5(b). The optimal sequence is identified by following these bold arrows backwards from the best final state.

The algorithm we have just described is called the **Viterbi algorithm**, after its inventor, Andrew Viterbi. Like the filtering algorithm, its time complexity is linear in  $t$ , the length of the sequence. Unlike filtering, which uses constant space, its space requirement is also linear in  $t$ . This is because the Viterbi algorithm needs to keep the pointers that identify the best sequence leading to each state. Viterbi algorithm

One final practical point: numerical underflow is a significant issue for the Viterbi algorithm. In Figure 14.5(b), the probabilities are getting smaller and smaller—and this is just a toy example. Real applications in DNA analysis or message decoding may have thousands or millions of steps. One possible solution is simply to normalize  $\mathbf{m}$  at each step; this rescaling does not affect correctness because  $\max(cx, cy) = c \cdot \max(x, y)$ . A second solution is to use log probabilities everywhere and replace multiplication by addition. Again, correctness is unaffected because the log function is monotonic, so  $\max(\log x, \log y) = \log \max(x, y)$ .

## 14.3 Hidden Markov Models

The preceding section developed algorithms for temporal probabilistic reasoning using a general framework that was independent of the specific form of the transition and sensor models and independent of the nature of the state and evidence variables. In this and the next two sections, we discuss more concrete models and applications that illustrate the power of the basic algorithms and in some cases allow further improvements.

We begin with the **hidden Markov model**, or **HMM**. An HMM is a temporal probabilistic model in which the state of the process is described by a *single, discrete* random variable. The possible values of the variable are the possible states of the world. The umbrella example described in the preceding section is therefore an HMM, since it has just one state variable:  $Rain_t$ . What happens if you have a model with two or more state variables? You can still fit it into the HMM framework by combining the variables into a single “megavariable” whose values are all possible tuples of values of the individual state variables. We will see that the restricted structure of HMMs allows for a simple and elegant matrix implementation of all the basic algorithms.<sup>6</sup> Hidden Markov model

Although HMMs require the *state* to be a single, discrete variable, there is no corresponding restriction on the *evidence* variables. This is because the evidence variables are always observed, which means that there is no need to keep track of any distribution over their values. (If a variable is not observed, it can simply be dropped from the model for that time step.) There can be many evidence variables, both discrete and continuous.

<sup>6</sup> The reader unfamiliar with basic operations on vectors and matrices might wish to consult Appendix A before proceeding with this section.

### 14.3.1 Simplified matrix algorithms

With a single, discrete state variable  $X_t$ , we can give concrete form to the representations of the transition model, the sensor model, and the forward and backward messages. Let the state variable  $X_t$  have values denoted by integers  $1, \dots, S$ , where  $S$  is the number of possible states. The transition model  $\mathbf{P}(X_t | X_{t-1})$  becomes an  $S \times S$  matrix  $\mathbf{T}$ , where

$$\mathbf{T}_{ij} = P(X_t = j | X_{t-1} = i).$$

That is,  $\mathbf{T}_{ij}$  is the probability of a transition from state  $i$  to state  $j$ . For example, if we number the states *Rain=true* and *Rain=false* as 1 and 2, respectively, then the transition matrix for the umbrella world defined in Figure 14.2 is

$$\mathbf{T} = \mathbf{P}(X_t | X_{t-1}) = \begin{pmatrix} 0.7 & 0.3 \\ 0.3 & 0.7 \end{pmatrix}.$$

#### Observation matrix

We also put the sensor model in matrix form. In this case, because the value of the evidence variable  $E_t$  is known at time  $t$  (call it  $e_t$ ), we need only specify, for each state, how likely it is that the state causes  $e_t$  to appear: we need  $P(e_t | X_t = i)$  for each state  $i$ . For mathematical convenience we place these values into an  $S \times S$  diagonal **observation matrix**,  $\mathbf{O}_t$ , one for each time step. The  $i$ th diagonal entry of  $\mathbf{O}_t$  is  $P(e_t | X_t = i)$  and the other entries are 0. For example, on day 1 in the umbrella world of Figure 14.5,  $U_1 = \text{true}$ , and on day 3,  $U_3 = \text{false}$ , so we have

$$\mathbf{O}_1 = \begin{pmatrix} 0.9 & 0 \\ 0 & 0.2 \end{pmatrix}; \quad \mathbf{O}_3 = \begin{pmatrix} 0.1 & 0 \\ 0 & 0.8 \end{pmatrix}.$$

Now, if we use column vectors to represent the forward and backward messages, all the computations become simple matrix–vector operations. The forward equation (14.5) becomes

$$\mathbf{f}_{1:t+1} = \alpha \mathbf{O}_{t+1} \mathbf{T}^\top \mathbf{f}_{1:t} \tag{14.12}$$

and the backward equation (14.9) becomes

$$\mathbf{b}_{k+1:t} = \mathbf{T} \mathbf{O}_{k+1} \mathbf{b}_{k+2:t}. \tag{14.13}$$

From these equations, we can see that the time complexity of the forward–backward algorithm (Figure 14.4) applied to a sequence of length  $t$  is  $O(S^2 t)$ , because each step requires multiplying an  $S$ -element vector by an  $S \times S$  matrix. The space requirement is  $O(St)$ , because the forward pass stores  $t$  vectors of size  $S$ .

Besides providing an elegant description of the filtering and smoothing algorithms for HMMs, the matrix formulation reveals opportunities for improved algorithms. The first is a simple variation on the forward–backward algorithm that allows smoothing to be carried out in *constant* space, independently of the length of the sequence. The idea is that smoothing for any particular time slice  $k$  requires the simultaneous presence of both the forward and backward messages,  $\mathbf{f}_{1:k}$  and  $\mathbf{b}_{k+1:t}$ , according to Equation (14.8). The forward–backward algorithm achieves this by storing the  $\mathbf{f}$ s computed on the forward pass so that they are available during the backward pass. Another way to achieve this is with a single pass that propagates both  $\mathbf{f}$  and  $\mathbf{b}$  in the same direction. For example, the “forward” message  $\mathbf{f}$  can be propagated backward if we manipulate Equation (14.12) to work in the other direction:

$$\mathbf{f}_{1:t} = \alpha' (\mathbf{T}^\top)^{-1} \mathbf{O}_{t+1}^{-1} \mathbf{f}_{1:t+1}.$$

The modified smoothing algorithm works by first running the standard forward pass to compute  $\mathbf{f}_{t:t}$  (forgetting all the intermediate results) and then running the backward pass for both

     $\mathbf{B} \leftarrow \mathbf{O}_{t-d}^{-1} \mathbf{T}^{-1} \mathbf{B} \mathbf{O}_t$ 
  else  $\mathbf{B} \leftarrow \mathbf{B} \mathbf{O}_t$ 
   $t \leftarrow t + 1$ 
  if  $t > d + 1$  then return NORMALIZE( $\mathbf{f} \times \mathbf{B} \mathbf{1}$ ) else return null

```

**Figure 14.6** An algorithm for smoothing with a fixed time lag of  $d$  steps, implemented as an online algorithm that outputs the new smoothed estimate given the observation for a new time step. Notice that the final output NORMALIZE( $\mathbf{f} \times \mathbf{B} \mathbf{1}$ ) is just  $\alpha \mathbf{f} \times \mathbf{b}$ , by Equation (14.14).

---

**b** and **f** together, using them to compute the smoothed estimate at each step. Since only one copy of each message is needed, the storage requirements are constant (i.e., independent of  $t$ , the length of the sequence). There are two significant restrictions on this algorithm: it requires that the transition matrix be invertible and that the sensor model have no zeroes—that is, that every observation be possible in every state.

A second area in which the matrix formulation reveals an improvement is in *online* smoothing with a fixed lag. The fact that smoothing can be done in constant space suggests that there should exist an efficient recursive algorithm for online smoothing—that is, an algorithm whose time complexity is independent of the length of the lag. Let us suppose that the lag is  $d$ ; that is, we are smoothing at time slice  $t - d$ , where the current time is  $t$ . By Equation (14.8), we need to compute

$$\alpha \mathbf{f}_{1:t-d} \times \mathbf{b}_{t-d+1:t}$$

for slice  $t - d$ . Then, when a new observation arrives, we need to compute

$$\alpha \mathbf{f}_{1:t-d+1} \times \mathbf{b}_{t-d+2:t+1}$$

for slice  $t - d + 1$ . How can this be done incrementally? First, we can compute  $\mathbf{f}_{1:t-d+1}$  from  $\mathbf{f}_{1:t-d}$ , using the standard filtering process, Equation (14.5).

Computing the backward message incrementally is trickier, because there is no simple relationship between the old backward message  $\mathbf{b}_{t-d+1:t}$  and the new backward message  $\mathbf{b}_{t-d+2:t+1}$ . Instead, we will examine the relationship between the old backward message  $\mathbf{b}_{t-d+1:t}$  and the backward message at the front of the sequence,  $\mathbf{b}_{t+1:t}$ . To do this, we apply

Equation (14.13)  $d$  times to get

$$\mathbf{b}_{t-d+1:t} = \left( \prod_{i=t-d+1}^t \mathbf{T} \mathbf{O}_i \right) \mathbf{b}_{t+1:t} = \mathbf{B}_{t-d+1:t} \mathbf{1}, \quad (14.14)$$

where the matrix  $\mathbf{B}_{t-d+1:t}$  is the product of the sequence of  $\mathbf{T}$  and  $\mathbf{O}$  matrices and  $\mathbf{1}$  is a vector of 1s.  $\mathbf{B}$  can be thought of as a “transformation operator” that transforms a later backward message into an earlier one. A similar equation holds for the new backward messages *after* the next observation arrives:

$$\mathbf{b}_{t-d+2:t+1} = \left( \prod_{i=t-d+2}^{t+1} \mathbf{T} \mathbf{O}_i \right) \mathbf{b}_{t+2:t+1} = \mathbf{B}_{t-d+2:t+1} \mathbf{1}. \quad (14.15)$$

Examining the product expressions in Equations (14.14) and (14.15), we see that they have a simple relationship: to get the second product, “divide” the first product by the first element  $\mathbf{T} \mathbf{O}_{t-d+1}$ , and multiply by the new last element  $\mathbf{T} \mathbf{O}_{t+1}$ . In matrix language, then, there is a simple relationship between the old and new  $\mathbf{B}$  matrices:

$$\mathbf{B}_{t-d+2:t+1} = \mathbf{O}_{t-d+1}^{-1} \mathbf{T}^{-1} \mathbf{B}_{t-d+1:t} \mathbf{T} \mathbf{O}_{t+1}. \quad (14.16)$$

This equation provides an incremental update for the  $\mathbf{B}$  matrix, which in turn (through Equation (14.15)) allows us to compute the new backward message  $\mathbf{b}_{t-d+2:t+1}$ . The complete algorithm, which requires storing and updating  $\mathbf{f}$  and  $\mathbf{B}$ , is shown in Figure 14.6.

### 14.3.2 Hidden Markov model example: Localization

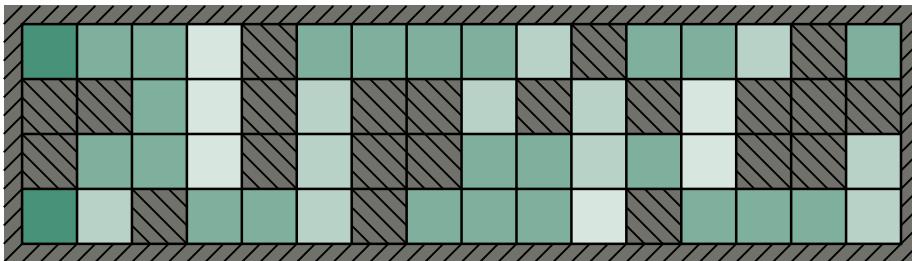

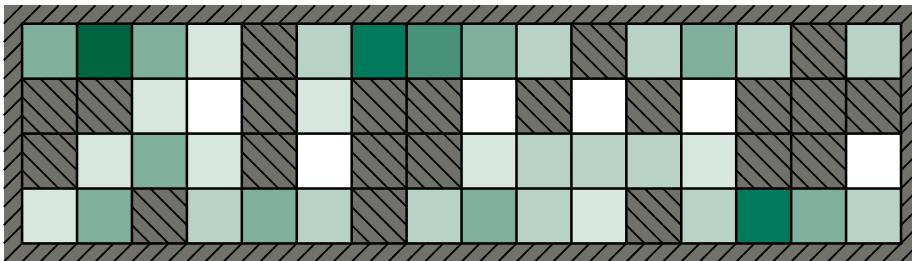

On page 151, we introduced a simple form of the **localization** problem for the vacuum world. In that version, the robot had a single nondeterministic *Move* action and its sensors reported perfectly whether or not obstacles lay immediately to the north, south, east, and west; the robot’s belief state was the set of possible locations it could be in.

Here we make the problem slightly more realistic by allowing for noise in the sensors, and formalizing the idea that the robot moves randomly—it is equally likely to move to any adjacent empty square. The state variable  $X_t$  represents the location of the robot on the discrete grid; the domain of this variable is the set of empty squares, which we will label by the integers  $\{1, \dots, S\}$ . Let  $\text{NEIGHBORS}(i)$  be the set of empty squares that are adjacent to  $i$  and let  $N(i)$  be the size of that set. Then the transition model for the *Move* action says that the robot is equally likely to end up at any neighboring square:

$$P(X_{t+1} = j | X_t = i) = \mathbf{T}_{ij} = \begin{cases} 1/N(i) & \text{if } j \in \text{NEIGHBORS}(i) \\ 0 & \text{otherwise.} \end{cases}$$

We don’t know where the robot starts, so we will assume a uniform distribution over all the squares; that is,  $P(X_0 = i) = 1/S$ . For the particular environment we consider (Figure 14.7),  $S = 42$  and the transition matrix  $\mathbf{T}$  has  $42 \times 42 = 1764$  entries.

The sensor variable  $E_t$  has 16 possible values, each a four-bit sequence giving the presence or absence of an obstacle in each of the compass directions NESW. For example, 1010 means that the north and south sensors report an obstacle and the east and west do not. Suppose that each sensor’s error rate is  $\epsilon$  and that errors occur independently for the four sensor directions. In that case, the probability of getting all four bits right is  $(1 - \epsilon)^4$  and the probability of getting them all wrong is  $\epsilon^4$ . Furthermore, if  $d_{it}$  is the discrepancy—the number of

(a) Posterior distribution over robot location after  $E_1 = 1011$ (b) Posterior distribution over robot location after  $E_1 = 1011, E_2 = 1010$ 

**Figure 14.7** Posterior distribution over robot location: (a) after one observation  $E_1 = 1011$  (i.e., obstacles to the north, south, and west); (b) after a random move to an adjacent location and a second observation  $E_2 = 1010$  (i.e., obstacles to the north and south). The darkness of each square corresponds to the probability that the robot is at that location. The sensor error rate for each bit is  $\epsilon = 0.2$ .

bits that are different—between the true values for square  $i$  and the actual reading  $e_t$ , then the probability that a robot in square  $i$  would receive a sensor reading  $e_t$  is

$$P(E_t = e_t | X_t = i) = (\mathbf{O}_t)_{ii} = (1 - \epsilon)^{4 - d_{it}} \epsilon^{d_{it}}.$$

For example, the probability that a square with obstacles to the north and south would produce a sensor reading 1110 is  $(1 - \epsilon)^3 \epsilon^1$ .

Given the matrices  $\mathbf{T}$  and  $\mathbf{O}_t$ , the robot can use Equation (14.12) to compute the posterior distribution over locations—that is, to work out where it is. Figure 14.7 shows the distributions  $\mathbf{P}(X_1 | E_1 = 1011)$  and  $\mathbf{P}(X_2 | E_1 = 1011, E_2 = 1010)$ . This is the same maze we saw before in Figure 4.18 (page 152), but there we used logical filtering to find the locations that were *possible*, assuming perfect sensing. Those same locations are still the most *likely* with noisy sensing, but now *every* location has some nonzero probability because any location could produce any sensor values.

In addition to filtering to estimate its current location, the robot can use smoothing (Equation (14.13)) to work out where it was at any given past time—for example, where it began at time 0—and it can use the Viterbi algorithm to work out the most likely path it has taken to get where it is now. Figure 14.8 shows the localization error and Viterbi path error for various values of the per-bit sensor error rate  $\epsilon$ . Even when  $\epsilon$  is 0.20—which means that the overall sensor reading is wrong 59% of the time—the robot is usually able to work out its location to within two squares after 20 observations. This is because of the algorithm’s ability to integrate evidence over time and to take into account the probabilistic constraints imposed

**Figure 14.8** Performance of HMM localization as a function of the length of the observation sequence for various different values of the sensor error probability  $\epsilon$ ; data averaged over 400 runs. (a) The localization error, defined as the Manhattan distance from the true location. (b) The Viterbi path error, defined as the average Manhattan distance of states on the Viterbi path from corresponding states on the true path.

on the location sequence by the transition model. When  $\epsilon$  is 0.10 or less, the robot needs only a few observations to work out where it is and to track its position accurately. When  $\epsilon$  is 0.40, both the localization error and the Viterbi path error remain large; in other words, the robot is lost. This is because a sensor with an error probability of 0.40 provides too little information to counteract the loss of information about the robot’s position that comes from the unpredictable random motion.

The state variable for the example we have considered in this section is a physical location in the world. Other problems can, of course, include other aspects of the world. Exercise 14.ROOM asks you to consider a version of the vacuum robot that has the policy of going straight for as long as it can; only when it encounters an obstacle does it change to a new heading. To model this robot, each state in the model consists of a *(location, heading)* pair. For the environment in Figure 14.7, which has 42 empty squares, this leads to 168 states and a transition matrix with  $168^2 = 28,224$  entries—still a manageable number.

If we add the possibility of dirt in each of the 42 squares, the number of states is multiplied by  $2^{42}$  and the transition matrix has more than  $10^{29}$  entries—no longer a manageable number. In general, if the state is composed of  $n$  discrete variables with at most  $d$  values each, the corresponding HMM transition matrix will have size  $O(d^{2n})$  and the per-update computation time will also be  $O(d^{2n})$ .

For these reasons, although HMMs have many uses in areas ranging from speech recognition to molecular biology, they are fundamentally limited in their ability to represent complex processes. In the terminology introduced in Chapter 2, HMMs are an atomic representation: states of the world have no internal structure and are simply labeled by integers. Section 14.5 shows how to use dynamic Bayesian networks—a factored representation—to model domains with many state variables. The next section shows how to handle domains with continuous state variables, which of course lead to an infinite state space.

## 14.4 Kalman Filters

---

Imagine watching a small bird flying through dense jungle foliage at dusk: you glimpse brief, intermittent flashes of motion; you try hard to guess where the bird is and where it will appear next so that you don't lose it. Or imagine that you are a World War II radar operator peering at a faint, wandering blip that appears once every 10 seconds on the screen. Or, going back further still, imagine you are Kepler trying to reconstruct the motions of the planets from a collection of highly inaccurate angular observations taken at irregular and imprecisely measured intervals.

In all these cases, you are doing filtering: estimating state variables (here, the position and velocity of a moving object) from noisy observations over time. If the variables were discrete, we could model the system with a hidden Markov model. This section examines methods for handling continuous variables, using an algorithm called **Kalman filtering**, after one of its inventors, Rudolf Kalman.

The bird's flight might be specified by six continuous variables at each time point; three for position ( $X_t, Y_t, Z_t$ ) and three for velocity ( $\dot{X}_t, \dot{Y}_t, \dot{Z}_t$ ). We will need suitable conditional densities to represent the transition and sensor models; as in Chapter 13, we will use **linear-Gaussian** distributions. This means that the next state  $\mathbf{X}_{t+1}$  must be a linear function of the current state  $\mathbf{X}_t$ , plus some Gaussian noise, a condition that turns out to be quite reasonable in practice. Consider, for example, the  $X$ -coordinate of the bird, ignoring the other coordinates for now. Let the time interval between observations be  $\Delta$ , and assume constant velocity during the interval; then the position update is given by  $X_{t+\Delta} = X_t + \dot{X} \Delta$ . Adding Gaussian noise (to account for wind variation, etc.), we obtain a linear-Gaussian transition model:

$$P(X_{t+\Delta} = x_{t+\Delta} | X_t = x_t, \dot{X}_t = \dot{x}_t) = \mathcal{N}(x_{t+\Delta}; x_t + \dot{x}_t \Delta, \sigma^2).$$

The Bayesian network structure for a system with position vector  $\mathbf{X}_t$  and velocity  $\dot{\mathbf{X}}_t$  is shown in Figure 14.9. Note that this is a very specific form of linear-Gaussian model; the general form will be described later in this section and covers a vast array of applications beyond the simple motion examples of the first paragraph. The reader might wish to consult Appendix A for some of the mathematical properties of Gaussian distributions; for our immediate purposes, the most important is that a **multivariate Gaussian** distribution for  $d$  variables is specified by a  $d$ -element mean  $\mu$  and a  $d \times d$  covariance matrix  $\Sigma$ .

### 14.4.1 Updating Gaussian distributions

In Chapter 13 on page 441, we alluded to a key property of the linear-Gaussian family of distributions: it remains closed under Bayesian updating. (That is, given any evidence, the posterior is still in the linear-Gaussian family.) Here we make this claim precise in the context of filtering in a temporal probability model. The required properties correspond to the two-step filtering calculation in Equation (14.5):

1. If the current distribution  $\mathbf{P}(\mathbf{X}_t | \mathbf{e}_{1:t})$  is Gaussian and the transition model  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{x}_t)$  is linear-Gaussian, then the one-step predicted distribution given by

$$\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t}) = \int_{\mathbf{x}_t} \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{x}_t) P(\mathbf{x}_t | \mathbf{e}_{1:t}) d\mathbf{x}_t \quad (14.17)$$

is also a Gaussian distribution.

**Figure 14.9** Bayesian network structure for a linear dynamical system with position  $\mathbf{X}_t$ , velocity  $\dot{\mathbf{X}}_t$ , and position measurement  $\mathbf{Z}_t$ .

2. If the prediction  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t})$  is Gaussian and the sensor model  $\mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1})$  is linear-Gaussian, then, after conditioning on the new evidence, the updated distribution

$$\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t+1}) = \alpha \mathbf{P}(\mathbf{e}_{t+1} | \mathbf{X}_{t+1}) \mathbf{P}(\mathbf{X}_{t+1} | \mathbf{e}_{1:t}) \quad (14.18)$$

is also a Gaussian distribution.

Thus, the FORWARD operator for Kalman filtering takes a Gaussian forward message  $\mathbf{f}_{1:t}$ , specified by a mean  $\mu_t$  and covariance  $\Sigma_t$ , and produces a new multivariate Gaussian forward message  $\mathbf{f}_{1:t+1}$ , specified by a mean  $\mu_{t+1}$  and covariance  $\Sigma_{t+1}$ . So if we start with a Gaussian prior  $\mathbf{f}_{1:0} = \mathbf{P}(\mathbf{X}_0) = \mathcal{N}(\mu_0, \Sigma_0)$ , filtering with a linear-Gaussian model produces a Gaussian state distribution for all time.

► This seems to be a nice, elegant result, but why is it so important? The reason is that except for a few special cases such as this, *filtering with continuous or hybrid (discrete and continuous) networks generates state distributions whose representation grows without bound over time*. This statement is not easy to prove in general, but Exercise 14.KFSW shows what happens for a simple example.

#### 14.4.2 A simple one-dimensional example

We have said that the FORWARD operator for the Kalman filter maps a Gaussian into a new Gaussian. This translates into computing a new mean and covariance from the previous mean and covariance. Deriving the update rule in the general (multivariate) case requires rather a lot of linear algebra, so we will stick to a very simple univariate case for now, and later give the results for the general case. Even for the univariate case, the calculations are somewhat tedious, but we feel that they are worth seeing because the usefulness of the Kalman filter is tied so intimately to the mathematical properties of Gaussian distributions.

The temporal model we consider describes a **random walk** of a single continuous state variable  $X_t$  with a noisy observation  $Z_t$ . An example might be the “consumer confidence” index, which can be modeled as undergoing a random Gaussian-distributed change each month and is measured by a random consumer survey that also introduces Gaussian sampling noise. The prior distribution is assumed to be Gaussian with variance  $\sigma_0^2$ :

$$P(x_0) = \alpha e^{-\frac{1}{2} \left( \frac{(x_0 - \mu_0)^2}{\sigma_0^2} \right)}.$$

(For simplicity, we use the same symbol  $\alpha$  for all normalizing constants in this section.) The transition model adds a Gaussian perturbation of constant variance  $\sigma_x^2$  to the current state:

$$P(x_{t+1} | x_t) = \alpha e^{-\frac{1}{2} \left( \frac{(x_{t+1} - x_t)^2}{\sigma_x^2} \right)}.$$

The sensor model assumes Gaussian noise with variance  $\sigma_z^2$ :

$$P(z_t | x_t) = \alpha e^{-\frac{1}{2} \left( \frac{(z_t - x_t)^2}{\sigma_z^2} \right)}.$$

Now, given the prior  $P(x_0)$ , the one-step predicted distribution comes from Equation (14.17):

$$\begin{aligned} P(x_1) &= \int_{-\infty}^{\infty} P(x_1 | x_0) P(x_0) dx_0 = \alpha \int_{-\infty}^{\infty} e^{-\frac{1}{2} \left( \frac{(x_1 - x_0)^2}{\sigma_x^2} \right)} e^{-\frac{1}{2} \left( \frac{(x_0 - \mu_0)^2}{\sigma_0^2} \right)} dx_0 \\ &= \alpha \int_{-\infty}^{\infty} e^{-\frac{1}{2} \left( \frac{\sigma_0^2(x_1 - x_0)^2 + \sigma_x^2(x_0 - \mu_0)^2}{\sigma_0^2 \sigma_x^2} \right)} dx_0. \end{aligned}$$

This integral looks rather complicated. The key to progress is to notice that the exponent is the sum of two expressions that are *quadratic* in  $x_0$  and hence is itself a quadratic in  $x_0$ . A simple trick known as **completing the square** allows the rewriting of any quadratic  $ax_0^2 + bx_0 + c$  as the sum of a squared term  $a(x_0 - \frac{-b}{2a})^2$  and a residual term  $c - \frac{b^2}{4a}$  that is independent of  $x_0$ . In this case, we have  $a = (\sigma_0^2 + \sigma_x^2)/(\sigma_0^2 \sigma_x^2)$ ,  $b = -2(\sigma_0^2 x_1 + \sigma_x^2 \mu_0)/(\sigma_0^2 \sigma_x^2)$ , and  $c = (\sigma_0^2 x_1^2 + \sigma_x^2 \mu_0^2)/(\sigma_0^2 \sigma_x^2)$ . The residual term can be taken outside the integral, giving us

$$P(x_1) = \alpha e^{-\frac{1}{2} \left( c - \frac{b^2}{4a} \right)} \int_{-\infty}^{\infty} e^{-\frac{1}{2} \left( a(x_0 - \frac{-b}{2a})^2 \right)} dx_0.$$

Completing the square

Now the integral is just the integral of a Gaussian over its full range, which is simply 1. Thus, we are left with only the residual term from the quadratic. Plugging back in the expressions for  $a$ ,  $b$ , and  $c$  and simplifying, we obtain

$$P(x_1) = \alpha e^{-\frac{1}{2} \left( \frac{(x_1 - \mu_0)^2}{\sigma_0^2 + \sigma_x^2} \right)}.$$

That is, the one-step predicted distribution is a Gaussian with the same mean  $\mu_0$  and a variance equal to the sum of the original variance  $\sigma_0^2$  and the transition variance  $\sigma_x^2$ .

To complete the update step, we need to condition on the observation at the first time step, namely,  $z_1$ . From Equation (14.18), this is given by

$$\begin{aligned} P(x_1 | z_1) &= \alpha P(z_1 | x_1) P(x_1) \\ &= \alpha e^{-\frac{1}{2} \left( \frac{(z_1 - x_1)^2}{\sigma_z^2} \right)} e^{-\frac{1}{2} \left( \frac{(x_1 - \mu_0)^2}{\sigma_0^2 + \sigma_x^2} \right)}. \end{aligned}$$

Once again, we combine the exponents and complete the square (Exercise 14.KALM), obtaining the following expression for the posterior:

$$P(x_1 | z_1) = \alpha e^{-\frac{1}{2} \frac{\left( x_1 - \frac{(\sigma_0^2 + \sigma_x^2)z_1 + \sigma_z^2 \mu_0}{\sigma_0^2 + \sigma_x^2 + \sigma_z^2} \right)^2}{(\sigma_0^2 + \sigma_x^2)\sigma_z^2 / (\sigma_0^2 + \sigma_x^2 + \sigma_z^2)}}. \quad (14.19)$$

Thus, after one update cycle, we have a new Gaussian distribution for the state variable.

From the Gaussian formula in Equation (14.19), we see that the new mean and standard deviation can be calculated from the old mean and standard deviation as follows:

$$\mu_{t+1} = \frac{(\sigma_t^2 + \sigma_x^2)z_{t+1} + \sigma_z^2 \mu_t}{\sigma_t^2 + \sigma_x^2 + \sigma_z^2} \quad \text{and} \quad \sigma_{t+1}^2 = \frac{(\sigma_t^2 + \sigma_x^2)\sigma_z^2}{\sigma_t^2 + \sigma_x^2 + \sigma_z^2}. \quad (14.20)$$

**Figure 14.10** Stages in the Kalman filter update cycle for a random walk with a prior given by  $\mu_0=0.0$  and  $\sigma_0=1.5$ , transition noise given by  $\sigma_x=2.0$ , sensor noise given by  $\sigma_z=1.0$ , and a first observation  $z_1=2.5$  (marked on the  $x$ -axis). Notice how the prediction  $P(x_1)$  is flattened out, relative to  $P(x_0)$ , by the transition noise. Notice also that the mean of the posterior distribution  $P(x_1 | z_1)$  is slightly to the left of the observation  $z_1$  because the mean is a weighted average of the prediction and the observation.

Figure 14.10 shows one update cycle of the Kalman filter in the one-dimensional case for particular values of the transition and sensor models.

Equation (14.20) plays exactly the same role as the general filtering equation (14.5) or the HMM filtering equation (14.12). Because of the special nature of Gaussian distributions, however, the equations have some interesting additional properties.

First, we can interpret the calculation for the new mean  $\mu_{t+1}$  as a *weighted mean* of the new observation  $z_{t+1}$  and the old mean  $\mu_t$ . If the observation is unreliable, then  $\sigma_z^2$  is large and we pay more attention to the old mean; if the old mean is unreliable ( $\sigma_t^2$  is large) or the process is highly unpredictable ( $\sigma_x^2$  is large), then we pay more attention to the observation.

Second, notice that the update for the variance  $\sigma_{t+1}^2$  is *independent of the observation*. We can therefore compute in advance what the sequence of variance values will be. Third, the sequence of variance values converges quickly to a fixed value that depends only on  $\sigma_x^2$  and  $\sigma_z^2$ , thereby substantially simplifying the subsequent calculations. (See Exercise 14.VARI.)

### 14.4.3 The general case

The preceding derivation illustrates the key property of Gaussian distributions that allows Kalman filtering to work: the fact that the exponent is a quadratic form. This is true not just for the univariate case; the full multivariate Gaussian distribution has the form

$$\mathcal{N}(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = \alpha e^{-\frac{1}{2}((\mathbf{x}-\boldsymbol{\mu})^\top \boldsymbol{\Sigma}^{-1} (\mathbf{x}-\boldsymbol{\mu}))}.$$

Multiplying out the terms in the exponent, we see that the exponent is also a quadratic function of the values  $x_i$  in  $\mathbf{x}$ . Thus, filtering preserves the Gaussian nature of the state distribution.

Let us first define the general temporal model used with Kalman filtering. Both the transition model and the sensor model are required to be a *linear* transformation with additive Gaussian noise. Thus, we have

$$\begin{aligned} P(\mathbf{x}_{t+1} | \mathbf{x}_t) &= \mathcal{N}(\mathbf{x}_{t+1}; \mathbf{F}\mathbf{x}_t, \Sigma_x) \\ P(\mathbf{z}_t | \mathbf{x}_t) &= \mathcal{N}(\mathbf{z}_t; \mathbf{H}\mathbf{x}_t, \Sigma_z), \end{aligned} \quad (14.21)$$

where  $\mathbf{F}$  and  $\Sigma_x$  are matrices describing the linear transition model and transition noise covariance, and  $\mathbf{H}$  and  $\Sigma_z$  are the corresponding matrices for the sensor model. Now the update equations for the mean and covariance, in their full, hairy horribleness, are

$$\begin{aligned} \mu_{t+1} &= \mathbf{F}\mu_t + \mathbf{K}_{t+1}(\mathbf{z}_{t+1} - \mathbf{H}\mu_t) \\ \Sigma_{t+1} &= (\mathbf{I} - \mathbf{K}_{t+1}\mathbf{H})(\mathbf{F}\Sigma_t\mathbf{F}^\top + \Sigma_x), \end{aligned} \quad (14.22)$$

where  $\mathbf{K}_{t+1} = (\mathbf{F}\Sigma_t\mathbf{F}^\top + \Sigma_x)\mathbf{H}^\top(\mathbf{H}(\mathbf{F}\Sigma_t\mathbf{F}^\top + \Sigma_x)\mathbf{H}^\top + \Sigma_z)^{-1}$  is the **Kalman gain matrix**. Believe it or not, these equations make some intuitive sense. For example, consider the update for the mean state estimate  $\mu$ . The term  $\mathbf{F}\mu_t$  is the *predicted* state at  $t+1$ , so  $\mathbf{H}\mu_t$  is the *predicted* observation. Therefore, the term  $\mathbf{z}_{t+1} - \mathbf{H}\mu_t$  represents the error in the predicted observation. This is multiplied by  $\mathbf{K}_{t+1}$  to correct the predicted state; hence,  $\mathbf{K}_{t+1}$  is a measure of *how seriously to take the new observation relative to the prediction*. As in Equation (14.20), we also have the property that the variance update is independent of the observations. The sequence of values for  $\Sigma_t$  and  $\mathbf{K}_t$  can therefore be computed offline, and the actual calculations required during online tracking are quite modest.

To illustrate these equations at work, we have applied them to the problem of tracking an object moving on the  $X$ - $Y$  plane. The state variables are  $\mathbf{X} = (X, Y, \dot{X}, \dot{Y})^\top$ , so  $\mathbf{F}$ ,  $\Sigma_x$ ,  $\mathbf{H}$ , and  $\Sigma_z$  are  $4 \times 4$  matrices. Figure 14.11(a) shows the true trajectory, a series of noisy observations, and the trajectory estimated by Kalman filtering, along with the covariances indicated by the one-standard-deviation contours. The filtering process does a good job of tracking the actual motion, and, as expected, the variance quickly reaches a fixed point.

We can also derive equations for *smoothing* as well as filtering with linear-Gaussian models. The smoothing results are shown in Figure 14.11(b). Notice how the variance in the position estimate is sharply reduced, except at the ends of the trajectory (why?), and that the estimated trajectory is much smoother.

#### 14.4.4 Applicability of Kalman filtering

The Kalman filter and its elaborations are used in a vast array of applications. The “classical” application is in radar tracking of aircraft and missiles. Related applications include acoustic tracking of submarines and ground vehicles and visual tracking of vehicles and people. In a slightly more esoteric vein, Kalman filters are used to reconstruct particle trajectories from bubble-chamber photographs and ocean currents from satellite surface measurements. The range of application is much larger than just the tracking of motion: any system characterized by continuous state variables and noisy measurements will do. Such systems include pulp mills, chemical plants, nuclear reactors, plant ecosystems, and national economies.

The fact that Kalman filtering can be applied to a system does not mean that the results will be valid or useful. The assumptions made—linear-Gaussian transition and sensor models—are very strong. The **extended Kalman filter (EKF)** attempts to overcome nonlinearities in the system being modeled. A system is **nonlinear** if the transition model cannot be described as a matrix multiplication of the state vector, as in Equation (14.21). The EKF

Extended Kalman filter (EKF)  
Nonlinear

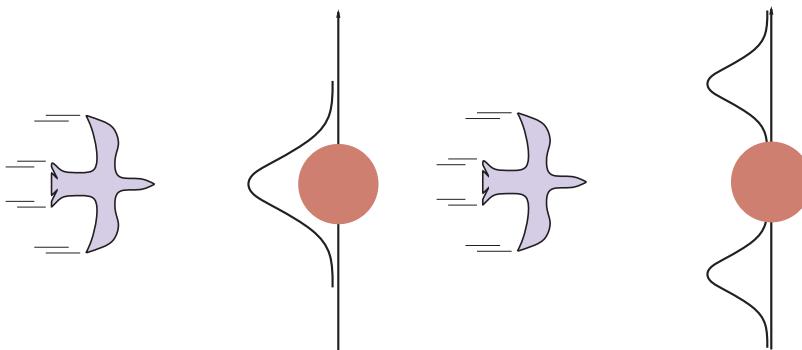

**Figure 14.11** (a) Results of Kalman filtering for an object moving on the  $X-Y$  plane, showing the true trajectory (left to right), a series of noisy observations, and the trajectory estimated by Kalman filtering. Variance in the position estimate is indicated by the ovals. (b) The results of Kalman smoothing for the same observation sequence.

works by modeling the system as *locally* linear in  $\mathbf{x}_t$  in the region of  $\mathbf{x}_t = \mu_t$ , the mean of the current state distribution. This works well for smooth, well-behaved systems and allows the tracker to maintain and update a Gaussian state distribution that is a reasonable approximation to the true posterior. A detailed example is given in Chapter 26.

What does it mean for a system to be “unsmooth” or “poorly behaved”? Technically, it means that there is significant nonlinearity in system response within the region that is “close” (according to the covariance  $\Sigma_t$ ) to the current mean  $\mu_t$ . To understand this idea in nontechnical terms, consider the example of trying to track a bird as it flies through the jungle. The bird appears to be heading at high speed straight for a tree trunk. The Kalman filter, whether regular or extended, can make only a Gaussian prediction of the location of the bird, and the mean of this Gaussian will be centered on the trunk, as shown in Figure 14.12(a). A reasonable model of the bird, on the other hand, would predict evasive action to one side or the other, as shown in Figure 14.12(b). Such a model is highly nonlinear, because the bird’s decision varies sharply depending on its precise location relative to the trunk.

To handle examples like these, we clearly need a more expressive language for representing the behavior of the system being modeled. Within the control theory community, for which problems such as evasive maneuvering by aircraft raise the same kinds of difficulties, the standard solution is the **switching Kalman filter**. In this approach, multiple Kalman filters run in parallel, each using a different model of the system—for example, one for straight flight, one for sharp left turns, and one for sharp right turns. A weighted sum of predictions is used, where the weight depends on how well each filter fits the current data. We will see in the next section that this is simply a special case of the general dynamic Bayesian network model, obtained by adding a discrete “maneuver” state variable to the network shown in Figure 14.9. Switching Kalman filters are discussed further in Exercise 14.KFSW.

**Figure 14.12** A bird flying toward a tree (top views). (a) A Kalman filter will predict the location of the bird using a single Gaussian centered on the obstacle. (b) A more realistic model allows for the bird’s evasive action, predicting that it will fly to one side or the other.

## 14.5 Dynamic Bayesian Networks

**Dynamic Bayesian networks**, or **DBNs**, extend the semantics of standard Bayesian networks to handle temporal probability models of the kind described in Section 14.1. We have already seen examples of DBNs: the umbrella network in Figure 14.2 and the Kalman filter network in Figure 14.9. In general, each slice of a DBN can have any number of state variables  $\mathbf{X}_t$  and evidence variables  $\mathbf{E}_t$ . For simplicity, we assume that the variables, their links, and their conditional distributions are exactly replicated from slice to slice and that the DBN represents a first-order Markov process, so that each variable can have parents only in its own slice or the immediately preceding slice. In this way, the DBN corresponds to a Bayesian network with infinitely many variables.

It should be clear that every hidden Markov model can be represented as a DBN with a single state variable and a single evidence variable. It is also the case that every discrete-variable DBN can be represented as an HMM; as explained in Section 14.3, we can combine all the state variables in the DBN into a single state variable whose values are all possible tuples of values of the individual state variables. Now, if every HMM is a DBN and every DBN can be translated into an HMM, what’s the difference? The difference is that, *by decomposing the state of a complex system into its constituent variables, we can take advantage of sparseness in the temporal probability model.*

To see what this means in practice, remember that in Section 14.3 we said that an HMM representation for a temporal process with  $n$  discrete variables, each with up to  $d$  values, needs a transition matrix of size  $O(d^{2n})$ . The DBN representation, on the other hand, has size  $O(nd^k)$  if the number of parents of each variable is bounded by  $k$ . In other words, the DBN representation is linear rather than exponential in the number of variables. For the vacuum robot with 42 possibly dirty locations, the number of probabilities required is reduced from  $5 \times 10^{29}$  to a few thousand.

We have already explained that every Kalman filter model can be represented in a DBN with continuous variables and linear–Gaussian conditional distributions (Figure 14.9). It should be clear from the discussion at the end of the preceding section that *not* every DBN can be represented by a Kalman filter model. In a Kalman filter, the current state distribution

Dynamic Bayesian  
network

**Figure 14.13** Left: Specification of the prior, transition model, and sensor model for the umbrella DBN. Subsequent slices are copies of slice 1. Right: A simple DBN for robot motion in the X–Y plane.

is always a single multivariate Gaussian distribution—that is, a single “bump” in a particular location. DBNs, on the other hand, can model arbitrary distributions.

For many real-world applications, this flexibility is essential. Consider, for example, the current location of my keys. They might be in my pocket, on the bedside table, on the kitchen counter, dangling from the front door, or locked in the car. A single Gaussian bump that included all these places would have to allocate significant probability to the keys being in mid-air above the front garden. Aspects of the real world such as purposive agents, obstacles, and pockets introduce “nonlinearities” that require combinations of discrete and continuous variables in order to get reasonable models.

### 14.5.1 Constructing DBNs

To construct a DBN, one must specify three kinds of information: the prior distribution over the state variables,  $\mathbf{P}(\mathbf{X}_0)$ ; the transition model  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{X}_t)$ ; and the sensor model  $\mathbf{P}(\mathbf{E}_t | \mathbf{X}_t)$ . To specify the transition and sensor models, one must also specify the topology of the connections between successive slices and between the state and evidence variables. Because the transition and sensor models are assumed to be time-homogeneous—the same for all  $t$ —it is most convenient simply to specify them for the first slice. For example, the complete DBN specification for the umbrella world is given by the three-node network shown in Figure 14.13(a). From this specification, the complete DBN with an unbounded number of time slices can be constructed as needed by copying the first slice.

Let us now consider a more interesting example: monitoring a battery-powered robot moving in the X–Y plane, as introduced at the end of Section 14.1. First, we need state variables, which will include both  $\mathbf{X}_t = (X_t, Y_t)$  for position and  $\dot{\mathbf{X}}_t = (\dot{X}_t, \dot{Y}_t)$  for velocity. We assume some method of measuring position—perhaps a fixed camera or onboard GPS (Global Positioning System)—yielding measurements  $\mathbf{Z}_t$ . The position at the next time step depends on the current position and velocity, as in the standard Kalman filter model. The velocity at the next step depends on the current velocity and the state of the battery. We add  $Battery_t$  to

represent the actual battery charge level, which has as parents the previous battery level and the velocity, and we add  $BMeter_t$ , which measures the battery charge level. This gives us the basic model shown in Figure 14.13(b).

It is worth looking in more depth at the nature of the sensor model for  $BMeter_t$ . Let us suppose, for simplicity, that both  $Battery_t$  and  $BMeter_t$  can take on discrete values 0 through 5. (Exercise 14.BATT asks you to relate this discrete model to a corresponding continuous model.) If the meter is always accurate, then the CPT  $\mathbf{P}(BMeter_t | Battery_t)$  should have probabilities of 1.0 “along the diagonal” and probabilities of 0.0 elsewhere. In reality, noise always creeps into measurements. For continuous measurements, a Gaussian distribution with a small variance might be used.<sup>7</sup> For our discrete variables, we can approximate a Gaussian using a distribution in which the probability of error drops off in the appropriate way, so that the probability of a large error is very small. We use the term **Gaussian error model** to cover both the continuous and discrete versions.

Anyone with hands-on experience of robotics, computerized process control, or other forms of automatic sensing will readily testify to the fact that small amounts of measurement noise are often the least of one’s problems. Real sensors *fail*. When a sensor fails, it does not necessarily send a signal saying, “Oh, by the way, the data I’m about to send you is a load of nonsense.” Instead, it simply sends the nonsense. The simplest kind of failure is called a **transient failure**, where the sensor occasionally decides to send some nonsense. For example, the battery level sensor might have a habit of sending a reading of 0 when someone bumps the robot, even if the battery is fully charged.

Let’s see what happens when a transient failure occurs with a Gaussian error model that doesn’t accommodate such failures. Suppose, for example, that the robot is sitting quietly and observes 20 consecutive battery readings of 5. Then the battery meter has a temporary seizure and the next reading is  $BMeter_{21} = 0$ . What will the simple Gaussian error model lead us to believe about  $Battery_{21}$ ? According to Bayes’ rule, the answer depends on both the sensor model  $\mathbf{P}(BMeter_{21} = 0 | Battery_{21})$  and the prediction  $\mathbf{P}(Battery_{21} | BMeter_{1:20})$ . If the probability of a large sensor error is significantly less than the probability of a transition to  $Battery_{21} = 0$ , even if the latter is very unlikely, then the posterior distribution will assign a high probability to the battery’s being empty.

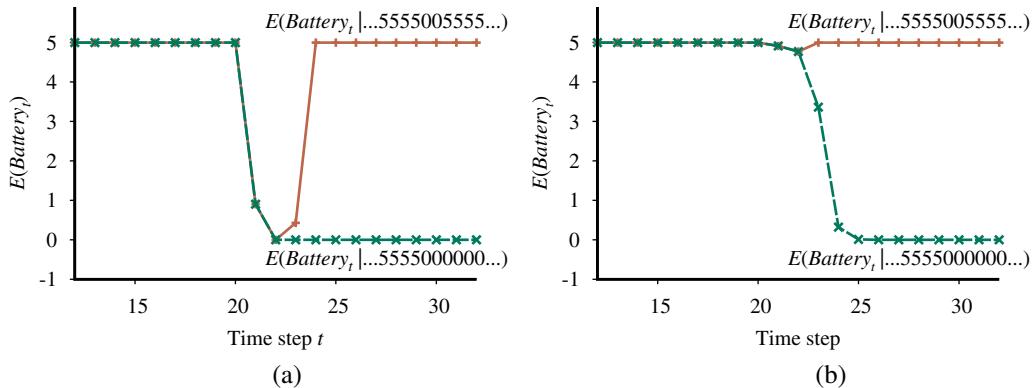

A second reading of 0 at  $t = 22$  will make this conclusion almost certain. If the transient failure then disappears and the reading returns to 5 from  $t = 23$  onwards, the estimate for the battery level will quickly return to 5. (This does not mean the algorithm thinks the battery magically recharged itself, which may be physically impossible; instead, the algorithm now believes that the battery was never low and the extremely unlikely hypothesis that the battery meter had two consecutive huge errors must be the right explanation.) This course of events is illustrated in the upper curve of Figure 14.14(a), which shows the expected value (see Appendix A) of  $Battery_t$  over time, using a discrete Gaussian error model.

Despite the recovery, there is a time ( $t = 22$ ) when the robot is convinced that its battery is empty; presumably, then, it should send out a mayday signal and shut down. Alas, its oversimplified sensor model has led it astray. The moral of the story is simple: *for the system to handle sensor failure properly, the sensor model must include the possibility of failure.*

<sup>7</sup> Strictly speaking, a Gaussian distribution is problematic because it assigns nonzero probability to large negative charge levels. The **beta distribution** is sometimes a better choice for a variable whose range is restricted.

Gaussian error model

Transient failure

**Figure 14.14** (a) Upper curve: trajectory of the expected value of  $Battery_t$  for an observation sequence consisting of all 5s except for 0s at  $t=21$  and  $t=22$ , using a simple Gaussian error model. Lower curve: trajectory when the observation remains at 0 from  $t=21$  onwards. (b) The same experiment run with the transient failure model. The transient failure is handled well, but the persistent failure results in excessive pessimism about the battery charge.

The simplest kind of failure model for a sensor allows a certain probability that the sensor will return some completely incorrect value, regardless of the true state of the world. For example, if the battery meter fails by returning 0, we might say that

$$P(BMeter_t = 0 | Battery_t = 5) = 0.03,$$

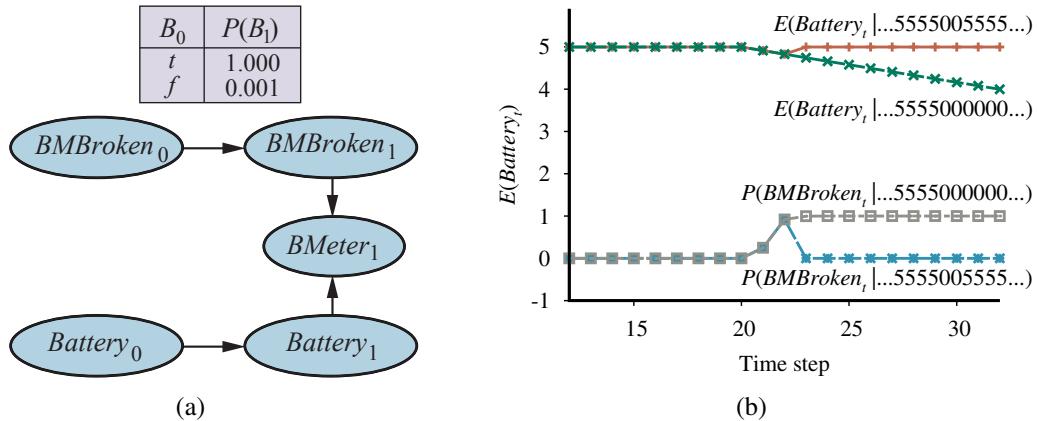

Transient failure model

which is presumably much larger than the probability assigned by the simple Gaussian error model. Let's call this the **transient failure model**. How does it help when we are faced with a reading of 0? Provided that the *predicted* probability of an empty battery, according to the readings so far, is much less than 0.03, then the best explanation of the observation  $BMeter_{21}=0$  is that the sensor has temporarily failed. Intuitively, we can think of the belief about the battery level as having a certain amount of “inertia” that helps to overcome temporary blips in the meter reading. The upper curve in Figure 14.14(b) shows that the transient failure model can handle transient failures without a catastrophic change in beliefs.

So much for temporary blips. What about a persistent sensor failure? Sadly, failures of this kind are all too common. If the sensor returns 20 readings of 5 followed by 20 readings of 0, then the transient sensor failure model described in the preceding paragraph will result in the robot gradually coming to believe that its battery is empty when in fact it may be that the meter has failed. The lower curve in Figure 14.14(b) shows the belief “trajectory” for this case. By  $t=25$ —five readings of 0—the robot is convinced that its battery is empty. Obviously, we would prefer the robot to believe that its battery meter is broken—if indeed this is the more likely event.

Persistent failure model

Unsurprisingly, to handle persistent failure, we need a **persistent failure model** that describes how the sensor behaves under normal conditions and after failure. To do this, we need to augment the state of the system with an additional variable, say,  $BMBroken$ , that describes the status of the battery meter. The persistence of failure must be modeled by an

**Figure 14.15** (a) A DBN fragment showing the sensor status variable required for modeling persistent failure of the battery sensor. (b) Upper curves: trajectories of the expected value of  $Battery_t$  for the “transient failure” and “permanent failure” observation sequences. Lower curves: probability trajectories for  $BMBroken$  given the two observation sequences.

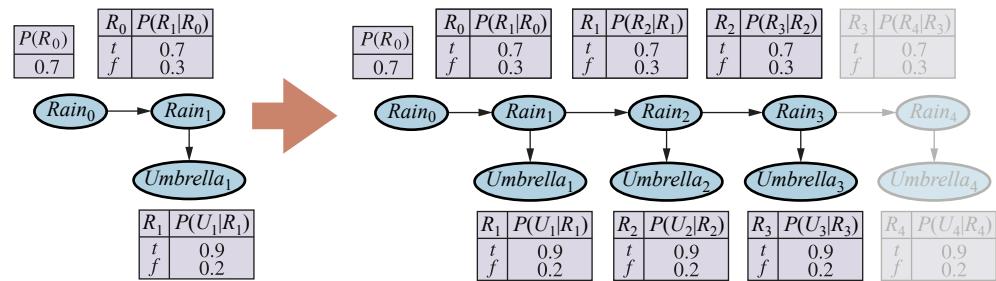

arc linking  $BMBroken_0$  to  $BMBroken_1$ . This **persistence arc** has a CPT that gives a small probability of failure in any given time step, say, 0.001, but specifies that the sensor stays broken once it breaks. When the sensor is OK, the sensor model for  $BMeter$  is identical to the transient failure model; when the sensor is broken, it says  $BMeter$  is always 0, regardless of the actual battery charge.

The persistent failure model for the battery sensor is shown in Figure 14.15(a). Its performance on the two data sequences (temporary blip and persistent failure) is shown in Figure 14.15(b). There are several things to notice about these curves. First, in the case of the temporary blip, the probability that the sensor is broken rises significantly after the second 0 reading, but immediately drops back to zero once a 5 is observed. Second, in the case of persistent failure, the probability that the sensor is broken rises quickly to almost 1 and stays there. Finally, once the sensor is known to be broken, the robot can only assume that its battery discharges at the “normal” rate. This is shown by the gradually descending level of  $E(Battery_t | \dots )$ .

So far, we have merely scratched the surface of the problem of representing complex processes. The variety of transition models is huge, encompassing topics as disparate as modeling the human endocrine system and modeling multiple vehicles driving on a freeway. Sensor modeling is also a vast subfield in itself. But dynamic Bayesian networks can model even subtle phenomena, such as sensor drift, sudden decalibration, and the effects of exogenous conditions (such as weather) on sensor readings.

### 14.5.2 Exact inference in DBNs

Having sketched some ideas for representing complex processes as DBNs, we now turn to the question of inference. In a sense, this question has already been answered: dynamic Bayesian networks *are* Bayesian networks, and we already have algorithms for inference in Bayesian networks. Given a sequence of observations, one can construct the full Bayesian network rep-

**Figure 14.16** Unrolling a dynamic Bayesian network: slices are replicated to accommodate the observation sequence  $\text{Umbrella}_{1:3}$ . Further slices have no effect on inferences within the observation period.

representation of a DBN by replicating slices until the network is large enough to accommodate the observations, as in Figure 14.16. This technique is called **unrolling**. (Technically, the DBN is equivalent to the semi-infinite network obtained by unrolling forever. Slices added beyond the last observation have no effect on inferences within the observation period and can be omitted.) Once the DBN is unrolled, one can use any of the inference algorithms—variable elimination, clustering methods, and so on—described in Chapter 13.

Unfortunately, a naive application of unrolling would not be particularly efficient. If we want to perform filtering or smoothing with a long sequence of observations  $\mathbf{e}_{1:t}$ , the unrolled network would require  $O(t)$  space and would thus grow without bound as more observations were added. Moreover, if we simply run the inference algorithm anew each time an observation is added, the inference time per update will also increase as  $O(t)$ .

Looking back to Section 14.2.1, we see that constant time and space per filtering update can be achieved if the computation can be done recursively. Essentially, the filtering update in Equation (14.5) works by *summing out* the state variables of the previous time step to get the distribution for the new time step. Summing out variables is exactly what the **variable elimination** (Figure 13.13) algorithm does, and it turns out that running variable elimination with the variables in temporal order exactly mimics the operation of the recursive filtering update in Equation (14.5). The modified algorithm keeps at most two slices in memory at any one time: starting with slice 0, we add slice 1, then sum out slice 0, then add slice 2, then sum out slice 1, and so on. In this way, we can achieve constant space and time per filtering update. (The same performance can be achieved by suitable modifications to the clustering algorithm.) Exercise 14.DBNE asks you to verify this fact for the umbrella network.

So much for the good news; now for the bad news: It turns out that the “constant” for the per-update time and space complexity is, in almost all cases, exponential in the number of state variables. What happens is that, as the variable elimination proceeds, the factors grow to include all the state variables (or, more precisely, all those state variables that have parents in the previous time slice). The maximum factor size is  $O(d^{n+k})$  and the total update cost per step is  $O(nd^{n+k})$ , where  $d$  is the domain size of the variables and  $k$  is the maximum number of parents of any state variable.

Of course, this is much less than the cost of HMM updating, which is  $O(d^{2n})$ , but it is still infeasible for large numbers of variables. This grim fact means is that *even though we can use DBNs to represent very complex temporal processes with many sparsely connected variables*,

*we cannot reason efficiently and exactly about those processes.* The DBN model itself, which represents the prior joint distribution over all the variables, is factorable into its constituent CPTs, but the posterior joint distribution conditioned on an observation sequence—that is, the forward message—is generally *not* factorable. The problem is intractable in general, so we must fall back on approximate methods.

### 14.5.3 Approximate inference in DBNs

Section 13.4 described two approximation algorithms: likelihood weighting (Figure 13.18) and Markov chain Monte Carlo (MCMC, Figure 13.20). Of the two, the former is most easily adapted to the DBN context. (An MCMC filtering algorithm is described briefly in the notes at the end of this chapter.) We will see, however, that several improvements are required over the standard likelihood weighting algorithm before a practical method emerges.

Recall that likelihood weighting works by sampling the nonevidence nodes of the network in topological order, weighting each sample by the likelihood it accords to the observed evidence variables. As with the exact algorithms, we could apply likelihood weighting directly to an unrolled DBN, but this would suffer from the same problems of increasing time and space requirements per update as the observation sequence grows. The problem is that the standard algorithm runs each sample in turn, all the way through the network.

Instead, we can simply run all  $N$  samples together through the DBN, one slice at a time. The modified algorithm fits the general pattern of filtering algorithms, with the set of  $N$  samples as the forward message. The first key innovation, then, is to *use the samples themselves as an approximate representation of the current state distribution.* This meets the requirement of a “constant” time per update, although the constant depends on the number of samples required to maintain an accurate approximation. There is also no need to unroll the DBN, because we need to have in memory only the current slice and the next slice. This approach is called **sequential importance sampling** or SIS.

In our discussion of likelihood weighting in Chapter 13, we pointed out that the algorithm’s accuracy suffers if the evidence variables are “downstream” from the variables being sampled, because in that case the samples are generated without any influence from the evidence and will nearly all have very low weights.

Now if we look at the typical structure of a DBN—say, the umbrella DBN in Figure 14.16—we see that indeed the early state variables will be sampled without the benefit of the later evidence. In fact, looking more carefully, we see that *none* of the state variables have *any* evidence variables among its ancestors! Hence, although the weight of each sample will depend on the evidence, the actual set of samples generated will be *completely independent* of the evidence. For example, even if the boss brings in the umbrella every day, the sampling process could still hallucinate endless days of sunshine.

What this means in practice is that the fraction of samples that remain reasonably close to the actual series of events (and therefore have non-negligible weights) drops exponentially with  $t$ , the length of the sequence. In other words, to maintain a given level of accuracy, we need to increase the number of samples exponentially with  $t$ . Given that a real-time filtering algorithm can use only a bounded number of samples, what happens in practice is that the error blows up after a very small number of update steps. Figure 14.19 on page 512 shows this effect for SIS applied to the grid-world localization problem from Section 14.3: even with 100,000 samples, the SIS approximation fails completely after about 20 steps.

Sequential  
importance sampling

     $W[i] \leftarrow \mathbf{P}(\mathbf{e} | \mathbf{X}_1 = S[i])$  // step 2
   $S \leftarrow$  WEIGHTED-SAMPLE-WITH-REPLACEMENT( $N$ ,  $S$ ,  $W$ ) // step 3
  return  $S$ 

```

**Figure 14.17** The particle filtering algorithm implemented as a recursive update operation with state (the set of samples). Each of the sampling operations involves sampling the relevant slice variables in topological order, much as in PRIOR-SAMPLE. The WEIGHTED-SAMPLE-WITH-REPLACEMENT operation can be implemented to run in  $O(N)$  expected time. The step numbers refer to the description in the text.

► Clearly, we need a better solution. The second key innovation is to *focus the set of samples on the high-probability regions of the state space*. This can be done by throwing away samples that have very low weight, according to the observations, while replicating those that have high weight. In that way, the population of samples will stay reasonably close to reality. If we think of samples as a resource for modeling the posterior distribution, then it makes sense to use more samples in regions of the state space where the posterior is higher.

#### Particle filtering

A family of algorithms called **particle filtering** is designed to do just that. (Another early name was **sequential importance sampling with resampling**, but for some reason it failed on catch on.) Particle filtering works as follows: First, we generate a population of  $N$  samples from the prior distribution  $\mathbf{P}(\mathbf{X}_0)$ . Then the update cycle is repeated for each time step:

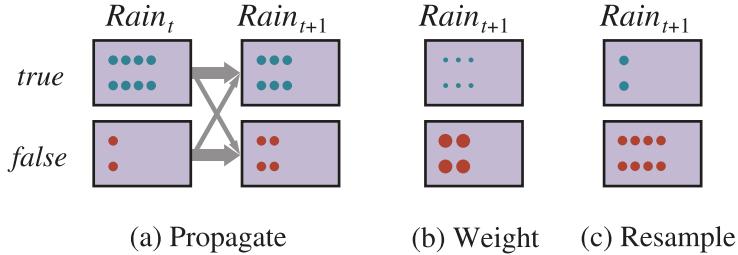

1. Each sample is propagated forward by sampling the next state value  $\mathbf{x}_{t+1}$  given the current value  $\mathbf{x}_t$  for the sample, based on the transition model  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{x}_t)$ .
2. Each sample is weighted by the likelihood it assigns to the new evidence,  $P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1})$ .
3. The population is *resampled* to generate a new population of  $N$  samples. Each new sample is selected from the current population; the probability that a particular sample is selected is proportional to its weight. The new samples are unweighted.

The algorithm is shown in detail in Figure 14.17, and its operation for the umbrella DBN is illustrated in Figure 14.18.

We can show that this algorithm is consistent—gives the correct probabilities as  $N$  tends to infinity—by examining the operations in one update cycle. We assume that the sample population starts with a correct representation of the forward message—that is,  $\mathbf{f}_{1:t} = \mathbf{P}(\mathbf{X}_t | \mathbf{e}_{1:t})$  at time  $t$ . Writing  $N(\mathbf{x}_t | \mathbf{e}_{1:t})$  for the number of samples occupying state  $\mathbf{x}_t$  after observations  $\mathbf{e}_{1:t}$  have been processed, we therefore have

$$N(\mathbf{x}_t | \mathbf{e}_{1:t}) / N = P(\mathbf{x}_t | \mathbf{e}_{1:t}) \quad (14.23)$$

for large  $N$ . Now we propagate each sample forward by sampling the state variables at  $t + 1$ ,

**Figure 14.18** The particle filtering update cycle for the umbrella DBN with  $N = 10$ , showing the sample populations of each state. (a) At time  $t$ , 8 samples indicate rain and 2 indicate  $\neg$ rain. Each is propagated forward by sampling the next state through the transition model. At time  $t + 1$ , 6 samples indicate rain and 4 indicate  $\neg$ rain. (b)  $\neg$ umbrella is observed at  $t + 1$ . Each sample is weighted by its likelihood for the observation, as indicated by the size of the circles. (c) A new set of 10 samples is generated by weighted random selection from the current set, resulting in 2 samples that indicate rain and 8 that indicate  $\neg$ rain.

given the values for the sample at  $t$ . The number of samples reaching state  $\mathbf{x}_{t+1}$  from each  $\mathbf{x}_t$  is the transition probability times the population of  $\mathbf{x}_t$ ; hence, the total number of samples reaching  $\mathbf{x}_{t+1}$  is

$$N(\mathbf{x}_{t+1} | \mathbf{e}_{1:t}) = \sum_{\mathbf{x}_t} P(\mathbf{x}_{t+1} | \mathbf{x}_t) N(\mathbf{x}_t | \mathbf{e}_{1:t}).$$

Now we weight each sample by its likelihood for the evidence at  $t + 1$ . A sample in state  $\mathbf{x}_{t+1}$  receives weight  $P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1})$ . The total weight of the samples in  $\mathbf{x}_{t+1}$  after seeing  $\mathbf{e}_{t+1}$  is therefore

$$W(\mathbf{x}_{t+1} | \mathbf{e}_{1:t+1}) = P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1}) N(\mathbf{x}_{t+1} | \mathbf{e}_{1:t}).$$

Now for the resampling step. Since each sample is replicated with probability proportional to its weight, the number of samples in state  $\mathbf{x}_{t+1}$  after resampling is proportional to the total weight in  $\mathbf{x}_{t+1}$  before resampling:

$$\begin{aligned} N(\mathbf{x}_{t+1} | \mathbf{e}_{1:t+1})/N &= \alpha W(\mathbf{x}_{t+1} | \mathbf{e}_{1:t+1}) \\ &= \alpha P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1}) N(\mathbf{x}_{t+1} | \mathbf{e}_{1:t}) \\ &= \alpha P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1}) \sum_{\mathbf{x}_t} P(\mathbf{x}_{t+1} | \mathbf{x}_t) N(\mathbf{x}_t | \mathbf{e}_{1:t}) \\ &= \alpha N P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1}) \sum_{\mathbf{x}_t} P(\mathbf{x}_{t+1} | \mathbf{x}_t) P(\mathbf{x}_t | \mathbf{e}_{1:t}) \quad (\text{by 14.23}) \\ &= \alpha' P(\mathbf{e}_{t+1} | \mathbf{x}_{t+1}) \sum_{\mathbf{x}_t} P(\mathbf{x}_{t+1} | \mathbf{x}_t) P(\mathbf{x}_t | \mathbf{e}_{1:t}) \\ &= P(\mathbf{x}_{t+1} | \mathbf{e}_{1:t+1}) \quad (\text{by 14.5}). \end{aligned}$$

Therefore the sample population after one update cycle correctly represents the forward message at time  $t + 1$ .

Particle filtering is *consistent*, therefore, but is it *efficient*? For many practical cases, it seems that the answer is yes: particle filtering seems to maintain a good approximation to the true posterior using a constant number of samples. Figure 14.19 shows that particle filtering does a good job on the grid-world localization problem with only a thousand samples. It also

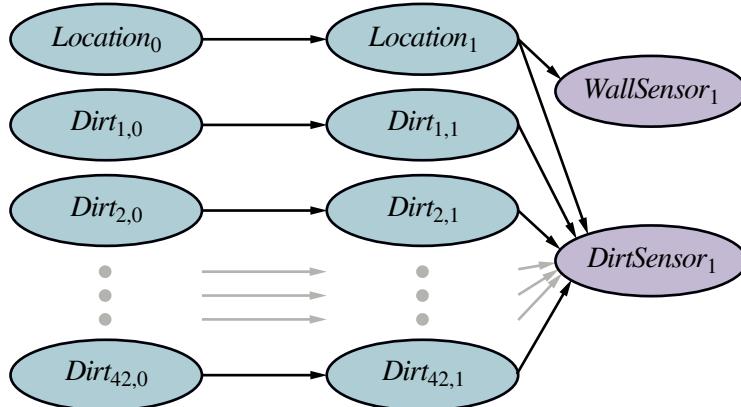

**Figure 14.19** Max norm error in the grid-world location estimate (compared to exact inference) for likelihood weighting (sequential importance sampling) with 100,000 samples and particle filtering with 1,000 samples; data averaged over 50 runs.

works on real-world problems: the algorithm supports thousands of applications in science and engineering. (Some references are given at the end of the chapter.) It handles combinations of discrete and continuous variables as well as nonlinear and non-Gaussian models for continuous variables. Under certain assumptions—in particular, that the probabilities in the transition and sensor models are bounded away from 0 and 1—it is also possible to prove that the approximation maintains bounded error with high probability, as the figure suggests.

The particle filtering algorithm does have weaknesses, however. Let's see how it performs for the vacuum world with dirt added. Recall from Section 14.3.2 that this increases the state space size by a factor of  $2^{42}$ , making exact HMM inference infeasible. We want the robot to wander around and build a map of where the dirt is located. (This is a simple example of **simultaneous localization and mapping** or **SLAM**, which we cover in more depth in Chapter 26.) Let  $Dirt_{i,t}$  mean that square  $i$  is dirty at time  $t$  and let  $DirtSensor_t$  be true if and only if the robot detects dirt at time  $t$ . We'll assume that, in any given square, dirt persists with probability  $p$ , whereas a clean square becomes dirty with probability  $1 - p$  (which means that each square is dirty half the time, on average). The robot has a dirt sensor for its current location; the sensor is accurate with probability 0.9. Figure 14.20 shows the DBN.

For simplicity, we'll start by assuming that the robot has a perfect location sensor, rather than the noisy wall sensor. The algorithm's performance is shown in Figure 14.21(a), where its estimates for dirt are compared to the results of exact inference. (We'll see shortly how exact inference is possible.) For low values of the dirt persistence  $p$ , the error remains small—but this is no great achievement, because for every square the true posterior for dirt is close to 0.5 if the robot hasn't visited that square recently. For higher values of  $p$ , the dirt stays around longer, so visiting a square yields more useful information that is valid over a longer period. Perhaps surprisingly, particle filtering does worse for higher values of  $p$ . It fails completely when  $p=1$ , even though that seems like the easiest case: the dirt arrives at time 0 and stays put forever, so after a few tours of the world, the robot should have a close-to-perfect dirt map. Why does particle filtering fail in this case?

**Figure 14.20** A dynamic Bayes net for simultaneous localization and mapping in the stochastic-dirt vacuum world. Dirty squares persist with probability  $p$ , and clean squares become dirty with probability  $1 - p$ . The local dirt sensor is 90% accurate, for the square in which the robot is currently located.

**Figure 14.21** (a) Performance of the standard particle filtering algorithm with 1,000 particles, showing RMS error in marginal dirt probabilities compared to exact inference for different values of the dirt persistence  $p$ . (b) Performance of Rao-Blackwellized particle filtering (100 particles) compared to ground truth, for both exact location sensing and noisy wall sensing and with deterministic dirt. Data averaged over 20 runs.

It turns out that the theoretical condition requiring that “the probabilities in the transition and sensor models are strictly greater than 0 and less than 1” is more than mere mathematical pedantry. What happens is first each particle initially contains 42 guesses from  $\mathbf{P}(\mathbf{X}_0)$  about which squares have dirt and which do not. Then, the state for each particle is projected forward in time according to the transition model. Unfortunately, the transition model for deterministic dirt is deterministic: the dirt stays exactly where it is. Thus, the initial guesses in each particle are never updated by the evidence.

The chance that the initial guesses are all correct is  $2^{-42}$  or about  $2 \times 10^{-13}$ , so it is vanishingly unlikely that a thousand particles (or even a million particles) will include one with the correct dirt map. Typically, the best particle out of a thousand will get about 32 right and 10 wrong, and usually there will be only one such particle, or perhaps a handful. One of those best particles will come to dominate the total likelihood as time progresses and the diversity of the population of particles will collapse. Then, because all the particles agree on a single, incorrect map, the algorithm becomes convinced that that map is correct and never changes its mind.

Fortunately, the problem of simultaneous localization and mapping has a special structure: conditioned on the sequence of robot locations, the dirt statuses of the individual squares are independent (Exercise 14.RBPF). More specifically,

$$\begin{aligned} & \mathbf{P}(Dirt_{1,0:t}, \dots, Dirt_{42,0:t} | DirtSensor_{1:t}, WallSensor_{1:t}, Location_{1:t}) \\ &= \prod_i \mathbf{P}(Dirt_{i,0:t} | DirtSensor_{1:t}, Location_{1:t}). \end{aligned} \quad (14.24)$$

Rao-Blackwellization

This means it is useful to apply a statistical trick called **Rao-Blackwellization**, which is based on the simple idea that exact inference is always more accurate than sampling, even if it's only for a subset of the variables. (See Exercise 14.RAOB.) For the SLAM problem, we run particle filtering on the robot location and then, for each particle, we run exact HMM inference for each dirt square independently, conditioned on the location sequence in that particle. Each particle therefore contains a sampled location plus 42 exact marginal posteriors for the 42 squares—exact, that is, assuming that the hypothesized location trajectory followed by that particle is correct. This approach, called the **Rao-Blackwellized particle filter**, handles the case of deterministic dirt with no difficulty, gradually building an exact dirt map with either exact location sensing or noisy wall sensing, as shown in Figure 14.21(b).

Rao-Blackwellized  
particle filter

In cases that do not satisfy the kind of conditional independence structure exemplified by Equation (14.24), Rao-Blackwellization is not applicable. The notes at the end of the chapter mention a number of algorithms that have been proposed to handle the general problem of filtering with static variables. None has the elegance and broad applicability of the particle filter, but several are effective in practice on certain classes of problems.

## Summary

---

This chapter has addressed the general problem of representing and reasoning about probabilistic temporal processes. The main points are as follows:

- The changing state of the world is handled by using a set of random variables to represent the state at each point in time.
- Representations can be designed to (roughly) satisfy the **Markov property**, so that the future is independent of the past given the present. Combined with the assumption that the process is **time-homogeneous**, this greatly simplifies the representation.
- A temporal probability model can be thought of as containing a **transition model** describing the state evolution and a **sensor model** describing the observation process.
- The principal inference tasks in temporal models are **filtering (state estimation)**, **prediction**, **smoothing**, and computing the **most likely explanation**. Each of these tasks

can be achieved using simple, recursive algorithms whose run time is linear in the length of the sequence.

- Three families of temporal models were studied in more depth: **hidden Markov models**, **Kalman filters**, and **dynamic Bayesian networks** (which include the other two as special cases).
- Unless special assumptions are made, as in Kalman filters, exact inference with many state variables is intractable. In practice, the **particle filtering** algorithm and its descendants are an effective family of approximation algorithms.

## Bibliographical and Historical Notes

---

Many of the basic ideas for estimating the state of dynamical systems came from the mathematician C. F. Gauss (1809), who formulated a deterministic least-squares algorithm for the problem of estimating orbits from astronomical observations. A. A. Markov (1913) developed what was later called the **Markov assumption** in his analysis of stochastic processes; he estimated a first-order Markov chain on letters from the text of *Eugene Onegin*. The general theory of Markov chains and their mixing times is covered by Levin *et al.* (2008).

Significant classified work on filtering was done during World War II by Wiener (1942) for continuous-time processes and by Kolmogorov (1941) for discrete-time processes. Although this work led to important technological developments over the next 20 years, its use of a frequency-domain representation made many calculations quite cumbersome. Direct state-space modeling of the stochastic process turned out to be simpler, as shown by Peter Swerling (1959) and Rudolf Kalman (1960). The latter paper described what is now known as the Kalman filter for forward inference in linear systems with Gaussian noise; Kalman's results had, however, been obtained previously by the Danish astronomer Thorvold Thiele (1880) and by the Russian physicist Ruslan Stratonovich (1959). After a visit to NASA Ames Research Center in 1960, Kalman saw the applicability of the method to the tracking of rocket trajectories, and the filter was later implemented for the Apollo missions.

Key results on smoothing were derived by Rauch *et al.* (1965), and the impressively named Rauch–Tung–Striebel smoother is still a standard technique today. Many early results are gathered in Gelb (1974). Bar-Shalom and Fortmann (1988) give a more modern treatment with a Bayesian flavor, as well as many references to the vast literature on the subject. Chatfield (1989) and Box *et al.* (2016) cover the control theory approach to time series analysis.

The hidden Markov model and associated algorithms for inference and learning, including the forward–backward algorithm, were developed by Baum and Petrie (1966). The Viterbi algorithm first appeared in (Viterbi, 1967). Similar ideas also appeared independently in the Kalman filtering community (Rauch *et al.*, 1965).

The forward–backward algorithm was one of the main precursors of the general formulation of the EM algorithm (Dempster *et al.*, 1977); see also Chapter 21. Constant-space smoothing appears in Binder *et al.* (1997b), as does the divide-and-conquer algorithm developed in Exercise 14.ISLE. Constant-time fixed-lag smoothing for HMMs first appeared in Russell and Norvig (2003).

HMMs have found many applications in language processing (Charniak, 1993), speech recognition (Rabiner and Juang, 1993), machine translation (Och and Ney, 2003), computa-

tional biology (Krogh *et al.*, 1994; Baldi *et al.*, 1994), financial economics (Bhar and Hamori, 2004) and other fields. There have been several extensions to the basic HMM model: for example, the Hierarchical HMM (Fine *et al.*, 1998) and Layered HMM (Oliver *et al.*, 2004) introduce structure back into the model, replacing the single state variable of HMMs.

Dynamic Bayesian networks (DBNs) can be viewed as a sparse encoding of a Markov process and were first used in AI by Dean and Kanazawa (1989b), Nicholson and Brady (1992), and Kjaerulff (1992). The last work extends the HUGIN Bayes net system to accommodate dynamic Bayesian networks. The book by Dean and Wellman (1991) helped popularize DBNs and the probabilistic approach to planning and control within AI. Murphy (2002) provides a thorough analysis of DBNs.

Dynamic Bayesian networks have become popular for modeling a variety of complex motion processes in computer vision (Huang *et al.*, 1994; Intille and Bobick, 1999). Like HMMs, they have found applications in speech recognition (Zweig and Russell, 1998; Livescu *et al.*, 2003), robot localization (Theocharous *et al.*, 2004), and genomics (Murphy and Mian, 1999; Li *et al.*, 2011). Other application areas include gesture analysis (Suk *et al.*, 2010), driver fatigue detection (Yang *et al.*, 2010), and urban traffic modeling (Hofleitner *et al.*, 2012).

The link between HMMs and DBNs, and between the forward–backward algorithm and Bayesian network propagation, was explicated by Smyth *et al.* (1997). A further unification with Kalman filters (and other statistical models) appears in Roweis and Ghahramani (1999). Procedures exist for learning the parameters (Binder *et al.*, 1997a; Ghahramani, 1998) and structures (Friedman *et al.*, 1998) of DBNs. **Continuous-time Bayesian networks** (Nodelman *et al.*, 2002) are the discrete-state, continuous-time analog of DBNs, avoiding the need to choose a particular duration for time steps.

The first sampling algorithms for filtering (also called sequential Monte Carlo methods) were developed in the control theory community by Handschin and Mayne (1969), and the resampling idea that is the core of particle filtering appeared in a Russian control journal (Zaritskii *et al.*, 1975). It was later reinvented in statistics as **sequential importance sampling with resampling**, or **SIR** (Rubin, 1988; Liu and Chen, 1998), in control theory as particle filtering (Gordon *et al.*, 1993; Gordon, 1994), in AI as **survival of the fittest** (Kanazawa *et al.*, 1995), and in computer vision as **condensation** (Isard and Blake, 1996).

#### Evidence reversal

The paper by Kanazawa *et al.* (1995) includes an improvement called **evidence reversal** whereby the state at time  $t + 1$  is sampled conditional on both the state at time  $t$  and the evidence at time  $t + 1$ . This allows the evidence to influence sample generation directly and was proved by Doucet (1997) and Liu and Chen (1998) to reduce the approximation error.

Particle filtering has been applied in many areas, including tracking complex motion patterns in video (Isard and Blake, 1996), predicting the stock market (de Freitas *et al.*, 2000), and diagnosing faults on planetary rovers (Verma *et al.*, 2004). Since its invention, tens of thousands of papers have been published on applications and variants of the algorithm. Scalable implementations on parallel hardware have become important; although one might think it straightforward to distribute  $N$  particles across up to  $N$  processor threads, the basic algorithm requires synchronized communication among threads for the resampling step (Hendeby *et al.*, 2010). The **particle cascade algorithm** (Paige *et al.*, 2015) removes the synchronization requirement, resulting in much faster parallel computation.

The **Rao-Blackwellized particle filter** is due to Doucet *et al.* (2000) and Murphy and Russell (2001); its application to practical localization and mapping problems in robotics is

described in Chapter 26. Many other algorithms have been proposed to handle more general filtering problems with static or nearly-static variables, including the resample–move algorithm (Gilks and Berzuini, 2001), the Liu–West algorithm (Liu and West, 2001), the Storvik filter (Storvik, 2002), the extended parameter filter (Erol *et al.*, 2013), and the assumed parameter filter (Erol *et al.*, 2017). The latter is a hybrid of particle filtering with a much older idea called **assumed-density filter**. An assumed-density filter assumes that the posterior distribution over states at time  $t$  belongs to a particular finitely parameterized family; if the projection and update steps take it outside this family, the distribution is projected back to give the best approximation within the family. For DBNs, the Boyen–Koller algorithm (Boyen *et al.*, 1999) and the **factored frontier** algorithm (Murphy and Weiss, 2001) assume that the posterior distribution can be approximated well by a product of small factors.

MCMC methods (see Section 13.4.2) can be applied to the filtering problem; for example, Gibbs sampling can be applied directly to an unrolled DBN. The **particle MCMC** family of algorithms (Andrieu *et al.*, 2010; Lindsten *et al.*, 2014) combines MCMC on the unrolled temporal model with particle filtering to generate the MCMC proposals; although it provably converges to the correct posterior distribution in the general case (i.e., with both static and dynamic variables), it is an offline algorithm. To avoid the problem of increasing update times as the unrolled network grows, the **decayed MCMC** filter (Marthi *et al.*, 2002) prefers to sample more recent state variables, with a probability that decreases for variables further in the past.

The book by Doucet *et al.* (2001) collects many important papers on **sequential Monte Carlo** (SMC) algorithms, of which particle filtering is the most important instance. There are useful tutorials by Arulampalam *et al.* (2002) and Doucet and Johansen (2011). There are also several theoretical results concerning conditions under which SMC methods retain a bounded error indefinitely compared to the true posterior (Crisan and Doucet, 2002; Del Moral, 2004; Del Moral *et al.*, 2006).

# CHAPTER 15

## MAKING SIMPLE DECISIONS

*In which we see how an agent should make decisions so that it gets what it wants in an uncertain world—at least as much as possible and on average.*

In this chapter, we fill in the details of how utility theory combines with probability theory to yield a decision-theoretic agent—an agent that can make rational decisions based on what it believes and what it wants. Such an agent can make decisions in contexts in which uncertainty and conflicting goals leave a logical agent with no way to decide. A goal-based agent has a binary distinction between good (goal) and bad (non-goal) states, while a decision-theoretic agent assigns a continuous range of values to states, and thus can more easily choose a better state even when no best state is available.

Section 15.1 introduces the basic principle of decision theory: the maximization of expected utility. Section 15.2 shows that the behavior of a rational agent can be modeled by maximizing a utility function. Section 15.3 discusses the nature of utility functions in more detail, and in particular their relation to individual quantities such as money. Section 15.4 shows how to handle utility functions that depend on several quantities. In Section 15.5, we describe the implementation of decision-making systems. In particular, we introduce a formalism called a **decision network** (also known as an **influence diagram**) that extends Bayesian networks by incorporating actions and utilities. Section 15.6 shows how a decision-theoretic agent can calculate the value of acquiring new information to improve its decisions.

While Sections 15.1–15.6 assume that the agent operates with a given, known utility function, Section 15.7 relaxes this assumption. We discuss the consequences of preference uncertainty on the part of the machine—the most important of which is deference to humans.

### 15.1 Combining Beliefs and Desires under Uncertainty

We begin with an agent that, like all agents, has to make a decision. It has available some actions  $a$ . There may be uncertainty about the current state, so we'll assume that the agent assigns a probability  $P(s)$  to each possible current state  $s$ . There may also be uncertainty about the action outcomes; the transition model is given by  $P(s'|s, a)$ , the probability that action  $a$  in state  $s$  reaches state  $s'$ . Because we're primarily interested in the outcome  $s'$ , we'll also use the abbreviated notation  $P(\text{RESULT}(a)=s')$ , the probability of reaching  $s'$  by doing  $a$  in the current state, whatever that is. The two are related as follows:

$$P(\text{RESULT}(a)=s') = \sum_s P(s)P(s'|s, a).$$

Decision theory, in its simplest form, deals with choosing among actions based on the desirability of their *immediate* outcomes; that is, the environment is assumed to be episodic in the

sense defined on page 63. (This assumption is relaxed in Chapter 16.) The agent’s preferences are captured by a **utility function**,  $U(s)$ , which assigns a single number to express the desirability of a state. The **expected utility** of an action given the evidence,  $EU(a)$ , is just the average utility value of the outcomes, weighted by the probability that the outcome occurs:

$$EU(a) = \sum_{s'} P(\text{RESULT}(a)=s') U(s'). \quad (15.1)$$

The principle of **maximum expected utility** (**MEU**) says that a rational agent should choose the action that maximizes the agent’s expected utility:

$$\underset{a}{\operatorname{argmax}} EU(a).$$

In a sense, the MEU principle could be seen as a prescription for intelligent behavior. All an intelligent agent has to do is calculate the various quantities, maximize utility over its actions, and away it goes. But this does not mean that the AI problem is *solved* by the definition!

The MEU principle *formalizes* the general notion that an intelligent agent should “do the right thing,” but does not *operationalize* that advice. Estimating the probability distribution  $P(s)$  over possible states of the world, which folds into  $P(\text{RESULT}(a)=s')$ , requires perception, learning, knowledge representation, and inference. Computing  $P(\text{RESULT}(a)=s')$  itself requires a causal model of the world. There may be many actions to consider, and computing the outcome utilities  $U(s')$  may itself require further searching or planning because an agent may not know how good a state is until it knows where it can get to from that state. An AI system acting on behalf of a human may not know the human’s true utility function, so there may be uncertainty about  $U$ . In summary, decision theory is not a panacea that solves the AI problem—but it does provide the beginnings of a basic mathematical framework that is general enough to define the AI problem.

The MEU principle has a clear relation to the idea of performance measures introduced in Chapter 2. The basic idea is simple. Consider the environments that could lead to an agent having a given percept history, and consider the different agents that we could design. *If an agent acts so as to maximize a utility function that correctly reflects the performance measure, then the agent will achieve the highest possible performance score (averaged over all the possible environments).* This is the central justification for the MEU principle itself. While the claim may seem tautological, it does in fact embody a very important transition from the external performance measure to an internal utility function. The performance measure gives a score for a history—a sequence of states. Thus it is applied retrospectively after an agent completes a sequence of actions. The utility function applies to the very next state, so it can be used to guide actions step by step.

## 15.2 The Basis of Utility Theory

Intuitively, the principle of Maximum Expected Utility (MEU) seems like a reasonable way to make decisions, but it is by no means obvious that it is the *only* rational way. After all, why should maximizing the *average* utility be so special? What’s wrong with an agent that maximizes the weighted sum of the cubes of the possible utilities, or tries to minimize the worst possible loss? Could an agent act rationally just by expressing preferences between states, without giving them numeric values? Finally, why should a utility function with the required properties exist at all? We shall see.

Utility function  
Expected utility

### 15.2.1 Constraints on rational preferences

These questions can be answered by writing down some constraints on the preferences that a rational agent should have and then showing that the MEU principle can be derived from the constraints. We use the following notation to describe an agent's preferences:

$A \succ B$  the agent prefers  $A$  over  $B$ .

$A \sim B$  the agent is indifferent between  $A$  and  $B$ .

$A \asymp B$  the agent prefers  $A$  over  $B$  or is indifferent between them.

Now the obvious question is, what sorts of things are  $A$  and  $B$ ? They could be states of the world, but more often than not there is uncertainty about what is really being offered. For example, an airline passenger who is offered “the pasta dish or the chicken” does not know what lurks beneath the tinfoil cover.<sup>1</sup> The pasta could be delicious or congealed, the chicken juicy or overcooked beyond recognition. We can think of the set of outcomes for each action as a **lottery**—think of each action as a ticket. A lottery  $L$  with possible outcomes  $S_1, \dots, S_n$  that occur with probabilities  $p_1, \dots, p_n$  is written

$$L = [p_1, S_1; p_2, S_2; \dots; p_n, S_n].$$

In general, each outcome  $S_i$  of a lottery can be either an atomic state or another lottery. The primary issue for utility theory is to understand how preferences between complex lotteries are related to preferences between the underlying states in those lotteries. To address this issue we list six constraints that we require any reasonable preference relation to obey:

Lottery

Orderability

Transitivity

Continuity

Substitutability

Monotonicity

- **Orderability:** Given any two lotteries, a rational agent must either prefer one or else rate them as equally preferable. That is, the agent cannot avoid deciding. As noted on page 412, refusing to bet is like refusing to allow time to pass.

Exactly one of  $(A \succ B)$ ,  $(B \succ A)$ , or  $(A \sim B)$  holds.

- **Transitivity:** Given any three lotteries, if an agent prefers  $A$  to  $B$  and prefers  $B$  to  $C$ , then the agent must prefer  $A$  to  $C$ .

$$(A \succ B) \wedge (B \succ C) \Rightarrow (A \succ C).$$

- **Continuity:** If some lottery  $B$  is between  $A$  and  $C$  in preference, then there is some probability  $p$  for which the rational agent will be indifferent between getting  $B$  for sure and the lottery that yields  $A$  with probability  $p$  and  $C$  with probability  $1 - p$ .

$$A \succ B \succ C \Rightarrow \exists p [p, A; 1 - p, C] \sim B.$$

- **Substitutability:** If an agent is indifferent between two lotteries  $A$  and  $B$ , then the agent is indifferent between two more complex lotteries that are the same except that  $B$  is substituted for  $A$  in one of them. This holds regardless of the probabilities and the other outcome(s) in the lotteries.

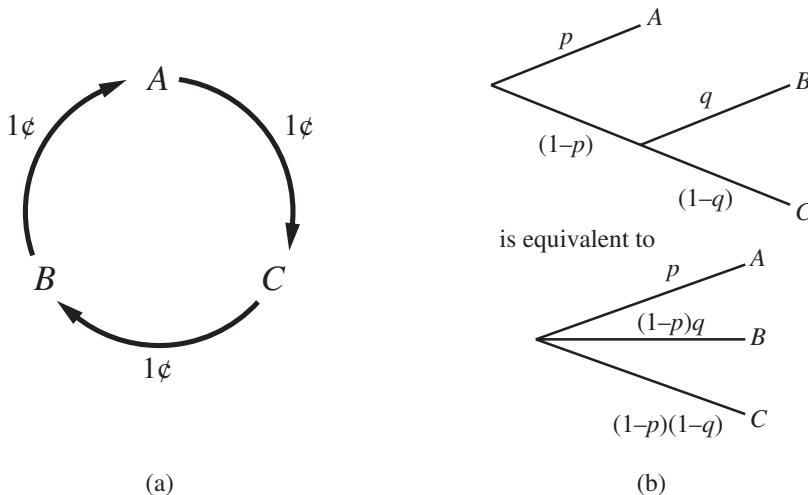

$$A \sim B \Rightarrow [p, A; 1 - p, C] \sim [p, B; 1 - p, C].$$

This also holds if we substitute  $\succ$  for  $\sim$  in this axiom.

- **Monotonicity:** Suppose two lotteries have the same two possible outcomes,  $A$  and  $B$ . If an agent prefers  $A$  to  $B$ , then the agent must prefer the lottery that has a higher probability for  $A$  (and vice versa).

$$A \succ B \Rightarrow (p > q \Leftrightarrow [p, A; 1 - p, B] \succ [q, A; 1 - q, B]).$$

<sup>1</sup> We apologize to readers whose local airlines no longer offer food on long flights.

**Figure 15.1** (a) Nontransitive preferences  $A \succ B \succ C \succ A$  can result in irrational behavior: a cycle of exchanges each costing one cent. (b) The decomposability axiom.

- **Decomposability:** Compound lotteries can be reduced to simpler ones using the laws of probability. This has been called the “no fun in gambling” rule: as Figure 15.1(b) shows, it compresses two consecutive lotteries into a single equivalent lottery.<sup>2</sup>

$$[p, A; 1 - p, [q, B; 1 - q, C]] \sim [p, A; (1 - p)q, B; (1 - p)(1 - q), C].$$

These constraints are known as the axioms of utility theory. Each axiom can be motivated by showing that an agent that violates it will exhibit patently irrational behavior in some situations. For example, we can motivate transitivity by making an agent with nontransitive preferences give us all its money. Suppose that the agent has the nontransitive preferences  $A \succ B \succ C \succ A$ , where  $A$ ,  $B$ , and  $C$  are goods that can be freely exchanged. If the agent currently has  $A$ , then we could offer to trade  $C$  for  $A$  plus one cent. The agent prefers  $C$ , and so would be willing to make this trade. We could then offer to trade  $B$  for  $C$ , extracting another cent, and finally trade  $A$  for  $B$ . This brings us back where we started from, except that the agent has given us three cents (Figure 15.1(a)). We can keep going around the cycle until the agent has no money at all. Clearly, the agent has acted irrationally in this case.

### 15.2.2 Rational preferences lead to utility

Notice that the axioms of utility theory are really axioms about preferences—they say nothing about a utility function. But in fact from the axioms of utility we can derive the following consequences (for the proof, see von Neumann and Morgenstern, 1944):

- **Existence of Utility Function:** If an agent’s preferences obey the axioms of utility, then there exists a function  $U$  such that  $U(A) > U(B)$  if and only if  $A$  is preferred to  $B$ , and  $U(A) = U(B)$  if and only if the agent is indifferent between  $A$  and  $B$ . That is,

$$U(A) > U(B) \Leftrightarrow A \succ B \quad \text{and} \quad U(A) = U(B) \Leftrightarrow A \sim B.$$

<sup>2</sup> We can account for the enjoyment of gambling by encoding gambling events into the state description; for example, “Have \$10 and gambled” could be preferred to “Have \$10 and didn’t gamble.”

- **Expected Utility of a Lottery:** The utility of a lottery is the sum of the probability of each outcome times the utility of that outcome.

$$U([p_1, S_1; \dots; p_n, S_n]) = \sum_i p_i U(S_i).$$

In other words, once the probabilities and utilities of the possible outcome states are specified, the utility of a compound lottery involving those states is completely determined. Because the outcome of a nondeterministic action is a lottery, it follows that an agent can act rationally—that is, consistently with its preferences—only by choosing an action that maximizes expected utility according to Equation (15.1).

The preceding theorems establish that (assuming the constraints on rational preferences) a utility function *exists* for any rational agent. The theorems do not establish that the utility function is *unique*. It is easy to see, in fact, that an agent's behavior would not change if its utility function  $U(S)$  were transformed according to

$$U'(S) = aU(S) + b, \quad (15.2)$$

where  $a$  and  $b$  are constants and  $a > 0$ ; a positive affine transformation.<sup>3</sup> This fact was noted in Chapter 6 (page 213) for two-player games of chance; here, we see that it applies to all kinds of decision scenarios.

As in game-playing, in a deterministic environment an agent needs only a preference ranking on states—the numbers don't matter. This is called a **value function** or **ordinal utility function**.

It is important to remember that the existence of a utility function that describes an agent's preference behavior does not necessarily mean that the agent is *explicitly* maximizing that utility function in its own deliberations. As we showed in Chapter 2, rational behavior can be generated in any number of ways. A rational agent might be implemented with a table lookup (if the number of possible states is small enough).

By observing a rational agent's behavior, an observer can learn about the utility function that represents what the agent is actually trying to achieve (even if the agent doesn't know it). We return to this point in Section 15.7.

Value function  
Ordinal utility  
function

### 15.3 Utility Functions

---

Utility functions map from lotteries to real numbers. We know they must obey the axioms of orderability, transitivity, continuity, substitutability, monotonicity, and decomposability. Is that all we can say about utility functions? Strictly speaking, that is it: an agent can have any preferences it likes. For example, an agent might prefer to have a prime number of dollars in its bank account; in which case, if it had \$16 it would give away \$3. This might be unusual, but we can't call it irrational. An agent might prefer a dented 1973 Ford Pinto to a shiny new Mercedes. The agent might prefer prime numbers of dollars only when it owns the Pinto, but when it owns the Mercedes, it might prefer more dollars to fewer. Fortunately, the preferences of real agents are usually more systematic and thus easier to deal with.

<sup>3</sup> In this sense, utilities resemble temperatures: a temperature in Fahrenheit is 1.8 times the Celsius temperature plus 32, but converting from one to the other doesn't make you hotter or colder.

### 15.3.1 Utility assessment and utility scales

If we want to build a decision-theoretic system that helps a human make decisions or acts on his or her behalf, we must first work out what the human's utility function is. This process, often called **preference elicitation**, involves presenting choices to the human and using the observed preferences to pin down the underlying utility function.

Preference elicitation

Equation (15.2) says that there is no absolute scale for utilities, but it is helpful, nonetheless, to establish *some* scale on which utilities can be recorded and compared for any particular problem. A scale can be established by fixing the utilities of any two particular outcomes, just as we fix a temperature scale by fixing the freezing point and boiling point of water. Typically, we fix the utility of a “best possible prize” at  $U(S) = u_{\top}$  and a “worst possible catastrophe” at  $U(S) = u_{\perp}$ . (Both of these should be finite.) **Normalized utilities** use a scale with  $u_{\perp} = 0$  and  $u_{\top} = 1$ . With such a scale, an England fan might assign a utility of 1 to England winning the World Cup and a utility of 0 to England failing to qualify.

Normalized utilities

Given a utility scale between  $u_{\top}$  and  $u_{\perp}$ , we can assess the utility of any particular prize  $S$  by asking the agent to choose between  $S$  and a **standard lottery**  $[p, u_{\top}; (1 - p), u_{\perp}]$ . The probability  $p$  is adjusted until the agent is indifferent between  $S$  and the standard lottery. Assuming normalized utilities, the utility of  $S$  is given by  $p$ . Once this is done for each prize, the utilities for all lotteries involving those prizes are determined. Suppose, for example, we want to know how much our England fan values the outcome of England reaching the semi-final and then losing. We compare that outcome to a standard lottery with probability  $p$  of winning the trophy and probability  $1 - p$  of an ignominious failure to qualify. If there is indifference at  $p = 0.3$ , then 0.3 is the value of reaching the semi-final and then losing.

Standard lottery

In medical, transportation, environmental and other decision problems, people's lives are at stake. (Yes, there are things more important than England's fortunes in the World Cup.) In such cases,  $u_{\perp}$  is the value assigned to immediate death (or in the really worst cases, many deaths). *Although nobody feels comfortable with putting a value on human life, it is a fact that tradeoffs on matters of life and death are made all the time.* Aircraft are given a complete overhaul at intervals, rather than after every trip. Cars are manufactured in a way that trades off costs against accident survival rates. We tolerate a level of air pollution that kills four million people a year.

Paradoxically, a refusal to put a monetary value on life can mean that life is *undervalued*. Ross Shachter describes a government agency that commissioned a study on removing asbestos from schools. The decision analysts performing the study assumed a particular dollar value for the life of a school-age child, and argued that the rational choice under that assumption was to remove the asbestos. The agency, morally outraged at the idea of setting the value of a life, rejected the report out of hand. It then decided against asbestos removal—implicitly asserting a lower value for the life of a child than that assigned by the analysts.

Currently several agencies of the U.S. government, including the Environmental Protection Agency, the Food and Drug Administration, and the Department of Transportation, use the **value of a statistical life** to determine the costs and benefits of regulations and interventions. Typical values in 2019 are roughly \$10 million.

Value of a statistical life

Some attempts have been made to find out the value that people place on their own lives. One common “currency” used in medical and safety analysis is the **micromort**, a one in a million chance of death. If you ask people how much they would pay to avoid a risk—for

Micromort

example, to avoid playing Russian roulette with a million-barreled revolver—they will respond with very large numbers, perhaps tens of thousands of dollars, but their actual behavior reflects a much lower monetary value for a micromort.

For example, in the UK, driving in a car for 230 miles incurs a risk of one micromort. Over the life of your car—say, 92,000 miles—that’s 400 micromorts. People appear to be willing to pay about \$12,000 more for a safer car that halves the risk of death. Thus, their car-buying action says they have a value of \$60 per micromort. A number of studies have confirmed a figure in this range across many individuals and risk types. However, government agencies such as the U.S. Department of Transportation typically set a lower figure; they will spend only about \$6 in road repairs per expected life saved. Of course, these calculations hold only for small risks. Most people won’t agree to kill themselves, even for \$60 million.

QALY

Another measure is the **QALY**, or quality-adjusted life year. Patients are willing to accept a shorter life expectancy to avoid a disability. For example, kidney patients on average are indifferent between living two years on dialysis and one year at full health.

### 15.3.2 The utility of money

Utility theory has its roots in economics, and economics provides one obvious candidate for a utility measure: money (or more specifically, an agent’s total net assets). The almost universal exchangeability of money for all kinds of goods and services suggests that money plays a significant role in human utility functions.

Monotonic preference

It will usually be the case that an agent prefers more money to less, all other things being equal. We say that the agent exhibits a **monotonic preference** for more money. This does not mean that money behaves as a utility function, because it says nothing about preferences between *lotteries* involving money.

Expected monetary value

Suppose you have triumphed over the other competitors in a television game show. The host now offers you a choice: either you can take the \$1,000,000 prize or you can gamble it on the flip of a coin. If the coin comes up heads, you end up with nothing, but if it comes up tails, you get \$2,500,000. If you’re like most people, you would decline the gamble and pocket the million. Are you being irrational?

Assuming the coin is fair, the **expected monetary value** (EMV) of the gamble is  $\frac{1}{2}(\$0) + \frac{1}{2}(\$2,500,000) = \$1,250,000$ , which is more than the original \$1,000,000. But that does not necessarily mean that accepting the gamble is a better decision. Suppose we use  $S_n$  to denote the state of possessing total wealth  $\$n$ , and that your current wealth is  $\$k$ . Then the expected utilities of the two actions of accepting and declining the gamble are

$$EU(\text{Accept}) = \frac{1}{2}U(S_k) + \frac{1}{2}U(S_{k+2,500,000}),$$

$$EU(\text{Decline}) = U(S_{k+1,000,000}).$$

To determine what to do, we need to assign utilities to the outcome states. Utility is not directly proportional to monetary value, because the utility for your first million is very high (or so they say), whereas the utility for an additional million is smaller. Suppose you assign a utility of 5 to your current financial status ( $S_k$ ), a 9 to the state  $S_{k+2,500,000}$ , and an 8 to the state  $S_{k+1,000,000}$ . Then the rational action would be to decline, because the expected utility of accepting is only 7 (less than the 8 for declining). On the other hand, a billionaire would most likely have a utility function that is locally linear over the range of a few million more, and thus would accept the gamble.

**Figure 15.2** The utility of money. (a) Empirical data for Mr. Beard over a limited range. (b) A typical curve for the full range.

In a pioneering study of actual utility functions, Grayson (1960) found that the utility of money was almost exactly proportional to the *logarithm* of the amount. (This idea was first suggested by Bernoulli (1738); see Exercise 15.STPT.) One particular utility curve, for a certain Mr. Beard, is shown in Figure 15.2(a). The data obtained for Mr. Beard's preferences are consistent with a utility function

$$U(S_{k+n}) = -263.31 + 22.09 \log(n + 150,000)$$

for the range between  $n = -\$150,000$  and  $n = \$800,000$ .

We should not assume that this is the definitive utility function for monetary value, but it is likely that most people have a utility function that is concave for positive wealth. Going into debt is bad, but preferences between different levels of debt can display a reversal of the concavity associated with positive wealth. For example, someone already  $\$10,000,000$  in debt might well accept a gamble on a fair coin with a gain of  $\$10,000,000$  for heads and a loss of  $\$20,000,000$  for tails.<sup>4</sup> This yields the S-shaped curve shown in Figure 15.2(b).

If we restrict our attention to the positive part of the curves, where the slope is decreasing, then for any lottery  $L$ , the utility of being faced with that lottery is less than the utility of being handed the expected monetary value of the lottery as a sure thing:

$$U(L) < U(S_{EMV(L)}).$$

That is, agents with curves of this shape are **risk-averse**: they prefer a sure thing with a payoff that is less than the expected monetary value of a gamble. On the other hand, in the “desperate” region at large negative wealth in Figure 15.2(b), the behavior is **risk-seeking**. The value an agent will accept in lieu of a lottery is called the **certainty equivalent** of the lottery. Studies have shown that most people will accept about  $\$400$  in lieu of a gamble that gives  $\$1000$  half the time and  $\$0$  the other half—that is, the certainty equivalent of the lottery is  $\$400$ , while the EMV is  $\$500$ .

The difference between the EMV of a lottery and its certainty equivalent is called the **insurance premium**. Risk aversion is the basis for the insurance industry, because it means that

Risk-averse

Risk-seeking

Certainty equivalent

Insurance premium

<sup>4</sup> Such behavior might be called desperate, but it is rational if one is already in a desperate situation.

insurance premiums are positive. People would rather pay a small insurance premium than gamble the price of their house against the chance of a fire. From the insurance company's point of view, the price of the house is very small compared with the firm's total reserves. This means that the insurer's utility curve is approximately linear over such a small region, and the gamble costs the company almost nothing.

Risk-neutral

Notice that for *small* changes in wealth relative to the current wealth, almost any curve will be approximately linear. An agent that has a linear curve is said to be **risk-neutral**. For gambles with small sums, therefore, we expect risk neutrality. In a sense, this justifies the simplified procedure that proposed small gambles to assess probabilities and to justify the axioms of probability in Section 12.2.3.

### 15.3.3 Expected utility and post-decision disappointment

The rational way to choose the best action,  $a^*$ , is to maximize expected utility:

$$a^* = \operatorname{argmax}_a EU(a).$$

If we have calculated the expected utility correctly according to our probability model, and if the probability model correctly reflects the underlying stochastic processes that generate the outcomes, then, on average, we will get the utility we expect if the whole process is repeated many times.

Unbiased

In reality, however, our model usually oversimplifies the real situation, either because we don't know enough (e.g., when making a complex investment decision) or because the computation of the true expected utility is too difficult (e.g., when making a move in backgammon, needing to take into account all possible future dice rolls). In that case, we are really working with *estimates*  $\widehat{EU}(a)$  of the true expected utility. We will assume, kindly perhaps, that the estimates are **unbiased**—that is, the expected value of the error,  $E(\widehat{EU}(a) - EU(a))$ , is zero. In that case, it still seems reasonable to choose the action with the highest estimated utility and to expect to receive that utility, on average, when the action is executed.

Unfortunately, the real outcome will usually be significantly *worse* than we estimated, even though the estimate was unbiased! To see why, consider a decision problem in which there are  $k$  choices, each of which has true estimated utility of 0. Suppose that the error in each utility estimate is independent and has a unit normal distribution—that is, a Gaussian with zero mean and standard deviation of 1, shown as the bold curve in Figure 15.3. Now, as we actually start to generate the estimates, some of the errors will be negative (pessimistic) and some will be positive (optimistic). Because we select the action with the *highest* utility estimate, we are favoring the overly optimistic estimates, and that is the source of the bias.

Order statistic

It is a straightforward matter to calculate the distribution of the maximum of the  $k$  estimates and hence quantify the extent of our disappointment. (This calculation is a special case of computing an **order statistic**, the distribution of any particular ranked element of a sample.) Suppose that each estimate  $X_i$  has a probability density function  $f(x)$  and cumulative distribution  $F(x)$ . (As explained in Appendix A, the cumulative distribution  $F$  measures the probability that the cost is less than or equal to any given amount—that is, it integrates the original density  $f$ .) Now let  $X^*$  be the largest estimate, i.e.,  $\max\{X_1, \dots, X_k\}$ . Then the cumulative distribution for  $X^*$  is

$$\begin{aligned} P(\max\{X_1, \dots, X_k\} \leq x) &= P(X_1 \leq x, \dots, X_k \leq x) \\ &= P(X_1 \leq x) \dots P(X_k \leq x) = F(x)^k. \end{aligned}$$

**Figure 15.3** Unjustified optimism caused by choosing the best of  $k$  options: we assume that each option has a true utility of 0 but a utility estimate that is distributed according to a unit normal (brown curve). The other curves show the distributions of the maximum of  $k$  estimates for  $k = 3, 10$ , and  $30$ .

The probability density function is the derivative of the cumulative distribution function, so the density for  $X^*$ , the maximum of  $k$  estimates, is

$$P(x) = \frac{d}{dx} (F(x)^k) = kf(x)(F(x))^{k-1}.$$

These densities are shown for different values of  $k$  in Figure 15.3 for the case where  $f(x)$  is the unit normal. For  $k = 3$ , the density for  $X^*$  has a mean around 0.85, so the average disappointment will be about 85% of the standard deviation in the utility estimates. With more choices, extremely optimistic estimates are more likely to arise: for  $k = 30$ , the disappointment will be around twice the standard deviation in the estimates.

This tendency for the estimated expected utility of the best choice to be too high is called the **optimizer's curse** (Smith and Winkler, 2006). It afflicts even the most seasoned decision analysts and statisticians. Serious manifestations include believing that an exciting new drug that has cured 80% of patients in a trial will cure 80% of patients (it's been chosen from  $k =$  thousands of candidate drugs) or that a mutual fund advertised as having above-average returns will continue to have them (it's been chosen to appear in the advertisement out of  $k =$  dozens of funds in the company's overall portfolio). It can even be the case that what appears to be the best choice may not be, if the variance in the utility estimate is high: a drug that has cured 9 of 10 patients and has been selected from thousands tried is probably *worse* than one that has cured 800 of 1000.

Optimizer's curse

The optimizer's curse crops up everywhere because of the ubiquity of utility-maximizing selection processes, so taking the utility estimates at face value is a bad idea. We can avoid the curse with a Bayesian approach that uses an explicit probability model  $\mathbf{P}(\widehat{EU}|EU)$  of the error in the utility estimates. Given this model and a prior on what we might reasonably expect the utilities to be, we treat the utility estimate as evidence and compute the posterior distribution for the true utility using Bayes' rule.

[Normative theory](#)  
[Descriptive theory](#)

### 15.3.4 Human judgment and irrationality

Decision theory is a **normative theory**: it describes how a rational agent *should* act. A **descriptive theory**, on the other hand, describes how actual agents—for example, humans—really do act. The application of economic theory would be greatly enhanced if the two coincided, but there appears to be some experimental evidence to the contrary. The evidence suggests that humans are “predictably irrational” (Ariely, 2009).

The best-known problem is the Allais paradox (Allais, 1953). People are given a choice between lotteries *A* and *B* and then between *C* and *D*, which have the following prizes:

<i>A</i> :	80% chance of \$4000	<i>C</i> :	20% chance of \$4000
<i>B</i> :	100% chance of \$3000	<i>D</i> :	25% chance of \$3000

Most people consistently prefer *B* over *A* (taking the sure thing), and *C* over *D* (taking the higher EMV). The normative analysis disagrees! We can see this most easily if we use the freedom implied by Equation (15.2) to set  $U(\$0) = 0$ . In that case, then  $B \succ A$  implies that  $U(\$3000) > 0.8U(\$4000)$ , whereas  $C \succ D$  implies exactly the reverse. In other words, there is no utility function that is consistent with these choices.

[Certainty effect](#)

One explanation for the apparently irrational preferences is the **certainty effect** (Kahneman and Tversky, 1979): people are strongly attracted to gains that are certain. There are several reasons why this may be so.

First, people may prefer to reduce their computational burden; by choosing certain outcomes, they don’t have to compute with probabilities. But the effect persists even when the computations involved are very easy ones.

Second, people may distrust the legitimacy of the stated probabilities. I trust that a coin flip is roughly 50/50 if I have control over the coin and the flip, but I may distrust the result if the flip is done by someone with a vested interest in the outcome.<sup>5</sup> In the presence of distrust, it might be better to go for the sure thing.<sup>6</sup>

Third, people may be accounting for their emotional state as well as their financial state. People know they would experience regret if they gave up a certain reward (*B*) for an 80% chance at a higher reward and then lost.

In other words, if *A* is chosen, there is a 20% chance of getting no money *and feeling like a complete idiot*, which is worse than just getting no money. So perhaps people who choose *B* over *A* and *C* over *D* are not irrational; they are willing to give up \$200 of EMV to avoid a 20% chance of feeling like an idiot.

A related problem is the Ellsberg paradox. Here the prizes are fixed, but the probabilities are underconstrained. Your payoff will depend on the color of a ball chosen from an urn. You are told that the urn contains 1/3 red balls, and 2/3 either black or yellow balls, but you don’t know how many black and how many yellow. Again, you are asked whether you prefer lottery *A* or *B*; and then *C* or *D*:

<i>A</i> :	\$100 for a red ball	<i>C</i> :	\$100 for a red or yellow ball
<i>B</i> :	\$100 for a black ball	<i>D</i> :	\$100 for a black or yellow ball.

It should be clear that if you think there are more red than black balls then you should prefer

<sup>5</sup> For example, the mathematician/magician Persi Diaconis can make a coin flip come out the way he wants every time (Landhuis, 2004).

<sup>6</sup> Even the sure thing may not be certain. Despite cast-iron promises, we have not yet received that \$27,000,000 from the Nigerian bank account of a previously unknown deceased relative.

A over B and C over D; if you think there are fewer red than black you should prefer the opposite. But it turns out that most people prefer A over B and also prefer D over C, even though there is no state of the world for which this is rational. It seems that people have **ambiguity aversion**: A gives you a 1/3 chance of winning, while B could be anywhere between 0 and 2/3. Similarly, D gives you a 2/3 chance, while C could be anywhere between 1/3 and 3/3. Most people elect the known probability rather than the unknown unknowns.

Ambiguity aversion

Yet another problem is that the exact wording of a decision problem can have a big impact on the agent's choices; this is called the **framing effect**. Experiments show that people like a medical procedure that is described as having a "90% survival rate" about twice as much as one described as having a "10% death rate," even though these two statements mean exactly the same thing. This discrepancy in judgment has been found in multiple experiments and is about the same whether the subjects are patients in a clinic, statistically sophisticated business school students, or experienced doctors.

Framing effect

People feel more comfortable making *relative* utility judgments rather than absolute ones. I may have little idea how much I might enjoy the various wines offered by a restaurant. The restaurant takes advantage of this by offering a \$200 bottle that nobody will buy, but which serves to skew upward the customer's estimate of the value of all wines, making a \$55 bottle seem like a bargain. This is called the **anchoring effect**.

Anchoring effect

If human informants insist on contradictory preference judgments, there is nothing that automated agents can do to be consistent with them. Fortunately, preference judgments made by humans are often open to revision in the light of further consideration. Paradoxes like the Allais and Ellsberg paradoxes are greatly reduced (but not eliminated) if the choices are explained better. In work at the Harvard Business School on assessing the utility of money, Keeney and Raiffa (1976, p. 210) found the following:

Subjects tend to be too risk-averse in the small and therefore ... the fitted utility functions exhibit unacceptably large risk premiums for lotteries with a large spread. ... Most of the subjects, however, can reconcile their inconsistencies and feel that they have learned an important lesson about how they want to behave. As a consequence, some subjects cancel their automobile collision insurance and take out more term insurance on their lives.

The evidence for human irrationality is also questioned by researchers in the field of **evolutionary psychology**, who point to the fact that our brain's decision-making mechanisms did not evolve to solve word problems with probabilities and prizes stated as decimal numbers. Let us grant, for the sake of argument, that the brain has built-in neural mechanisms for computing with probabilities and utilities, or something functionally equivalent. If so, the required inputs would be obtained through accumulated experience of outcomes and rewards rather than through linguistic presentations of numerical values.

Evolutionary psychology

It is far from obvious that we can directly access the brain's built-in neural mechanisms by presenting decision problems in linguistic/numerical form. The very fact that different wordings of the *same decision problem* elicit different choices suggests that the decision problem itself is not getting through. Spurred by this observation, psychologists have tried presenting problems in uncertain reasoning and decision making in "evolutionarily appropriate" forms; for example, instead of saying "90% survival rate," the experimenter might show 100 stick-figure animations of the operation, where the patient dies in 10 of them and survives in 90. With decision problems posed in this way, people's behavior seems to be much closer to the standard of rationality.

## 15.4 Multiattribute Utility Functions

**Multiattribute utility theory**

Decision making in the field of public policy involves high stakes, in both money and lives. For example, in deciding what levels of harmful emissions to allow from a power plant, policy makers must weigh the prevention of death and disability against the benefit of the power and the economic burden of mitigating the emissions. Picking a site for a new airport requires consideration of the disruption caused by construction; the cost of land; the distance from centers of population; the noise of flight operations; safety issues arising from local topography and weather conditions; and so on. Problems like these, in which outcomes are characterized by two or more attributes, are handled by **multiattribute utility theory**. In essence, it's the theory of comparing apples to oranges.

Let the attributes be  $\mathbf{X} = X_1, \dots, X_n$  and let  $\mathbf{x} = \langle x_1, \dots, x_n \rangle$  be a complete vector of assignments, where each  $x_i$  is either a numeric value or a discrete value with an assumed ordering on values. The analysis is easier if we arrange it so that higher values of an attribute always correspond to higher utilities: utilities are monotonically increasing. That means that we can't use, say, the number of deaths,  $d$  as an attribute; we would have to use  $-d$ . It also means that we can't use the room temperature,  $t$ , as an attribute. If the utility function for temperature has a peak at  $70^{\circ}\text{F}$  and falls off monotonically on either side, then we could split the attribute into two pieces. We could use  $t - 70$  to measure whether the room is warm enough, and  $70 - t$  to measure whether it is cool enough; both of these attributes would be monotonically increasing until they reach their maximum utility value at 0; the utility curve is flat from that point on, meaning that you don't get any more "warm enough" above  $70^{\circ}\text{F}$ , nor any more "cool enough" below  $70^{\circ}\text{F}$ .

The attributes in the airport problem could be:

- *Throughput*, measured by the number of flights per day;
- *Safety*, measured by minus the expected number of deaths per year;
- *Quietness*, measured by minus the number of people living under the flight paths;
- *Frugality*, measured by the negative cost of construction.

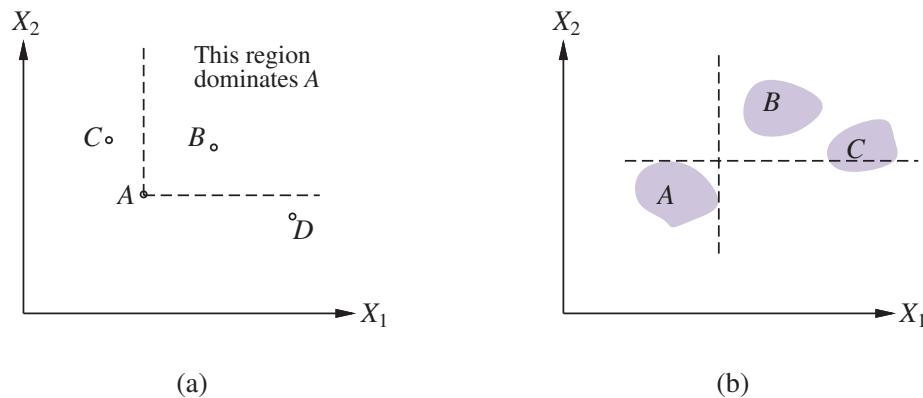

We begin by examining cases in which decisions can be made *without* combining the attribute values into a single utility value. Then we look at cases in which the utilities of attribute combinations can be specified very concisely.

**Strict dominance**

### 15.4.1 Dominance

Suppose that airport site  $S_1$  costs less, generates less noise pollution, and is safer than site  $S_2$ . One would not hesitate to reject  $S_2$ . We then say that there is **strict dominance** of  $S_1$  over  $S_2$ . In general, if an option is of lower value on all attributes than some other option, it need not be considered further. Strict dominance is often very useful in narrowing down the field of choices to the real contenders, although it seldom yields a unique choice. Figure 15.4(a) shows a schematic diagram for the two-attribute case.

That is fine for the deterministic case, in which the attribute values are known for sure. What about the general case, where the outcomes are uncertain? A direct analog of strict dominance can be constructed, where, despite the uncertainty, all possible concrete outcomes for  $S_1$  strictly dominate all possible outcomes for  $S_2$ . (See Figure 15.4(b).) Of course, this will probably occur even less often than in the deterministic case.

**Figure 15.4** Strict dominance. (a) Deterministic: Option A is strictly dominated by B but not by C or D. (b) Uncertain: A is strictly dominated by B but not by C.

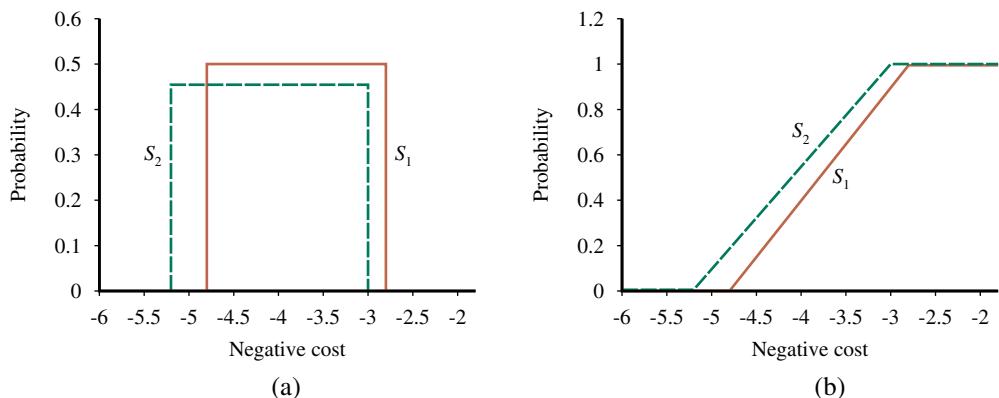

Fortunately, there is a more useful generalization called **stochastic dominance**, which occurs very frequently in real problems. Stochastic dominance is easiest to understand in the context of a single attribute. Suppose we believe that the cost of placing the airport at  $S_1$  is uniformly distributed between \$2.8 billion and \$4.8 billion and that the cost at  $S_2$  is uniformly distributed between \$3 billion and \$5.2 billion. Define the *Frugality* attribute to be the negative cost. Figure 15.5(a) shows the distributions for the frugality of sites  $S_1$  and  $S_2$ . Then, given only the information that the more frugal choice is better (all other things being equal), we can say that  $S_1$  stochastically dominates  $S_2$  (i.e.,  $S_2$  can be discarded). It is important to note that this does *not* follow from comparing the expected costs. For example, if we knew the cost of  $S_1$  to be *exactly* \$3.8 billion, then we would be *unable* to make a decision without additional information on the utility of money. (It might seem odd that *more* information on the cost of  $S_1$  could make the agent *less* able to decide. The paradox is resolved by noting that in the absence of exact cost information, the decision is easier to make but is more likely to be wrong.)

The exact relationship between the attribute distributions needed to establish stochastic dominance is best seen by examining the cumulative distributions, shown in Figure 15.5(b). If the cumulative distribution for  $S_1$  is always to the right of the cumulative distribution for  $S_2$ , then, stochastically speaking,  $S_1$  is cheaper than  $S_2$ . Formally, if two actions  $A_1$  and  $A_2$  lead to probability distributions  $p_1(x)$  and  $p_2(x)$  on attribute  $X$ , then  $A_1$  stochastically dominates  $A_2$  on  $X$  if

$$\forall x \int_{-\infty}^x p_1(x') dx' \leq \int_{-\infty}^x p_2(x') dx'.$$

The relevance of this definition to the selection of optimal decisions comes from the following property: *if  $A_1$  stochastically dominates  $A_2$ , then for any monotonically nondecreasing utility function  $U(x)$ , the expected utility of  $A_1$  is at least as high as the expected utility of  $A_2$ .* To see why this is true, consider the two expected utilities,  $\int p_1(x)U(x)dx$  and  $\int p_2(x)U(x)dx$ . Initially, it's not obvious why the first integral is bigger than the second, given that the stochastic dominance condition has a  $p_1$ -integral that is smaller than the  $p_2$ -integral.

Stochastic dominance

**Figure 15.5** Stochastic dominance. (a)  $S_1$  stochastically dominates  $S_2$  on frugality (negative cost). (b) Cumulative distributions for the frugality of  $S_1$  and  $S_2$ .

Instead of thinking about the integral over  $x$ , however, think about the integral over  $y$ , the cumulative probability, as shown in Figure 15.5(b). For any value of  $y$ , the corresponding value of  $x$  (and hence of  $U(x)$ ) is bigger for  $S_1$  than for  $S_2$ ; so if we integrate a bigger quantity over the whole range of  $y$ , we are bound to get a bigger result. Formally, it's just a substitution of  $y=P_1(x)$  in the integral for  $S_1$ 's expected value and  $y=P_2(x)$  in the integral for  $S_2$ 's. With these substitutions, we have  $dy=\frac{d}{dx}(P_1(x))dx=p_1(x)dx$  for  $S_1$  and  $dy=p_2(x)dx$  for  $S_2$ , hence

$$\int_{-\infty}^{\infty} p_1(x)U(x)dx = \int_0^1 U(P_1^{-1}(y))dy \geq \int_0^1 U(P_2^{-1}(y))dy = \int_{-\infty}^{\infty} p_2(x)U(x)dx.$$

This inequality allows us to prefer  $A_1$  to  $A_2$  in a single-attribute problem. More generally, if an action is stochastically dominated by another action on *all* attributes in a multiattribute problem, then it can be discarded.

The stochastic dominance condition might seem rather technical and perhaps not so easy to evaluate without extensive probability calculations. In fact, it can be decided very easily in many cases. For example, would you rather fall head-first onto concrete from 3 millimeters or 3 meters? Assuming you chose 3 millimeters—good choice! Why is it necessarily a better decision? There is a good deal of uncertainty about the degree of damage you will incur in both cases; but for any given level of damage, the probability that you'll incur at least that level of damage is higher when falling from 3 meters than from 3 millimeters. In other words, 3 millimeters stochastically dominates 3 meters on the *Safety* attribute.

This kind of reasoning comes as second nature to humans; it's so obvious we don't even think about it. Stochastic domination abounds in the airport problem too. Suppose, for example, that the construction transportation cost depends on the distance to the supplier. The cost itself is uncertain, but the greater the distance, the greater the cost. If  $S_1$  is closer than  $S_2$ , then  $S_1$  will dominate  $S_2$  on frugality. Although we will not present them here, algorithms exist for propagating this kind of qualitative information among uncertain variables in **qualitative probabilistic networks**, enabling a system to make rational decisions based on stochastic dominance, without using any numeric values.

### 15.4.2 Preference structure and multiattribute utility

Suppose we have  $n$  attributes, each of which has  $d$  distinct possible values. To specify the complete utility function  $U(x_1, \dots, x_n)$ , we need  $d^n$  values in the worst case. Multiattribute utility theory aims to identify additional structure in human preferences so that we don't need to specify all  $d^n$  values individually. Having identified some regularity in preference behavior, we then derive **representation theorems** to show that an agent with a certain kind of preference structure has a utility function

Representation theorem

$$U(x_1, \dots, x_n) = F[f_1(x_1), \dots, f_n(x_n)],$$

where  $F$  is (we hope) a simple function such as addition. Notice the similarity to the use of Bayesian networks to decompose the joint probability of several random variables.

As an example, suppose each  $x_i$  is the amount of money the agent has in a particular currency: dollars, euros, marks, lira, etc. The  $f_i$  functions could then convert each amount into a common currency, and  $F$  would then be simply addition.

#### Preferences without uncertainty

Let us begin with the deterministic case. On page 522 we noted that for deterministic environments, the agent has a value function, which we write here as  $V(x_1, \dots, x_n)$ ; the aim is to represent this function concisely. The basic regularity that arises in deterministic preference structures is called **preference independence**. Two attributes  $X_1$  and  $X_2$  are preferentially independent of a third attribute  $X_3$  if the preference between outcomes  $\langle x_1, x_2, x_3 \rangle$  and  $\langle x'_1, x'_2, x_3 \rangle$  does not depend on the particular value  $x_3$  for attribute  $X_3$ .

Preference independence

Going back to the airport example, where we have (among other attributes) *Quietness*, *Frugality*, and *Safety* to consider, one may propose that *Quietness* and *Frugality* are preferentially independent of *Safety*. For example, if we prefer an outcome with 20,000 people residing in the flight path and a construction cost of \$4 billion over an outcome with 70,000 people residing in the flight path and a cost of \$3.7 billion when the safety level is 0.006 deaths per billion passenger miles in both cases, then we would have the same preference when the safety level is 0.012 or 0.003; and the same independence would hold for preferences between any other pair of values for *Quietness* and *Frugality*. It is also apparent that *Frugality* and *Safety* are preferentially independent of *Quietness* and that *Quietness* and *Safety* are preferentially independent of *Frugality*.

We say that the set of attributes  $\{\text{Quietness}, \text{Frugality}, \text{Safety}\}$  exhibits **mutual preferential independence (MPI)**. MPI says that, whereas each attribute may be important, it does not affect the way in which one trades off the other attributes against each other.

Mutual preferential independence (MPI)

Mutual preferential independence is a complicated name, but it leads to a simple form for the agent's value function (Debreu, 1960): *If attributes  $X_1, \dots, X_n$  are mutually preferentially independent, then the agent's preferences can be represented by a value function*

$$V(x_1, \dots, x_n) = \sum_i V_i(x_i),$$

where each  $V_i$  refers only to the attribute  $X_i$ . For example, it might well be the case that the airport decision can be made using a value function

$$V(\text{quietness}, \text{frugality}, \text{safety}) = \text{quietness} \times 10^4 + \text{frugality} + \text{safety} \times 10^{12}.$$

A value function of this type is called an **additive value function**. Additive functions are an

Additive value function

extremely natural way to describe an agent's preferences and are valid in many real-world situations. For  $n$  attributes, assessing an additive value function requires assessing  $n$  separate one-dimensional value functions rather than one  $n$ -dimensional function; typically, this represents an exponential reduction in the number of preference experiments that are needed. Even when MPI does not strictly hold, as might be the case at extreme values of the attributes, an additive value function might still provide a good approximation to the agent's preferences. This is especially true when the violations of MPI occur in portions of the attribute ranges that are unlikely to occur in practice.

To understand MPI better, it helps to look at cases where it *doesn't* hold. Suppose you are at a medieval market, considering the purchase of some hunting dogs, some chickens, and some wicker cages for the chickens. The hunting dogs are very valuable, but if you don't have enough cages for the chickens, the dogs will eat the chickens; hence, the tradeoff between dogs and chickens depends strongly on the number of cages, and MPI is violated. The existence of these kinds of interactions among various attributes makes it much harder to assess the overall value function.

### Preferences with uncertainty

When uncertainty is present in the domain, we also need to consider the structure of preferences between lotteries and to understand the resulting properties of utility functions, rather than just value functions. The mathematics of this problem can become quite complicated, so we present just one of the main results to give a flavor of what can be done.

[Utility independence](#)

[Mutually utility independent](#)

[Multiplicative utility function](#)

The basic notion of **utility independence** extends preference independence to cover lotteries: a set of attributes **X** is utility independent of a set of attributes **Y** if preferences between lotteries on the attributes in **X** are independent of the particular values of the attributes in **Y**. A set of attributes is **mutually utility independent** (MUI) if each of its subsets is utility-independent of the remaining attributes. Again, it seems reasonable to propose that the airport attributes are MUI.

MUI implies that the agent's behavior can be described using a **multiplicative utility function** (Keeney, 1974). The general form of a multiplicative utility function is best seen by looking at the case for three attributes. For conciseness, we use  $U_i$  to mean  $U_i(x_i)$ :

$$U = k_1 U_1 + k_2 U_2 + k_3 U_3 + k_1 k_2 U_1 U_2 + k_2 k_3 U_2 U_3 + k_3 k_1 U_3 U_1 \\ + k_1 k_2 k_3 U_1 U_2 U_3.$$

Although this does not look very simple, it contains just three single-attribute utility functions and three constants. In general, an  $n$ -attribute problem exhibiting MUI can be modeled using  $n$  single-attribute utilities and  $n$  constants. Each of the single-attribute utility functions can be developed independently of the other attributes, and this combination will be guaranteed to generate the correct overall preferences. Additional assumptions are required to obtain a purely additive utility function.

## 15.5 Decision Networks

---

[Influence diagram](#)  
[Decision network](#)

In this section, we look at a general mechanism for making rational decisions. The notation is often called an **influence diagram** (Howard and Matheson, 1984), but we will use the more descriptive term **decision network**. Decision networks combine Bayesian networks

with additional node types for actions and utilities. We use the problem of picking an airport site as an example.

### 15.5.1 Representing a decision problem with a decision network

In its most general form, a decision network represents information about the agent's current state, its possible actions, the state that will result from the agent's action, and the utility of that state. It therefore provides a substrate for implementing utility-based agents of the type first introduced in Section 2.4.5. Figure 15.6 shows a decision network for the airport-siting problem. It illustrates the three types of nodes used:

- **Chance nodes** (ovals) represent random variables, just as they do in Bayesian networks. Chance nodes  
The agent could be uncertain about the construction cost, the level of air traffic and the potential for litigation, and the *Safety*, *Quietness*, and total *Frugality* variables, each of which also depends on the site chosen. Each chance node has associated with it a conditional distribution that is indexed by the state of the parent nodes. In decision networks, the parent nodes can include decision nodes as well as chance nodes. Note that each of the current-state chance nodes could be part of a large Bayesian network for assessing construction costs, air traffic levels, or litigation potentials.
- **Decision nodes** (rectangles) represent points where the decision maker has a choice of actions. In this case, the *AirportSite* action can take on a different value for each site under consideration. The choice influences the safety, quietness, and frugality of the solution. In this chapter, we assume that we are dealing with a single decision node. Chapter 16 deals with cases in which more than one decision must be made. Decision nodes
- **Utility nodes** (diamonds) represent the agent's utility function.<sup>7</sup> The utility node has as parents all variables describing the outcomes that directly affect utility. Associated with the utility node is a description of the agent's utility as a function of the parent attributes. The description could be just a tabulation of the function, or it might be a parameterized additive or linear function of the attribute values. For now, we will assume that the function is deterministic; that is, given the values of its parent variables, the value of the utility node is fully determined. Utility nodes

A simplified form is also used in many cases. The notation remains identical, but the chance nodes describing the outcome states are omitted. Instead, the utility node is connected directly to the current-state nodes and the decision node. In this case, rather than representing a utility function on outcome states, the utility node represents the *expected* utility associated with each action, as defined in Equation (15.1) on page 519; that is, the node is associated with an **action-utility function** (also known as a **Q-function** in reinforcement learning, as described in Chapter 23). Figure 15.7 shows the action-utility representation of the airport siting problem.

Notice that, because the *Quietness*, *Safety*, and *Frugality* chance nodes in Figure 15.6 refer to future states, they can never have their values set as evidence variables. Thus, the simplified version that omits these nodes can be used whenever the more general form can be used. Although the simplified form contains fewer nodes, the omission of an explicit description of the outcome of the siting decision means that it is less flexible with respect to changes in circumstances.

Action-utility  
function

<sup>7</sup> These nodes are also called **value nodes** in the literature.

**Figure 15.6** A decision network for the airport-siting problem.

**Figure 15.7** A simplified representation of the airport-siting problem. Chance nodes corresponding to outcome states have been factored out.

For example, in Figure 15.6, a change in aircraft noise levels can be reflected by a change in the conditional probability table associated with the *Quietness* node, whereas a change in the weight accorded to noise pollution in the utility function can be reflected by a change in the utility table. In the action-utility diagram, Figure 15.7, on the other hand, all such changes have to be reflected by changes to the action-utility table. Essentially, the action-utility formulation is a *compiled* version of the original formulation, obtained by summing out the outcome state variables.

### 15.5.2 Evaluating decision networks

Actions are selected by evaluating the decision network for each possible setting of the decision node. Once the decision node is set, it behaves exactly like a chance node that has been set as an evidence variable. The algorithm for evaluating decision networks is the following:

1. Set the evidence variables for the current state.
2. For each possible value of the decision node:
  - (a) Set the decision node to that value.
  - (b) Calculate the posterior probabilities for the parent nodes of the utility node, using a standard probabilistic inference algorithm.
  - (c) Calculate the resulting utility for the action.
3. Return the action with the highest utility.

This is a straightforward approach that can utilize any available Bayesian network algorithm and can be incorporated directly into the agent design given in Figure 12.1 on page 406. We will see in Chapter 16 that the possibility of executing several actions in sequence makes the problem much more interesting.

## 15.6 The Value of Information

In the preceding analysis, we have assumed that all relevant information, or at least all available information, is provided to the agent before it makes its decision. In practice, this is hardly ever the case. *One of the most important parts of decision making is knowing what questions to ask.* For example, a doctor cannot expect to be provided with the results of all possible diagnostic tests and questions at the time a patient first enters the consulting room. Tests are often expensive and sometimes hazardous (both directly and because of associated delays). Their importance depends on two factors: whether the test results would lead to a significantly better treatment plan, and how likely the various test results are.

This section describes **information value theory**, which enables an agent to choose what information to acquire. We assume that prior to selecting a “real” action represented by the decision node, the agent can acquire the value of any of the potentially observable chance variables in the model. Thus, information value theory involves a simplified form of sequential decision making—simplified because the observation actions affect only the agent’s **belief state**, not the external physical state. The value of any particular observation must derive from the potential to affect the agent’s eventual physical action; and this potential can be estimated directly from the decision model itself.

Information value theory

### 15.6.1 A simple example

Suppose an oil company is hoping to buy one of  $n$  indistinguishable blocks of ocean-drilling rights. Let us assume further that exactly one of the blocks contains oil that will generate net profits of  $C$  dollars, while the others are worthless. The asking price of each block is  $C/n$  dollars. If the company is risk-neutral, then it will be indifferent between buying a block and not buying one because the expected profit is zero in both cases.

Now suppose that a seismologist offers the company the results of a survey of block number 3, which indicates definitively whether the block contains oil. How much should the company be willing to pay for the information? The way to answer this question is to examine what the company would do if it had the information:

- With probability  $1/n$ , the survey will indicate oil in block 3. In this case, the company will buy block 3 for  $C/n$  dollars and make a profit of  $C - C/n = (n - 1)C/n$  dollars.

- With probability  $(n-1)/n$ , the survey will show that the block contains no oil, in which case the company will buy a different block. Now the probability of finding oil in one of the other blocks changes from  $1/n$  to  $1/(n-1)$ , so the company makes an expected profit of  $C/(n-1) - C/n = C/n(n-1)$  dollars.

Now we can calculate the expected profit, given access to the survey information:

$$\frac{1}{n} \times \frac{(n-1)C}{n} + \frac{n-1}{n} \times \frac{C}{n(n-1)} = C/n.$$

Thus, the information is worth  $C/n$  dollars to the company, and the company should be willing to pay the seismologist some significant fraction of this amount.

The value of information derives from the fact that *with* the information, one's course of action can be changed to suit the *actual* situation. One can discriminate according to the situation, whereas without the information, one has to do what's best on average over the possible situations. In general, the value of a given piece of information is defined to be the difference in expected value between best actions before and after information is obtained.

### 15.6.2 A general formula for perfect information

**Value of perfect information**

It is simple to derive a general mathematical formula for the value of information. We assume that exact evidence can be obtained about the value of some random variable  $E_j$  (that is, we learn  $E_j = e_j$ ), so the phrase **value of perfect information** (VPI) is used.<sup>8</sup>

In the agent's initial information state, the value of the current best action  $\alpha$  is, from Equation (15.1),

$$EU(\alpha) = \max_a \sum_{s'} P(\text{RESULT}(a) = s') U(s'),$$

and the value of the new best action (after the new evidence  $E_j = e_j$  is obtained) will be

$$EU(\alpha_{e_j}|e_j) = \max_a \sum_{s'} P(\text{RESULT}(a) = s' | e_j) U(s').$$

But  $E_j$  is a random variable whose value is *currently* unknown, so to determine the value of discovering  $E_j$  we must average over all possible values  $e_j$  that we might discover for  $E_j$ , using our *current* beliefs about its value:

$$VPI(E_j) = \left( \sum_{e_j} P(E_j = e_j) EU(\alpha_{e_j}|E_j = e_j) \right) - EU(\alpha).$$

To get some intuition for this formula, consider the simple case where there are only two actions,  $a_1$  and  $a_2$ , from which to choose. Their current expected utilities are  $U_1$  and  $U_2$ . The information  $E_j = e_j$  will yield some new expected utilities  $U'_1$  and  $U'_2$  for the actions, but before we obtain  $E_j$ , we will have some probability distributions over the possible values of  $U'_1$  and  $U'_2$  (which we assume are independent).

Suppose that  $a_1$  and  $a_2$  represent two different routes through a mountain range in winter:  $a_1$  is a nice, straight highway through a tunnel, and  $a_2$  is a winding dirt road over the top. Just

<sup>8</sup> There is no loss of expressiveness in requiring perfect information. Suppose we wanted to model the case in which we become somewhat more certain about a variable. We can do that by introducing *another* variable about which we learn perfect information. For example, suppose we initially have broad uncertainty about the variable *Temperature*. Then we gain the perfect knowledge *Thermometer* = 37; this gives us imperfect information about the true *Temperature*, and the uncertainty due to measurement error is encoded in the sensor model  $P(\text{Thermometer} | \text{Temperature})$ . See Exercise 15.VPIX for another example.

**Figure 15.8** Three generic cases for the value of information. In (a),  $a_1$  will almost certainly remain superior to  $a_2$ , so the information is not needed. In (b), the choice is unclear and the information is crucial. In (c), the choice is unclear, but because it makes little difference, the information is less valuable. (Note: The fact that  $U_2$  has a high peak in (c) means that its expected value is known with higher certainty than  $U_1$ .)

given this information,  $a_1$  is clearly preferable, because it is quite possible that  $a_2$  is blocked by snow, whereas it is unlikely that anything blocks  $a_1$ .  $U_1$  is therefore clearly higher than  $U_2$ . It is possible to obtain satellite reports  $E_j$  on the actual state of each road that would give new expectations,  $U'_1$  and  $U'_2$ , for the two crossings. The distributions for these expectations are shown in Figure 15.8(a). Obviously, in this case, it is not worth the expense of obtaining satellite reports, because it is unlikely that the information derived from them will change the plan. With no change, information has no value.

Now suppose that we are choosing between two different winding dirt roads of slightly different lengths and we are carrying a seriously injured passenger. Then, even when  $U_1$  and  $U_2$  are quite close, the distributions of  $U'_1$  and  $U'_2$  are very broad. There is a significant possibility that the second route will turn out to be clear while the first is blocked, and in this case the difference in utilities will be very high. The VPI formula indicates that it might be worthwhile getting the satellite reports. Such a situation is shown in Figure 15.8(b).

Finally, suppose that we are choosing between the two dirt roads in summertime, when blockage by snow is unlikely. In this case, satellite reports might show one route to be more scenic than the other because of flowering alpine meadows, or perhaps wetter because of recent rain. It is therefore quite likely that we would change our plan if we had the information. In this case, however, the difference in value between the two routes is still likely to be very small, so we will not bother to obtain the reports. This situation is shown in Figure 15.8(c).

In sum, *information has value to the extent that it is likely to cause a change of plan and to the extent that the new plan will be significantly better than the old plan.*

### 15.6.3 Properties of the value of information

One might ask whether it is possible for information to be deleterious: can it actually have negative expected value? Intuitively, one should expect this to be impossible. After all, one could in the worst case just ignore the information and pretend that one has never received it. This is confirmed by the following theorem, which applies to any decision-theoretic agent using any decision network with possible observations  $E_j$ :

- *The expected value of information is nonnegative:*

$$\forall j \quad VPI(E_j) \geq 0.$$

The theorem follows directly from the definition of VPI, and we leave the proof as an exercise (Exercise 15.NNVP). It is, of course, a theorem about *expected* value, not *actual* value. Additional information can easily lead to a plan that *turns out to* be worse than the original plan if the information happens to be misleading. For example, a medical test that gives a false positive result may lead to unnecessary surgery; but that does not mean that the test shouldn't be done.

It is important to remember that VPI depends on the current state of information. It can change as more information is acquired. For any given piece of evidence  $E_j$ , the value of acquiring it can go down (e.g., if another variable strongly constrains the posterior for  $E_j$ ) or up (e.g., if another variable provides a clue on which  $E_j$  builds, enabling a new and better plan to be devised). Thus, VPI is not additive. That is,

$$VPI(E_j, E_k) \neq VPI(E_j) + VPI(E_k) \quad (\text{in general}).$$

VPI is, however, order-independent. That is,

$$VPI(E_j, E_k) = VPI(E_j) + VPI(E_k | E_j) = VPI(E_k) + VPI(E_j | E_k) = VPI(E_k, E_j)$$

where the notation  $VPI(\cdot | E)$  denotes the VPI calculated according to the posterior distribution where  $E$  is already observed. Order independence distinguishes sensing actions from ordinary actions and simplifies the problem of calculating the value of a sequence of sensing actions. We return to this question in the next section.

#### 15.6.4 Implementation of an information-gathering agent

A sensible agent should ask questions in a reasonable order, should avoid asking questions that are irrelevant, should take into account the importance of each piece of information in relation to its cost, and should stop asking questions when that is appropriate. All of these capabilities can be achieved by using the value of information as a guide.

Figure 15.9 shows the overall design of an agent that can gather information intelligently before acting. For now, we assume that with each observable evidence variable  $E_j$ , there is an associated cost,  $C(E_j)$ , which reflects the cost of obtaining the evidence through tests, consultants, questions, or whatever. The agent requests what appears to be the most efficient observation in terms of utility gain per unit cost. We assume that the result of the action  $Request(E_j)$  is that the next percept provides the value of  $E_j$ . If no observation is worth its cost, the agent selects a “real” action.

Myopic

The agent algorithm we have described implements a form of information gathering that is called **myopic**. This is because it uses the VPI formula shortsightedly, calculating the value of information as if only a single evidence variable will be acquired. Myopic control is based on the same heuristic idea as greedy search and often works well in practice. (For example, it has been shown to outperform expert physicians in selecting diagnostic tests.) However, if there is no single evidence variable that will help a lot, a myopic agent might hastily take an action when it would have been better to request two or more variables first and then take action. The next section considers the possibility of obtaining multiple observations.

---

```

function INFORMATION-GATHERING-AGENT(percept) returns an action
  persistent: D, a decision network
    integrate percept into D
    j  $\leftarrow$  the value that maximizes  $VPI(E_j) / C(E_j)$ 
    if  $VPI(E_j) > C(E_j)$ 
      then return Request(Ej)
    else return the best action from D

```

**Figure 15.9** Design of a simple, myopic information-gathering agent. The agent works by repeatedly selecting the observation with the highest information value, until the cost of the next observation is greater than its expected benefit.

---

### 15.6.5 Nonmyopic information gathering

The fact that the value of a sequence of observations is invariant under permutations of the sequence is intriguing but doesn't, by itself, lead to efficient algorithms for optimal information gathering. Even if we restrict ourselves to choosing in advance a fixed subset of observations to collect, there are  $2^n$  possible such subsets from  $n$  potential observations. In the general case, we face an even more complex problem of finding an optimal *conditional plan* (as described in Section 11.5.2) that chooses an observation and then acts or chooses more observations, depending on the outcome. Such plans form trees, and the number of such trees is superexponential in  $n$ .<sup>9</sup>

For observations of variables in a decision network, it turns out that this problem is intractable even when the network is a polytree. There are, however, special cases in which the problem can be solved efficiently. Here we present one such case: the **treasure hunt** problem (or the **least-cost testing sequence** problem, for the less romantically inclined). There are  $n$  locations  $1, \dots, n$ ; each location  $i$  contains treasure with independent probability  $P(i)$ ; and it costs  $C(i)$  to check location  $i$ . This corresponds to a decision network where all the potential evidence variables  $Treasure_i$  are absolutely independent. The agent examines locations in some order until treasure is found; the question is, what is the optimal order?

Treasure hunt

To answer this question, we will need to consider the expected costs and success probabilities of various sequences of observations, assuming the agent stops when treasure is found. Let  $\mathbf{x}$  be such a sequence;  $\mathbf{xy}$  be the concatenation of sequences  $\mathbf{x}$  and  $\mathbf{y}$ ;  $C(\mathbf{x})$  be the expected cost of  $\mathbf{x}$ ;  $P(\mathbf{x})$  be the probability that sequence  $\mathbf{x}$  succeeds in finding treasure; and  $F(\mathbf{x}) = 1 - P(\mathbf{x})$  be the probability that it fails. Given these definitions, we have

$$C(\mathbf{xy}) = C(\mathbf{x}) + F(\mathbf{x})C(\mathbf{y}), \quad (15.3)$$

that is, the sequence  $\mathbf{xy}$  will definitely incur the cost of  $\mathbf{x}$  and, if  $\mathbf{x}$  fails, it will also incur the cost of  $\mathbf{y}$ .

The basic idea in any sequence optimization problem is to look at the change in cost, defined by  $\Delta = C(\mathbf{wxyz}) - C(\mathbf{wyxz})$ , when two adjacent subsequences  $\mathbf{x}$  and  $\mathbf{y}$  in a general sequence  $\mathbf{wxyz}$  are flipped. When the sequence is optimal, all such changes make the sequence worse. The first step is to show that the sign of the effect (increasing or decreasing

<sup>9</sup> The general problem of generating sequential behavior in a partially observable environment falls under the heading of **partially observable Markov decision processes**, which are described in Chapter 16.

the cost) doesn't depend on the context provided by  $\mathbf{w}$  and  $\mathbf{z}$ . We have

$$\begin{aligned}\Delta &= [C(\mathbf{w}) + F(\mathbf{w})C(\mathbf{xyz})] - [C(\mathbf{w}) + F(\mathbf{w})C(\mathbf{yxz})] \quad (\text{by Equation (15.3)}) \\ &= F(\mathbf{w})[C(\mathbf{xyz}) - C(\mathbf{yxz})] \\ &= F(\mathbf{w})[(C(\mathbf{xy}) + F(\mathbf{xy})C(\mathbf{z})) - (C(\mathbf{yx}) + F(\mathbf{yx})C(\mathbf{z}))] \quad (\text{by Equation (15.3)}) \\ &= F(\mathbf{w})[C(\mathbf{xy}) - C(\mathbf{yx})] \quad (\text{since } F(\mathbf{xy}) = F(\mathbf{yx})).\end{aligned}$$

So we have shown that the direction of the change in the cost of the whole sequence depends only on the direction of the change in cost of the pair of elements being flipped; the context of the pair doesn't matter. This gives us a way to sort the sequence by pairwise comparisons to obtain an optimal solution. Specifically, we now have

$$\begin{aligned}\Delta &= F(\mathbf{w})[(C(\mathbf{x}) + F(\mathbf{x})C(\mathbf{y})) - (C(\mathbf{y}) + F(\mathbf{y})C(\mathbf{x}))] \quad (\text{by Equation (15.3)}) \\ &= F(\mathbf{w})[C(\mathbf{x})(1 - F(\mathbf{y})) - C(\mathbf{y})(1 - F(\mathbf{x}))] = F(\mathbf{w})[C(\mathbf{x})P(\mathbf{y}) - C(\mathbf{y})P(\mathbf{x})].\end{aligned}$$

This holds for any sequences  $\mathbf{x}$  and  $\mathbf{y}$ , so it holds specifically when  $\mathbf{x}$  and  $\mathbf{y}$  are single observations of locations  $i$  and  $j$ , respectively. So we know that, for  $i$  and  $j$  to be adjacent in an optimal sequence, we must have  $C(i)P(j) \leq C(j)P(i)$ , or  $\frac{P(i)}{C(i)} \geq \frac{P(j)}{C(j)}$ . In other words, the optimal order ranks the locations according to the success probability per unit cost. Exercise [15.HUNT](#) asks you to determine whether this is in fact the policy followed by the algorithm in Figure 15.9 for this problem.

### 15.6.6 Sensitivity analysis and robust decisions

#### Sensitivity analysis

The practice of **sensitivity analysis** is widespread in technological disciplines: it means analyzing how much the output of a process changes as the model parameters are tweaked. Sensitivity analysis in probabilistic and decision-theoretic systems is particularly important because the probabilities used are typically either learned from data or estimated by human experts, which means that they are themselves subject to considerable uncertainty. Only in rare cases, such as the dice rolls in backgammon, are the probabilities objectively known.

For a utility-driven decision-making process, you can think of the output as either the actual decision made or the expected utility of that decision. Consider the latter first: because expectation depends on probabilities from the model, we can compute the derivative of the expected utility of any given action with respect to each of those probability values. (For example, if all the conditional probability distributions in the model are explicitly tabulated, then computing the expectation involves computing a ratio of two sum-of-product expressions; for more on this, see Chapter 21.) Thus, one can determine which parameters in the model have the largest effect on the expected utility of the final decision.

If, instead, we are concerned about the actual decision made, rather than its utility according to the model, then we can simply vary the parameters systematically (perhaps using binary search) to see whether the decision changes, and, if so, what is the smallest perturbation that causes such a change. One might think it doesn't matter that much which decision is made, only what its utility is. That's true, but in practice there may be a very substantial difference between the *real* utility of a decision and the utility *according to the model*.

If all reasonable perturbations of the parameters leave the optimal decision unchanged, then it is reasonable to assume the decision is a good one, even if the utility estimate for that decision is substantially incorrect. If, on the other hand, the optimal decision changes considerably as the parameters of the model change, then there is a good chance that the

model may produce a decision that is substantially suboptimal in reality. In that case, it is worth investing further effort to refine the model.

These intuitions have been formalized in several fields (control theory, decision analysis, risk management) that propose the notion of a **robust** or **minimax** decision—that is, one that gives the best result in the worst case. Here, “worst case” means worst with respect to all plausible variations in the parameter values of the model. Letting  $\theta$  stand for all the parameters in the model, the robust decision is defined by

$$a^* = \operatorname{argmax}_a \min_{\theta} EU(a; \theta).$$

Robust

In many cases, particularly in control theory, the robust approach leads to designs that work very reliably in practice. In other cases, it leads to overly conservative decisions. For example, when designing a self-driving car, the robust approach would assume the worst case for the behavior of the other vehicles on the road—that is, they are all driven by homicidal maniacs. In that case, the optimal solution for the car is to stay in the garage.

Bayesian decision theory offers an alternative to robust methods: if there is uncertainty about the parameters of the model, then model that uncertainty using hyperparameters.

Whereas the robust approach might say that some probability  $\theta_i$  in the model could be anywhere between 0.3 and 0.7, with the actual value chosen by an adversary to make things come out as badly as possible, the Bayesian approach would put a prior probability distribution on  $\theta_i$  and then proceed as before. This requires more modeling effort—for example, the Bayesian modeler must decide if parameters  $\theta_i$  and  $\theta_j$  are independent—but often results in better performance in practice.

In addition to parametric uncertainty, applications of decision theory in the real world also suffer from *structural* uncertainty. For example, the assumption of independence of *AirTraffic*, *Litigation*, and *Construction* in Figure 15.6 may be incorrect, and there may be additional variables that the model simply omits. At present, we do not have a good understanding of how to take this kind of uncertainty into account. One possibility is to keep an ensemble of models, perhaps generated by machine learning algorithms, in the hope that the ensemble captures the significant variations that matter.

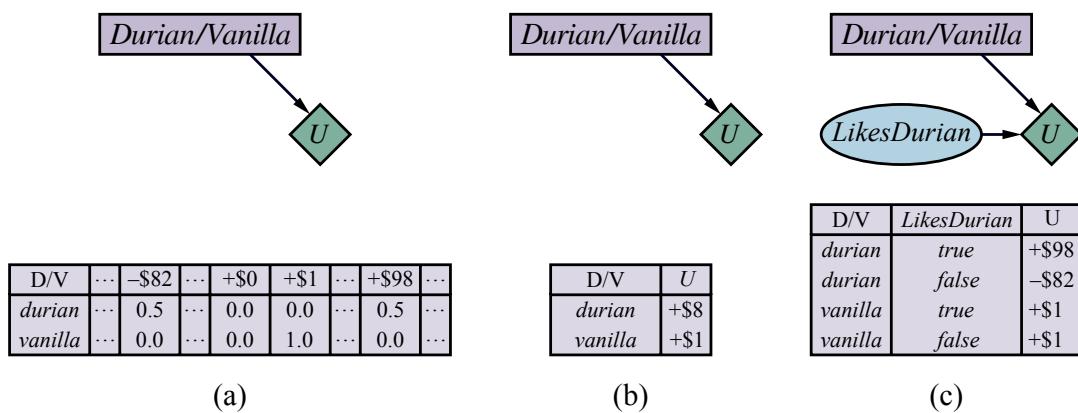

## 15.7 Unknown Preferences

---

In this section we discuss what happens when there is uncertainty about the utility function whose expected value is to be optimized. There are two versions of this problem: one in which an agent (machine or human) is uncertain about its *own* utility function, and another in which a machine is supposed to help a human but is uncertain about what the human wants.

### 15.7.1 Uncertainty about one's own preferences

Imagine that you are at an ice-cream shop in Thailand and they have only two flavors left: vanilla and durian. Both cost \$2. You know you have a moderate liking for vanilla and you'd be willing to pay up to \$3 for a vanilla ice cream on such a hot day, so there is a net gain of \$1 for choosing vanilla. On the other hand, you have no idea whether you like durian or not, but you've read on Wikipedia that the durian elicits different responses from different people: some find that “it surpasses in flavour all other fruits of the world” while others liken it to “sewage, stale vomit, skunk spray and used surgical swabs.”

**Figure 15.10** (a) A decision network for the ice cream choice with an uncertain utility function. (b) The network with the expected utility of each action. (c) Moving the uncertainty from the utility function into a new random variable.

To put some numbers on this, let's say there's a 50% chance you'll find it sublime (+\$100) and a 50% chance you'll hate it (-\$80 if the taste lingers all afternoon). Here, there's no uncertainty about what prize you're going to win—it's the same durian ice cream either way—but there's uncertainty about your own preferences for that prize.

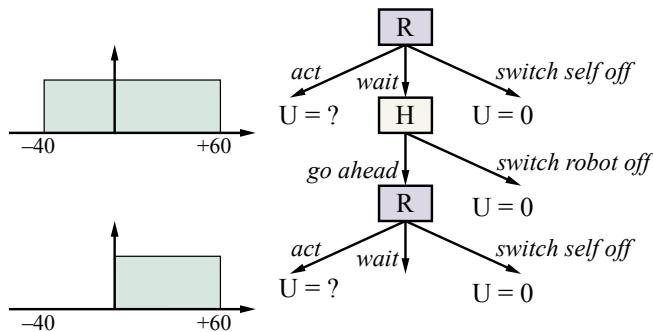

We could extend the decision network formalism to allow for uncertain utilities, as shown in Figure 15.10(a). If there is no more information to be obtained about your durian preferences, however—for example, if the shop won't let you taste it first—then the decision problem is identical to the one shown in Figure 15.10(b). We can simply replace the uncertain value of the durian with its expected net gain of  $(0.5 \times \$100) - (0.5 \times \$80) = \$2 = \$8$  and your decision will remain unchanged.

If it's possible for your beliefs about durian to change—perhaps you get a tiny taste, or you find out that all of your living relatives love durian—then the transformation in Figure 15.10(b) is not valid. It turns out, however, that we can still find an equivalent model in which the utility function is deterministic. Rather than saying there is uncertainty about the utility function, we move that uncertainty “into the world,” so to speak. That is, we create a new random variable *LikesDurian* with prior probabilities of 0.5 for *true* and *false*, as shown in Figure 15.10(c). With this extra variable, the utility function becomes deterministic, but we can still handle changing beliefs about your durian preferences.

The fact that unknown preferences can be modeled by ordinary random variables means that we can keep using the machinery and theorems developed for known preferences. On the other hand, it doesn't mean that we can always assume that preferences are known. The uncertainty is still there and still affects how agents should behave.

### 15.7.2 Deference to humans

Now let's turn to the second case mentioned above: a machine that is supposed to help a human but is uncertain about what the human wants. The full treatment of this case must be deferred to Chapter 17, where we discuss decisions involving more than one agent. Here, we ask one simple question: under what circumstances will such a machine defer to the human?

**Figure 15.11** The off-switch game.  $R$ , the robot, can choose to act now, with a highly uncertain payoff; to switch itself off; or to defer to  $H$ , the human.  $H$  can switch  $R$  off or let it go ahead.  $R$  now has the same choice again. Acting still has an uncertain payoff, but now  $R$  knows the payoff is nonnegative.

To study this question, let's consider a very simple scenario, as shown in Figure 15.11. Robbie is a software robot working for Harriet, a busy human, as her personal assistant. Harriet needs a hotel room for her next business meeting in Geneva. Robbie can act now—let's say he can book Harriet into a very expensive hotel near the meeting venue. He is quite unsure how much Harriet will like the hotel and its price; let's say he has a uniform probability for its net value to Harriet between  $-40$  and  $+60$ , with an average of  $+10$ . He could also “switch himself off”—less melodramatically, take himself out of the hotel booking process altogether—which we define (without loss of generality) to have value 0 to Harriet. If those were his two choices, he would go ahead and book the hotel, incurring a significant risk of making Harriet unhappy. (If the range were  $-60$  to  $+40$ , with average  $-10$ , he would switch himself off instead.) We'll give Robbie a third choice, however: explain his plan, wait, and let Harriet switch him off. Harriet can either switch him off or let him go ahead and book the hotel. What possible good could this do, one might ask, given that he could make both of those choices himself?

The point is that Harriet's choice—to switch Robbie off or let him go ahead—provides Robbie with information about Harriet's preferences. We'll assume, for now, that Harriet is rational, so if Harriet lets Robbie go ahead, it means the value to Harriet is positive. Now, as shown in Figure 15.11, Robbie's belief changes: it is uniform between 0 and  $+60$ , with an average of  $+30$ .

So, if we evaluate Robbie's initial choices from his point of view:

1. Acting now and booking the hotel has an expected value of  $+10$ .
2. Switching himself off has a value of 0.
3. Waiting and letting Harriet switch him off leads to two possible outcomes:
  - (a) There is a 40% chance, based on Robbie's uncertainty about Harriet's preferences, that she will hate the plan and will switch Robbie off, with value 0.
  - (b) There is a 60% chance Harriet will like the plan and allow Robbie to go ahead, with expected value  $+30$ .

Thus, waiting has expected value  $(0.4 \times 0) + (0.6 \times 30) = +18$ , which is better than the  $+10$  Robbie expects if he acts now.

The upshot is that Robbie has a positive incentive to defer to Harriet—that is, to allow himself to be switched off. This incentive comes directly from Robbie’s uncertainty about Harriet’s preferences. Robbie is aware that there’s a chance (40% in this example) that he might be about to do something that will make Harriet unhappy, in which case being switched off would be preferable to going ahead. Were Robbie already certain about Harriet’s preferences, he would just go ahead and make the decision (or switch himself off); there would be absolutely nothing to be gained from consulting Harriet, because, according to Robbie’s definite beliefs, he can already predict exactly what she is going to decide.

In fact, it is possible to prove the same result in the general case: as long as Robbie is not completely certain that he’s about to do what Harriet herself would do, he is better off allowing her to switch him off. Intuitively, her decision provides Robbie with information, and the expected value of information is always nonnegative. Conversely, if Robbie is certain about Harriet’s decision, her decision provides no new information, and so Robbie has no incentive to allow her to decide.

Formally, let  $P(u)$  be Robbie’s prior probability density over Harriet’s utility for the proposed action  $a$ . Then the value of going ahead with  $a$  is

$$EU(a) = \int_{-\infty}^{\infty} P(u) \cdot u du = \int_{-\infty}^0 P(u) \cdot u du + \int_0^{\infty} P(u) \cdot u du.$$

(We will see shortly why the integral is split up in this way.) On the other hand, the value of action  $d$ , deferring to Harriet, is composed of two parts: if  $u > 0$  then Harriet lets Robbie go ahead, so the value is  $u$ , but if  $u < 0$  then Harriet switches Robbie off, so the value is 0:

$$EU(d) = \int_{-\infty}^0 P(u) \cdot 0 du + \int_0^{\infty} P(u) \cdot u du.$$

Comparing the expressions for  $EU(a)$  and  $EU(d)$ , we see immediately that

$$EU(d) \geq EU(a)$$

because the expression for  $EU(d)$  has the negative-utility region zeroed out. The two choices have equal value only when the negative region has zero probability—that is, when Robbie is already certain that Harriet likes the proposed action.

There are some obvious elaborations on the model that are worth exploring immediately. The first elaboration is to impose a cost for Harriet’s time. In that case, Robbie is less inclined to bother Harriet if the downside risk is small. This is as it should be. And if Harriet is really grumpy about being interrupted, she shouldn’t be too surprised if Robbie occasionally does things she doesn’t like.

The second elaboration is to allow for some probability of human error—that is, Harriet might sometimes switch Robbie off even when his proposed action is reasonable, and she might sometimes let Robbie go ahead even when his proposed action is undesirable. It is straightforward to fold this error probability into the model (see Exercise 15.OFFS). As one might expect, the solution shows that Robbie is less inclined to defer to an irrational Harriet who sometimes acts against her own best interests. The more randomly she behaves, the more uncertain Robbie has to be about her preferences before deferring to her. Again, this is as it should be: for example, if Robbie is a self-driving car and Harriet is his naughty two-year-old passenger, Robbie should not allow Harriet to switch him off in the middle of the highway.

## Summary

---

This chapter shows how to combine utility theory with probability to enable an agent to select actions that will maximize its expected performance.

- **Probability theory** describes what an agent should believe on the basis of evidence, **utility theory** describes what an agent wants, and **decision theory** puts the two together to describe what an agent should do.
- We can use decision theory to build a system that makes decisions by considering all possible actions and choosing the one that leads to the best expected outcome. Such a system is known as a **rational agent**.
- Utility theory shows that an agent whose preferences between lotteries are consistent with a set of simple axioms can be described as possessing a utility function; furthermore, the agent selects actions as if maximizing its expected utility.
- **Multiattribute utility theory** deals with utilities that depend on several distinct attributes of states. **Stochastic dominance** is a particularly useful technique for making unambiguous decisions, even without precise utility values for attributes.
- **Decision networks** provide a simple formalism for expressing and solving decision problems. They are a natural extension of Bayesian networks, containing decision and utility nodes in addition to chance nodes.
- Sometimes, solving a problem involves finding more information before making a decision. The **value of information** is defined as the expected improvement in utility compared with making a decision without the information; it is particularly useful for guiding the process of information-gathering prior to making a final decision.
- When, as is often the case, it is impossible to specify the human's utility function completely and correctly, machines must operate under uncertainty about the true objective. This makes a significant difference when the possibility exists for the machine to acquire more information about human preferences. We showed by a simple argument that uncertainty about preferences ensures that the machine defers to the human, to the point of allowing itself to be switched off.

## Bibliographical and Historical Notes

---

In the 17th century treatise *L'art de Penser*, or *Port-Royal Logic*, Arnauld (1662) states:

To judge what one must do to obtain a good or avoid an evil, it is necessary to consider not only the good and the evil in itself, but also the probability that it happens or does not happen; and to view geometrically the proportion that all these things have together.

Modern texts talk of *utility* rather than good and evil, but this statement correctly notes that one should multiply utility by probability ("view geometrically") to give expected utility, and maximize that over all outcomes ("all these things") to "judge what one must do." It is remarkable how much Arnauld got right, more than 350 years ago, and only 8 years after Pascal and Fermat first showed how to use probability correctly.

Daniel Bernoulli (1738), investigating the St. Petersburg paradox (see Exercise 15.STPT), was the first to realize the importance of preference measurement for lotteries, writing "the

**Hedonic calculus**

*value* of an item must not be based on its *price*, but rather on the *utility* that it yields” (italics his). Utilitarian philosopher Jeremy Bentham (1823) proposed the **hedonic calculus** for weighing “pleasures” and “pains,” arguing that all decisions (not just monetary ones) could be reduced to utility comparisons.

Bernoulli’s introduction of utility—an internal, subjective quantity—to explain human behavior via a mathematical theory was an utterly remarkable proposal for its time. It was all the more remarkable for the fact that unlike monetary amounts, the utility values of various bets and prizes are not directly observable; instead, utilities are to be inferred from the preferences exhibited by an individual. It would be two centuries before the implications of the idea were fully worked out and it became broadly accepted by statisticians and economists.

The derivation of numerical utilities from preferences was first carried out by Ramsey (1931); the axioms for preference in the present text are closer in form to those rediscovered in *Theory of Games and Economic Behavior* (von Neumann and Morgenstern, 1944). Ramsey had derived subjective probabilities (not just utilities) from an agent’s preferences; Savage (1954) and Jeffrey (1983) carry out more recent constructions of this kind. Beardorff *et al.* (2002) show that a utility function does not suffice to represent nontransitive preferences and other anomalous situations.

**Decision analysis**

In the post-war period, decision theory became a standard tool in economics, finance, and management science. A field of **decision analysis** emerged to aid in making policy decisions more rational in areas such as military strategy, medical diagnosis, public health, engineering design, and resource management. The process involves a **decision maker** who states preferences between outcomes and a **decision analyst** who enumerates the possible actions and outcomes and elicits preferences from the decision maker to determine the best course of action. Von Winterfeldt and Edwards (1986) provide a nuanced perspective on decision analysis and its relationship to human preference structures. Smith (1988) gives an overview of the methodology of decision analysis.

Until the 1980s, multivariate decision problems were handled by constructing “decision trees” of all possible instantiations of the variables. Influence diagrams or decision networks, which take advantage of the same conditional independence properties as Bayesian networks, were introduced by Howard and Matheson (1984), based on earlier work at SRI (Miller *et al.*, 1976). Howard and Matheson’s algorithm constructed the complete (exponentially large) decision tree from the decision network. Shachter (1986) developed a method for making decisions based directly on a decision network, without the creation of an intermediate decision tree. This algorithm was also one of the first to provide complete inference for multiply connected Bayesian networks. Nilsson and Lauritzen (2000) link algorithms for decision networks to ongoing developments in clustering algorithms for Bayesian networks. The collection by Oliver and Smith (1990) has a number of useful early articles on decision networks, as does the 1990 special issue of the journal *Networks*. The text by Fenton and Neil (2018) provides a hands-on guide to solving real-world decision problems using decision networks. Papers on decision networks and utility modeling also appear regularly in the journals *Management Science* and *Decision Analysis*.

Surprisingly few early AI researchers adopted decision-theoretic tools after the early applications in medical decision making described in Chapter 12. One of the few exceptions was Jerry Feldman, who applied decision theory to problems in vision (Feldman and Yakimovsky, 1974) and planning (Feldman and Sproull, 1977). Rule-based expert systems of the

**Decision maker****Decision analyst**

late 1970s and early 1980s concentrated on answering questions, rather than on making decisions. Those systems that did recommend actions generally did so using condition–action rules rather than explicit representations of outcomes and preferences.

Decision networks offer a far more flexible approach, for example by allowing preferences to change while keeping the transition model constant, or vice versa. They also allow a principled calculation of what information to seek next. In the late 1980s, partly due to Pearl’s work on Bayes nets, decision-theoretic expert systems gained widespread acceptance (Horvitz *et al.*, 1988; Cowell *et al.*, 2002). In fact, from 1991 onward, the cover design of the journal *Artificial Intelligence* has depicted a decision network, although some artistic license appears to have been taken with the direction of the arrows.

Practical attempts to measure human utilities began with post-war decision analysis (see above). The micromort utility measure is discussed by Howard (1989). Thaler Thaler (1992) found that for a 1/1000 chance of death, a respondent wouldn’t pay more than \$200 to remove the risk, but wouldn’t accept \$50,000 to take on the risk.

The use of **QALYs** (quality-adjusted life years) to perform cost–benefit analyses of medical interventions and related social policies dates back at least to work by Klarman *et al.* (1968), although the term itself was first used by Zeckhauser and Shepard (1976). Like money, QALYs correspond directly to utilities only under fairly strong assumptions, such as risk neutrality, that are often violated (Beresniak *et al.*, 2015); nonetheless, QALYs are much widely used in practice, for example in forming National Health Service policies in the UK. See Russell (1990) for a typical example of an argument for a major change in public health policy on grounds of increased expected utility measured in QALYs.

Keeney and Raiffa (1976) give an introduction to **multiattribute utility theory**. They describe early computer implementations of methods for eliciting the necessary parameters for a multiattribute utility function and include extensive accounts of real applications of the theory. Abbas (2018) covers many advances since 1976. The theory was introduced to AI primarily by the work of Wellman (1985), who also investigated the use of stochastic dominance and qualitative probability models (Wellman, 1988, 1990a). Wellman and Doyle (1992) provide a preliminary sketch of how a complex set of utility-independence relationships might be used to provide a structured model of a utility function, in much the same way that Bayesian networks provide a structured model of joint probability distributions. Bacchus and Grove (1995, 1996) and La Mura and Shoham (1999) give further results along these lines. Boutilier *et al.* (2004) describe CP-nets, a fully worked out graphical model formalism for conditional *ceteris paribus* preference statements.

The **optimizer’s curse** was brought to the attention of decision analysts in a forceful way by Smith and Winkler (2006), who pointed out that the financial benefits to the client projected by analysts for their proposed course of action almost never materialized. They trace this directly to the bias introduced by selecting an optimal action and show that a more complete Bayesian analysis eliminates the problem.

The same underlying concept has been called **post-decision disappointment** by Harrison and March (1984) and was noted in the context of analyzing capital investment projects by Brown (1974). The optimizer’s curse is also closely related to the **winner’s curse** (Capen *et al.*, 1971; Thaler, 1992), which applies to competitive bidding in auctions: whoever wins the auction is very likely to have overestimated the value of the object in question. Capen *et al.* quote a petroleum engineer on the topic of bidding for oil-drilling rights: “If one wins a

[Post-decision  
disappointment](#)

[Winner’s curse](#)

tract against two or three others he may feel fine about his good fortune. But how should he feel if he won against 50 others? Ill."

The Allais paradox, due to Nobel Prize-winning economist Maurice Allais (1953), was tested experimentally to show that people are consistently inconsistent in their judgments (Tversky and Kahneman, 1982; Conlisk, 1989). The Ellsberg paradox on ambiguity aversion was introduced in the Ph.D. thesis of Daniel Ellsberg (1962).<sup>10</sup> Fox and Tversky (1995) describe a further study of ambiguity aversion. Machina (2005) gives an overview of choice under uncertainty and how it can vary from expected utility theory. See the classic text by Keeney and Raiffa (1976) and the more recent work by Abbas (2018) for an in-depth analysis of preferences with uncertainty.

#### Irrationality

2009 was a big year for popular books on human **irrationality**, including *Predictably Irrational* (Ariely, 2009), *Sway* (Brafman and Brafman, 2009), *Nudge* (Thaler and Sunstein, 2009), *Kluge* (Marcus, 2009), *How We Decide* (Lehrer, 2009) and *On Being Certain* (Burton, 2009). They complement the classic book *Judgment Under Uncertainty* (Kahneman *et al.*, 1982) and the article that started it all (Kahneman and Tversky, 1979). Kahneman himself provides an insightful and readable account in *Thinking: Fast and Slow* (Kahneman, 2011).

The field of evolutionary psychology (Buss, 2005), on the other hand, has run counter to this literature, arguing that humans are quite rational in evolutionarily appropriate contexts. Its adherents point out that irrationality is penalized by definition in an evolutionary context and show that in some cases it is an artifact of the experimental setup (Cummins and Allen, 1998). There has been a recent resurgence of interest in Bayesian models of cognition, overturning decades of pessimism (Elio, 2002; Chater and Oaksford, 2008; Griffiths *et al.*, 2008); this resurgence is not without its detractors, however (Jones and Love, 2011).

The theory of information value was explored first in the context of statistical experiments, where a quasi-utility (entropy reduction) was used (Lindley, 1956). The control theorist Ruslan Stratonovich (1965) developed the more general theory presented here, in which information has value by virtue of its ability to affect decisions. Stratonovich's work was not known in the West, where Ron Howard (1966) pioneered the same idea. His paper ends with the remark "If information value theory and associated decision theoretic structures do not in the future occupy a large part of the education of engineers, then the engineering profession will find that its traditional role of managing scientific and economic resources for the benefit of man has been forfeited to another profession." To date, the implied revolution in managerial methods has not occurred.

The myopic information-gathering algorithm described in the chapter is ubiquitous in the decision analysis literature; its basic outlines can be discerned in the original paper on influence diagrams (Howard and Matheson, 1984). Efficient calculation methods are studied by Dittmer and Jensen (1997). Laskey (1995) and Nielsen and Jensen (2003) discuss methods for sensitivity analysis in Bayesian networks and decision networks, respectively. The classic text *Robust and Optimal Control* (Zhou *et al.*, 1995) provides thorough coverage and comparison of the robust and decision-theoretic approaches to decisions under uncertainty.

The treasure hunt problem was solved independently by many authors, dating back at least to papers on sequential testing by Gluss (1959) and Mitten (1960). The style of proof

---

<sup>10</sup> Ellsberg later became a military analyst at the RAND Corporation and leaked documents known as the Pentagon Papers, thereby contributing to the end of the Vietnam war.

in this chapter draws on a basic result, due to Smith (1956), relating the value of a sequence to the value of the same sequence with two adjacent elements permuted. These results for independent tests were extended to more general tree and graph search problems (where the tests are partially ordered) by Kadane and Simon (1977). Results on the complexity of non-myopic calculations of the value of information were obtained by Krause and Guestrin (2009). Krause *et al.* (2008) identified cases where submodularity leads to a tractable approximation algorithm, drawing on the seminal work of Nemhauser *et al.* (1978) on submodular functions; Krause and Guestrin (2005) identify cases where an exact dynamic programming algorithm gives an efficient solution for both evidence subset election and conditional plan generation.

Harsanyi (1967) studied the problem of *incomplete* information in game theory, where players may not know each others' payoff functions exactly. He showed that such games were identical to games with *imperfect* information, where players are uncertain about the state of the world, via the trick of adding state variables referring to players' payoffs. Cyert and de Groot (1979) developed a theory of **adaptive utility** in which an agent could be uncertain about its own utility function and could obtain more information through experience.

Work on Bayesian preference elicitation (Chajewska *et al.*, 2000; Boutilier, 2002) begins from the assumption of a prior probability over the agent's utility function. Fern *et al.* (2014) propose a decision-theoretic model of **assistance** in which a robot tries to ascertain and assist with a human goal about which it is initially uncertain. The off-switch example in Section 15.7.2 is adapted from Hadfield-Menell *et al.* (2017b). Russell (2019) proposes a general framework for beneficial AI in which the off-switch game is a key example.

Adaptive utility

Assistance

# CHAPTER 16

## MAKING COMPLEX DECISIONS

*In which we examine methods for deciding what to do today, given that we may face another decision tomorrow.*

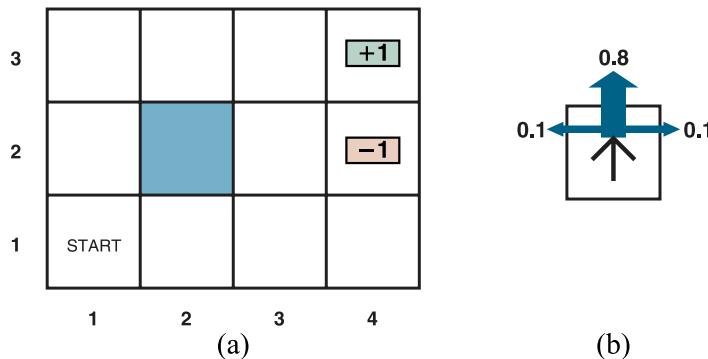

Sequential decision problem

In this chapter, we address the computational issues involved in making decisions in a stochastic environment. Whereas Chapter 15 was concerned with one-shot or episodic decision problems, in which the utility of each action’s outcome was well known, we are concerned here with **sequential decision problems**, in which the agent’s utility depends on a sequence of decisions. Sequential decision problems incorporate utilities, uncertainty, and sensing, and include search and planning problems as special cases. Section 16.1 explains how sequential decision problems are defined, and Section 16.2 describes methods for solving them to produce behaviors that are appropriate for a stochastic environment. Section 16.3 covers **multi-armed bandit** problems, a specific and fascinating class of sequential decision problems that arise in many contexts. Section 16.4 explores decision problems in partially observable environments and Section 16.5 describes how to solve them.

### 16.1 Sequential Decision Problems

Suppose that an agent is situated in the  $4 \times 3$  environment shown in Figure 16.1(a). Beginning in the start state, it must choose an action at each time step. The interaction with the environment terminates when the agent reaches one of the goal states, marked +1 or -1. Just as for search problems, the actions available to the agent in each state are given by `ACTIONS(s)`, sometimes abbreviated to `A(s)`; in the  $4 \times 3$  environment, the actions in every state are *Up*, *Down*, *Left*, and *Right*. We assume for now that the environment is **fully observable**, so that the agent always knows where it is.

If the environment were deterministic, a solution would be easy: [*Up*, *Up*, *Right*, *Right*, *Right*]. Unfortunately, the environment won’t always go along with this solution, because the actions are unreliable. The particular model of stochastic motion that we adopt is illustrated in Figure 16.1(b). Each action achieves the intended effect with probability 0.8, but the rest of the time, the action moves the agent at right angles to the intended direction. Furthermore, if the agent bumps into a wall, it stays in the same square. For example, from the start square (1,1), the action *Up* moves the agent to (1,2) with probability 0.8, but with probability 0.1, it moves right to (2,1), and with probability 0.1, it moves left, bumps into the wall, and stays in (1,1). In such an environment, the sequence [*Up*, *Up*, *Right*, *Right*, *Right*] goes up around the barrier and reaches the goal state at (4,3) with probability  $0.8^5 = 0.32768$ . There is also a small chance of accidentally reaching the goal by going the other way around with probability  $0.1^4 \times 0.8$ , for a grand total of 0.32776. (See also Exercise 16.MDPX.)

**Figure 16.1** (a) A simple, stochastic  $4 \times 3$  environment that presents the agent with a sequential decision problem. (b) Illustration of the transition model of the environment: the “intended” outcome occurs with probability 0.8, but with probability 0.2 the agent moves at right angles to the intended direction. A collision with a wall results in no movement. Transitions into the two terminal states have reward +1 and -1, respectively, and all other transitions have a reward of -0.04.

As in Chapter 3, the **transition model** (or just “model,” when the meaning is clear) describes the outcome of each action in each state. Here, the outcome is stochastic, so we write  $P(s'|s, a)$  for the probability of reaching state  $s'$  if action  $a$  is done in state  $s$ . (Some authors write  $T(s, a, s')$  for the transition model.) We will assume that transitions are **Markovian**: the probability of reaching  $s'$  from  $s$  depends only on  $s$  and not on the history of earlier states.

To complete the definition of the task environment, we must specify the utility function for the agent. Because the decision problem is sequential, the utility function will depend on a sequence of states and actions—an **environment history**—rather than on a single state. Later in this section, we investigate the nature of utility functions on histories; for now, we simply stipulate that for every transition from  $s$  to  $s'$  via action  $a$ , the agent receives a **Reward**  $R(s, a, s')$ . The rewards may be positive or negative, but they are bounded by  $\pm R_{\max}$ .<sup>1</sup>

For our particular example, the reward is -0.04 for all transitions except those entering terminal states (which have rewards +1 and -1). The utility of an environment history is just (for now) the *sum* of the rewards received. For example, if the agent reaches the +1 state after 10 steps, its total utility will be  $(9 \times -0.04) + 1 = 0.64$ . The negative reward of -0.04 gives the agent an incentive to reach (4,3) quickly, so our environment is a stochastic generalization of the search problems of Chapter 3. Another way of saying this is that the agent does not enjoy living in this environment and so it wants to leave as soon as possible.

To sum up: a sequential decision problem for a fully observable, stochastic environment with a Markovian transition model and additive rewards is called a **Markov decision process**, or **MDP**, and consists of a set of states (with an initial state  $s_0$ ); a set  $\text{ACTIONS}(s)$  of actions in each state; a transition model  $P(s'|s, a)$ ; and a reward function  $R(s, a, s')$ . Methods for solving MDPs usually involve **dynamic programming**: simplifying a problem by recursively breaking it into smaller pieces and remembering the optimal solutions to the pieces.

Reward

Markov decision process

Dynamic programming

<sup>1</sup> It is also possible to use costs  $c(s, a, s')$ , as we did in the definition of search problems in Chapter 3. The use of rewards is, however, standard in the literature on sequential decisions under uncertainty.

The next question is, what does a solution to the problem look like? No fixed action sequence can solve the problem, because the agent might end up in a state other than the goal. Therefore, a solution must specify what the agent should do for *any* state that the agent might reach. A solution of this kind is called a **policy**. It is traditional to denote a policy by  $\pi$ , and  $\pi(s)$  is the action recommended by the policy  $\pi$  for state  $s$ . No matter what the outcome of the action, the resulting state will be in the policy, and the agent will know what to do next.

Each time a given policy is executed starting from the initial state, the stochastic nature of the environment may lead to a different environment history. The quality of a policy is therefore measured by the *expected* utility of the possible environment histories generated by that policy. An **optimal policy** is a policy that yields the highest expected utility. We use  $\pi^*$  to denote an optimal policy. Given  $\pi^*$ , the agent decides what to do by consulting its current percept, which tells it the current state  $s$ , and then executing the action  $\pi^*(s)$ . A policy represents the agent function explicitly and is therefore a description of a simple reflex agent, computed from the information used for a utility-based agent.

The optimal policies for the world of Figure 16.1 are shown in Figure 16.2(a). There are two policies because the agent is exactly indifferent between going left and going up from (3,1): going left is safer but longer, while going up is quicker but risks falling into (4,2) by accident. In general there will often be multiple optimal policies.

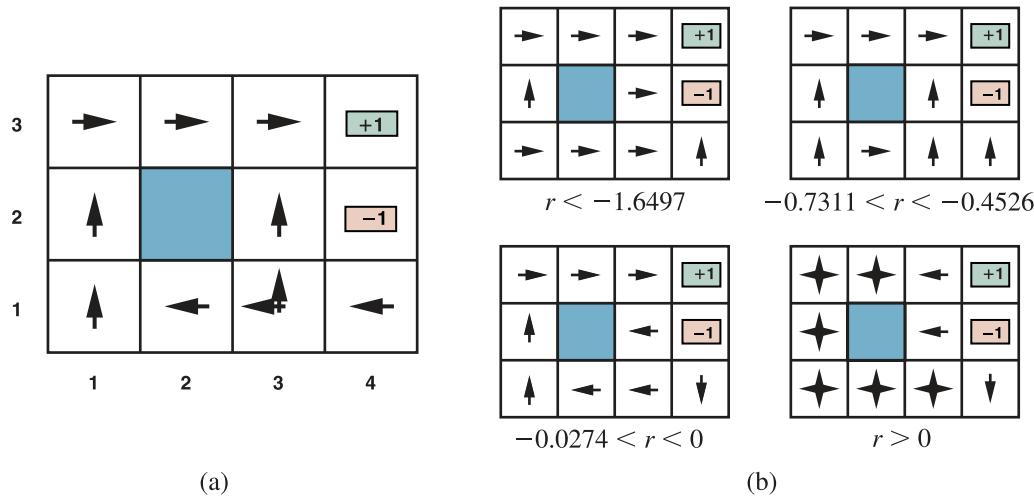

The balance of risk and reward changes depending on the value of  $r = R(s, a, s')$  for transitions between nonterminal states. The policies shown in Figure 16.2(a) are optimal for  $-0.0850 < r < -0.0273$ . Figure 16.2(b) shows optimal policies for four other ranges of  $r$ . When  $r < -1.6497$ , life is so painful that the agent heads straight for the nearest exit, even if the exit is worth  $-1$ . When  $-0.7311 < r < -0.4526$ , life is quite unpleasant; the agent takes the shortest route to the +1 state from (2,1), (3,1), and (3,2), but from (4,1) the cost of reaching +1 is so high that the agent prefers to dive straight into  $-1$ . When life is only slightly dreary ( $-0.0274 < r < 0$ ), the optimal policy takes *no risks at all*. In (4,1) and (3,2), the agent heads directly away from the  $-1$  state so that it cannot fall in by accident, even though this means banging its head against the wall quite a few times. Finally, if  $r > 0$ , then life is positively enjoyable and the agent avoids *both* exits. As long as the actions in (4,1), (3,2), and (3,3) are as shown, every policy is optimal, and the agent obtains infinite total reward because it never enters a terminal state. It turns out that there are nine optimal policies in all for various ranges of  $r$ ; Exercise 16.THR<sub>C</sub> asks you to find them.

The introduction of uncertainty brings MDPs closer to the real world than deterministic search problems. For this reason, MDPs have been studied in several fields, including AI, operations research, economics, and control theory. Dozens of solution algorithms have been proposed, several of which we discuss in Section 16.2. First, however, we spell out in more detail the definitions of utilities, optimal policies, and models for MDPs.

### 16.1.1 Utilities over time

In the MDP example in Figure 16.1, the performance of the agent was measured by a sum of rewards for the transitions experienced. This choice of performance measure is not arbitrary, but it is not the only possibility for the utility function<sup>2</sup> on environment histories, which we write as  $U_h([s_0, a_0, s_1, a_1 \dots, s_n])$ .

<sup>2</sup> In this chapter we use  $U$  for the utility function (to be consistent with the rest of the book), but many works about MDPs use  $V$  (for *value*) instead.

**Figure 16.2** (a) The optimal policies for the stochastic environment with  $r = -0.04$  for transitions between nonterminal states. There are two policies because in state (3,1) both *Left* and *Up* are optimal. (b) Optimal policies for four different ranges of  $r$ .

The first question to answer is whether there is a **finite horizon** or an **infinite horizon** for decision making. A finite horizon means that there is a *fixed* time  $N$  after which nothing matters—the game is over, so to speak. Thus,

$$U_h([s_0, a_0, s_1, a_1, \dots, s_{N+k}]) = U_h([s_0, a_0, s_1, a_1, \dots, s_N])$$

for all  $k > 0$ . For example, suppose an agent starts at (3,1) in the  $4 \times 3$  world of Figure 16.1, and suppose that  $N=3$ . Then, to have any chance of reaching the +1 state, the agent must head directly for it, and the optimal action is to go *Up*. On the other hand, if  $N=100$ , then there is plenty of time to take the safe route by going *Left*. So, with a finite horizon, an optimal action in a given state may depend on how much time is left. A policy that depends on the time is called **nonstationary**.

With no fixed time limit, on the other hand, there is no reason to behave differently in the same state at different times. Hence, an optimal action depends only on the current state, and the optimal policy is **stationary**. Policies for the infinite-horizon case are therefore simpler than those for the finite-horizon case, and we deal mainly with the infinite-horizon case in this chapter. (We will see later that for partially observable environments, the infinite-horizon case is not so simple.) Note that “infinite horizon” does not necessarily mean that all state sequences are infinite; it just means that there is no fixed deadline. There can be finite state sequences in an infinite-horizon MDP that contains a terminal state.

The next question we must decide is how to calculate the utility of state sequences. Throughout this chapter, we will **additive discounted rewards**: the utility of a history is

$$U_h([s_0, a_0, s_1, a_1, s_2, \dots]) = R(s_0, a_0, s_1) + \gamma R(s_1, a_1, s_2) + \gamma^2 R(s_2, a_2, s_3) + \dots,$$

where the **discount factor**  $\gamma$  is a number between 0 and 1. The discount factor describes the preference of an agent for current rewards over future rewards. When  $\gamma$  is close to 0, rewards in the distant future are viewed as insignificant. When  $\gamma$  is close to 1, an agent is more willing to wait for long-term rewards. When  $\gamma$  is exactly 1, discounted rewards reduce to the special

Finite horizon  
Infinite horizon

Nonstationary policy

Stationary policy

Additive discounted reward

Discount factor

## Additive reward

case of purely **additive rewards**. Notice that additivity was used implicitly in our use of path cost functions in heuristic search algorithms (Chapter 3).

There are several reasons why additive discounted rewards make sense. One is empirical: both humans and animals appear to value near-term rewards more highly than rewards in the distant future. Another is economic: if the rewards are monetary, then it really is better to get them sooner rather than later because early rewards can be invested and produce returns while you’re waiting for the later rewards. In this context, a discount factor of  $\gamma$  is equivalent to an interest rate of  $(1/\gamma) - 1$ . For example, a discount factor of  $\gamma=0.9$  is equivalent to an interest rate of 11.1%.

A third reason is uncertainty about the true rewards: they may never arrive for all sorts of reasons that are not taken into account in the transition model. Under certain assumptions, a discount factor of  $\gamma$  is equivalent to adding a probability  $1 - \gamma$  of accidental termination at every time step, independent of the action taken.

A fourth justification arises from a natural property of preferences over histories. In the terminology of multiattribute utility theory (see Section 15.4), each transition  $s_t \xrightarrow{a_t} s_{t+1}$  can be viewed as an **attribute** of the history  $[s_0, a_0, s_1, a_1, s_2 \dots]$ . In principle, the utility function could depend in arbitrarily complex ways on these attributes. There is, however, a highly plausible preference-independence assumption that can be made, namely that the agent’s preferences between state sequences are **stationary**.

Assume two histories  $[s_0, a_0, s_1, a_1, s_2, \dots]$  and  $[s'_0, a'_0, s'_1, a'_1, s'_2, \dots]$  begin with the same transition (i.e.,  $s_0 = s'_0$ ,  $a_0 = a'_0$ , and  $s_1 = s'_1$ ). Then stationarity for preferences means that the two histories should be preference-ordered the same way as the histories  $[s_1, a_1, s_2, \dots]$  and  $[s'_1, a'_1, s'_2, \dots]$ . In English, this means that if you prefer one future to another starting tomorrow, then you should still prefer that future if it were to start today instead. Stationarity is a fairly innocuous-looking assumption, but additive discounting is the only form of utility on histories that satisfies it.

A final justification for discounted rewards is that it conveniently makes some nasty infinities go away. With infinite horizons there is a potential difficulty: if the environment does not contain a terminal state, or if the agent never reaches one, then all environment histories will be infinitely long, and utilities with additive undiscounted rewards will generally be infinite. While we can agree that  $+\infty$  is better than  $-\infty$ , comparing two state sequences with  $+\infty$  utility is more difficult. There are three solutions, two of which we have seen already:

1. With discounted rewards, the utility of an infinite sequence is *finite*. In fact, if  $\gamma < 1$  and rewards are bounded by  $\pm R_{\max}$ , we have

$$U_h([s_0, a_0, s_1, \dots]) = \sum_{t=0}^{\infty} \gamma^t R(s_t, a_t, s_{t+1}) \leq \sum_{t=0}^{\infty} \gamma^t R_{\max} = \frac{R_{\max}}{1 - \gamma}, \quad (16.1)$$

using the standard formula for the sum of an infinite geometric series.

2. If the environment contains terminal states *and if the agent is guaranteed to get to one eventually*, then we will never need to compare infinite sequences. A policy that is guaranteed to reach a terminal state is called a **proper policy**. With proper policies, we can use  $\gamma=1$  (i.e., additive undiscounted rewards). The first three policies shown in Figure 16.2(b) are proper, but the fourth is improper. It gains infinite total reward by staying away from the terminal states when the reward for transitions between non-terminal states is positive. The existence of improper policies can cause the standard

## Stationary preference

## Proper policy

algorithms for solving MDPs to fail with additive rewards, and so provides a good reason for using discounted rewards.

3. Infinite sequences can be compared in terms of the **average reward** obtained per time step. Suppose that transitions to square (1,1) in the  $4 \times 3$  world have a reward of 0.1 while transitions to other nonterminal states have a reward of 0.01. Then a policy that does its best to stay in (1,1) will have higher average reward than one that stays elsewhere. Average reward is a useful criterion for some problems, but the analysis of average-reward algorithms is complex. Average reward

Additive discounted rewards present the fewest difficulties in evaluating histories, so we shall use them henceforth.

### 16.1.2 Optimal policies and the utilities of states

Having decided that the utility of a given history is the sum of discounted rewards, we can compare policies by comparing the *expected* utilities obtained when executing them. We assume the agent is in some initial state  $s$  and define  $S_t$  (a random variable) to be the state the agent reaches at time  $t$  when executing a particular policy  $\pi$ . (Obviously,  $S_0 = s$ , the state the agent is in now.) The probability distribution over state sequences  $S_1, S_2, \dots$ , is determined by the initial state  $s$ , the policy  $\pi$ , and the transition model for the environment.

The expected utility obtained by executing  $\pi$  starting in  $s$  is given by

$$U^\pi(s) = E \left[ \sum_{t=0}^{\infty} \gamma^t R(S_t, \pi(S_t), S_{t+1}) \right], \quad (16.2)$$

where the expectation  $E$  is with respect to the probability distribution over state sequences determined by  $s$  and  $\pi$ . Now, out of all the policies the agent could choose to execute starting in  $s$ , one (or more) will have higher expected utilities than all the others. We'll use  $\pi_s^*$  to denote one of these policies:

$$\pi_s^* = \underset{\pi}{\operatorname{argmax}} U^\pi(s). \quad (16.3)$$

Remember that  $\pi_s^*$  is a policy, so it recommends an action for every state; its connection with  $s$  in particular is that it's an optimal policy when  $s$  is the starting state. A remarkable consequence of using discounted utilities with infinite horizons is that the optimal policy is *independent* of the starting state. (Of course, the *action sequence* won't be independent; remember that a policy is a function specifying an action for each state.) This fact seems intuitively obvious: if policy  $\pi_a^*$  is optimal starting in  $a$  and policy  $\pi_b^*$  is optimal starting in  $b$ , then, when they reach a third state  $c$ , there's no good reason for them to disagree with each other, or with  $\pi_c^*$ , about what to do next.<sup>3</sup> So we can simply write  $\pi^*$  for an optimal policy.

Given this definition, the true utility of a state is just  $U^{\pi^*}(s)$ —that is, the expected sum of discounted rewards if the agent executes an optimal policy. We write this as  $U(s)$ , matching the notation used in Chapter 15 for the utility of an outcome. Figure 16.3 shows the utilities for the  $4 \times 3$  world. Notice that the utilities are higher for states closer to the +1 exit, because fewer steps are required to reach the exit.

<sup>3</sup> Although this seems obvious, it does not hold for finite-horizon policies or for other ways of combining rewards over time, such as taking the max. The proof follows directly from the uniqueness of the utility function on states, as shown in Section 16.2.1.

3	0.8516	0.9078	0.9578

1	0.7453	0.6953	0.6514
	1	2	3
			4

**Figure 16.3** The utilities of the states in the  $4 \times 3$  world with  $\gamma=1$  and  $r = -0.04$  for transitions to nonterminal states.

The utility function  $U(s)$  allows the agent to select actions by using the principle of maximum expected utility from Chapter 15—that is, choose the action that maximizes the reward for the next step plus the expected discounted utility of the subsequent state:

$$\pi^*(s) = \operatorname{argmax}_{a \in A(s)} \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U(s')]. \quad (16.4)$$

We have defined the utility of a state,  $U(s)$ , as the expected sum of discounted rewards from that point onwards. From this, it follows that there is a direct relationship between the utility of a state and the utility of its neighbors: *the utility of a state is the expected reward for the next transition plus the discounted utility of the next state, assuming that the agent chooses the optimal action.* That is, the utility of a state is given by

$$U(s) = \max_{a \in A(s)} \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U(s')]. \quad (16.5)$$

#### Bellman equation

This is called the **Bellman equation**, after Richard Bellman (1957). The utilities of the states—defined by Equation (16.2) as the expected utility of subsequent state sequences—are solutions of the set of Bellman equations. In fact, they are the *unique* solutions, as we show in Section 16.2.1.

Let us look at one of the Bellman equations for the  $4 \times 3$  world. The expression for  $U(1,1)$  is

$$\begin{aligned} \max\{ & [0.8(-0.04 + \gamma U(1,2)) + 0.1(-0.04 + \gamma U(2,1)) + 0.1(-0.04 + \gamma U(1,1))], \\ & [0.9(-0.04 + \gamma U(1,1)) + 0.1(-0.04 + \gamma U(1,2))], \\ & [0.9(-0.04 + \gamma U(1,1)) + 0.1(-0.04 + \gamma U(2,1))], \\ & [0.8(-0.04 + \gamma U(2,1)) + 0.1(-0.04 + \gamma U(1,2)) + 0.1(-0.04 + \gamma U(1,1))] \} \end{aligned}$$

where the four expressions correspond to *Up*, *Left*, *Down* and *Right* moves. When we plug in the numbers from Figure 16.3, with  $\gamma=1$ , we find that *Up* is the best action.

#### Q-function

Another important quantity is the **action-utility function**, or **Q-function**:  $Q(s, a)$  is the expected utility of taking a given action in a given state. The Q-function is related to utilities in the obvious way:

$$U(s) = \max_a Q(s, a). \quad (16.6)$$

Furthermore, the optimal policy can be extracted from the Q-function as follows:

$$\pi^*(s) = \operatorname{argmax}_a Q(s, a). \quad (16.7)$$

We can also develop a Bellman equation for Q-functions, noting that the expected total reward for taking an action is its immediate reward plus the discounted utility of the outcome state, which in turn can be expressed in terms of the Q-function:

$$\begin{aligned} Q(s, a) &= \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma U(s')] \\ &= \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma \max_{a'} Q(s', a')] \end{aligned} \quad (16.8)$$

Solving the Bellman equations for  $U$  (or for  $Q$ ) gives us what we need to find an optimal policy. The Q-function shows up again and again in algorithms for solving MDPs, so we shall use the following definition:

```
function Q-VALUE(mdp, s, a, U) returns a utility value
  return  $\sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma U[s']]$ 
```

### 16.1.3 Reward scales

Chapter 15 noted that the scale of utilities is arbitrary: an affine transformation leaves the optimal decision unchanged. We can replace  $U(s)$  by  $U'(s) = mU(s) + b$  where  $m$  and  $b$  are any constants such that  $m > 0$ . It is easy to see, from the definition of utilities as discounted sums of rewards, that a similar transformation of rewards will leave the optimal policy unchanged in an MDP:

$$R'(s, a, s') = mR(s, a, s') + b.$$

It turns out, however, that the additive reward decomposition of utilities leads to significantly more freedom in defining rewards. Let  $\Phi(s)$  be *any* function of the state  $s$ . Then, according to the **shaping theorem**, the following transformation leaves the optimal policy unchanged:

Shaping theorem

$$R'(s, a, s') = R(s, a, s') + \gamma\Phi(s') - \Phi(s). \quad (16.9)$$

To show that this is true, we need to prove that two MDPs,  $M$  and  $M'$ , have identical optimal policies as long as they differ only in their reward functions as specified in Equation (16.9).

We start from the Bellman equation for  $Q$ , the Q-function for MDP  $M$ :

$$Q(s, a) = \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma \max_{a'} Q(s', a')].$$

Now let  $Q'(s, a) = Q(s, a) - \Phi(s)$  and plug it into this equation; we get

$$Q'(s, a) + \Phi(s) = \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma \max_{a'} (Q'(s', a') + \Phi(s'))].$$

which then simplifies to

$$\begin{aligned} Q'(s, a) &= \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma\Phi(s') - \Phi(s) + \gamma \max_{a'} Q'(s', a')] \\ &= \sum_{s'} P(s' | s, a)[R'(s, a, s') + \gamma \max_{a'} Q'(s', a')]. \end{aligned}$$

In other words,  $Q'(s, a)$  satisfies the Bellman equation for MDP  $M'$ . Now we can extract the optimal policy for  $M'$  using Equation (16.7):

$$\pi_{M'}^*(s) = \operatorname{argmax}_a Q'(s, a) = \operatorname{argmax}_a Q(s, a) - \Phi(s) = \operatorname{argmax}_a Q(s, a) = \pi_M^*(s).$$

The function  $\Phi(s)$  is often called a **potential**, by analogy to the electrical potential (voltage) that gives rise to electric fields. The term  $\gamma\Phi(s') - \Phi(s)$  functions as a gradient of the potential. Thus, if  $\Phi(s)$  has higher value in states that have higher utility, the addition of  $\gamma\Phi(s') - \Phi(s)$  to the reward has the effect of leading the agent “uphill” in utility.

At first sight, it may seem rather counterintuitive that we can modify the reward in this way without changing the optimal policy. It helps if we remember that *all policies are optimal* with a reward function that is zero everywhere. This means, according to the shaping theorem, that all policies are optimal for any potential-based reward of the form  $R(s, a, s') = \gamma\Phi(s') - \Phi(s)$ . Intuitively, this is because with such a reward it doesn’t matter which way the agent goes from  $A$  to  $B$ . (This is easiest to see when  $\gamma=1$ : along any path the sum of rewards collapses to  $\Phi(B) - \Phi(A)$ , so all paths are equally good.) So adding a potential-based reward to any other reward shouldn’t change the optimal policy.

The flexibility afforded by the shaping theorem means that we can actually help out the agent by making the immediate reward more directly reflect what the agent should do. In fact, if we set  $\Phi(s)=U(s)$ , then the greedy policy  $\pi_G$  with respect to the modified reward  $R'$  is also an optimal policy:

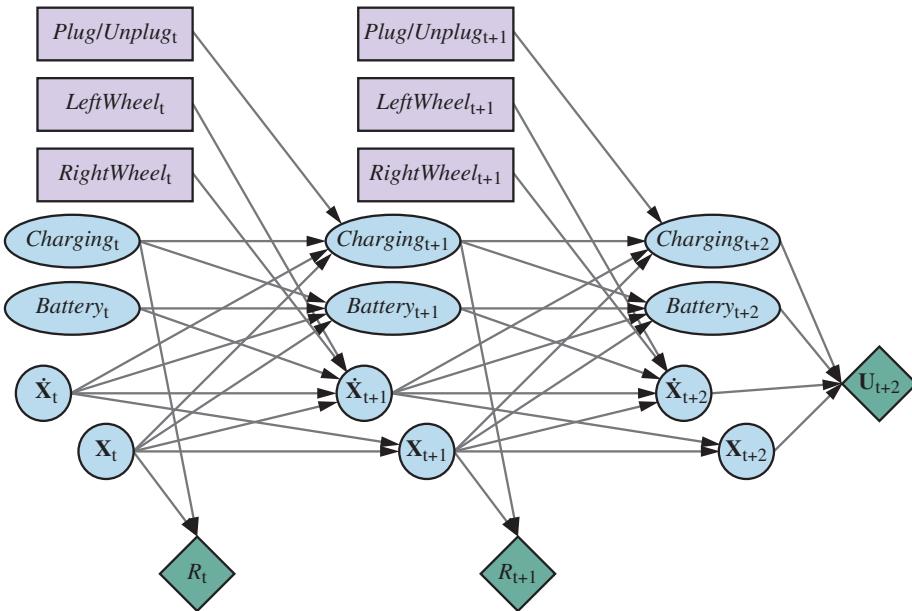

$$\begin{aligned}\pi_G(s) &= \operatorname{argmax}_a \sum_{s'} P(s' | s, a) R'(s, a, s') \\ &= \operatorname{argmax}_a \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma\Phi(s') - \Phi(s)] \\ &= \operatorname{argmax}_a \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U(s') - U(s)] \\ &= \operatorname{argmax}_a \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U(s')] \\ &= \pi^*(s) \quad (\text{by Equation (16.4)}).\end{aligned}$$

Of course, in order to set  $\Phi(s)=U(s)$ , we would need to know  $U(s)$ ; so there is no free lunch, but there is still considerable value in defining a reward function that is helpful to the extent possible. This is precisely what animal trainers do when they provide a small treat to the animal for each step in the target sequence.

#### 16.1.4 Representing MDPs

The simplest way to represent  $P(s' | s, a)$  and  $R(s, a, s')$  is with big, three-dimensional tables of size  $|S|^2|A|$ . This is fine for small problems such as the  $4 \times 3$  world, for which the tables have  $11^2 \times 4 = 484$  entries each. In some cases, the tables are **sparse**—most entries are zero because each state  $s$  can transition to only a bounded number of states  $s'$ —which means the tables are of size  $O(|S||A|)$ . For larger problems, even sparse tables are far too big.

Just as in Chapter 15, where Bayesian networks were extended with action and utility nodes to create decision networks, we can represent MDPs by extending dynamic Bayesian networks (DBNs, see Chapter 14) with decision, reward, and utility nodes to create **dynamic decision networks**, or DDNs. DDNs are **factored representations** in the terminology of

**Figure 16.4** A dynamic decision network for a mobile robot with state variables for battery level, charging status, location, and velocity, and action variables for the left and right wheel motors and for charging.

Chapter 2; they typically have an exponential complexity advantage over atomic representations and can model quite substantial real-world problems.

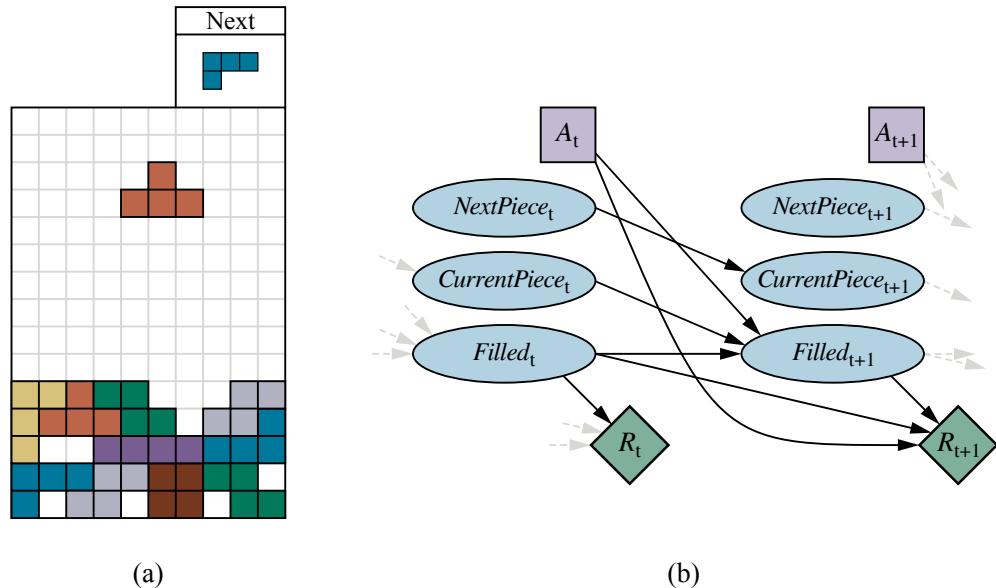

Figure 16.4, which is based on the DBN in Figure 14.13(b) (page 504), shows some elements of a slightly realistic model for a mobile robot that can charge itself. The state  $S_t$  is decomposed into four state variables:

- $\mathbf{X}_t$  consists of the two-dimensional location on a grid plus the orientation;
- $\dot{\mathbf{X}}_t$  is the rate of change of  $\mathbf{X}_t$ ;
- $Charging_t$  is true when the robot is plugged in to a power source;
- $Battery_t$  is the battery level, which we model as an integer in the range  $0, \dots, 5$ .

The state space for the MDP is the Cartesian product of the ranges of these four variables. The action is now a set  $\mathbf{A}_t$  of action variables, comprised of *Plug/Unplug*, which has three values (*plug*, *unplug*, and *noop*); *LeftWheel* for the power sent to the left wheel; and *RightWheel* for the power sent to the right wheel. The set of actions for the MDP is the Cartesian product of the ranges of these three variables. Notice that each action variable affects only a subset of the state variables.

The overall transition model is the conditional distribution  $\mathbf{P}(\mathbf{X}_{t+1} | \mathbf{X}_t, \mathbf{A}_t)$ , which can be computed as a product of conditional probabilities from the DDN. The reward here is a single variable that depends only on the location  $\mathbf{X}$  (for, say, arriving at a destination) and *Charging*, as the robot has to pay for electricity used; in this particular model, the reward doesn't depend on the action or the outcome state.

The network in Figure 16.4 has been projected two steps into the future. Notice that the network includes nodes for the *rewards* for times  $t$  and  $t + 1$ , but the *utility* for time  $t + 2$ . This

**Figure 16.5** (a) The game of Tetris. The T-shaped piece at the top center can be dropped in any orientation and in any horizontal position. If a row is completed, that row disappears and the rows above it move down, and the agent receives one point. The next piece (here, the L-shaped piece at top right) becomes the current piece, and a new next piece appears, chosen at random from the seven piece types. The game ends if the board fills up to the top. (b) The DDN for the Tetris MDP.

is because the agent must maximize the (discounted) sum of all future rewards, and  $U(\mathbf{X}_{t+3})$  represents the reward for all rewards from  $t + 3$  onwards. If a heuristic approximation to  $U$  is available, it can be included in the MDP representation in this way and used in lieu of further expansion. This approach is closely related to the use of bounded-depth search and heuristic evaluation functions for games in Chapter 6.

Another interesting and well-studied MDP is the game of Tetris (Figure 16.5(a)). The state variables for the game are the *CurrentPiece*, the *NextPiece*, and a bit-vector-valued variable *Filled* with one bit for each of the  $10 \times 20$  board locations. Thus, the state space has  $7 \times 7 \times 2^{200} \approx 10^{62}$  states. The DDN for Tetris is shown in Figure 16.5(b). Note that  $\text{Filled}_{t+1}$  is a deterministic function of  $\text{Filled}_t$  and  $A_t$ . It turns out that every policy for Tetris is proper (reaches a terminal state): eventually the board fills despite one's best efforts to empty it.

## 16.2 Algorithms for MDPs

In this section, we present four different algorithms for solving MDPs. The first three, **value iteration**, **policy iteration**, and **linear programming**, generate exact solutions offline. The fourth is a family of online approximate algorithms that includes **Monte Carlo planning**.

### 16.2.1 Value Iteration

The Bellman equation (Equation (16.5)) is the basis of the **value iteration** algorithm for solving MDPs. If there are  $n$  possible states, then there are  $n$  Bellman equations, one for each

---

```

function VALUE-ITERATION(mdp,  $\epsilon$ ) returns a utility function
  inputs: mdp, an MDP with states  $S$ , actions  $A(s)$ , transition model  $P(s' | s, a)$ ,
    rewards  $R(s, a, s')$ , discount  $\gamma$ 
     $\epsilon$ , the maximum error allowed in the utility of any state
  local variables:  $U$ ,  $U'$ , vectors of utilities for states in  $S$ , initially zero
     $\delta$ , the maximum relative change in the utility of any state

  repeat
     $U \leftarrow U'$ ;  $\delta \leftarrow 0$ 
    for each state  $s$  in  $S$  do
       $U'[s] \leftarrow \max_{a \in A(s)} Q\text{-VALUE}(mdp, s, a, U)$ 
      if  $|U'[s] - U[s]| > \delta$  then  $\delta \leftarrow |U'[s] - U[s]|$ 
    until  $\delta \leq \epsilon(1 - \gamma)/\gamma$ 
    return  $U$ 

```

**Figure 16.6** The value iteration algorithm for calculating utilities of states. The termination condition is from Equation (16.12).

---

state. The  $n$  equations contain  $n$  unknowns—the utilities of the states. So we would like to solve these simultaneous equations to find the utilities. There is one problem: the equations are *nonlinear*, because the “max” operator is not a linear operator. Whereas systems of linear equations can be solved quickly using linear algebra techniques, systems of nonlinear equations are more problematic. One thing to try is an *iterative* approach. We start with arbitrary initial values for the utilities, calculate the right-hand side of the equation, and plug it into the left-hand side—thereby updating the utility of each state from the utilities of its neighbors. We repeat this until we reach an equilibrium.

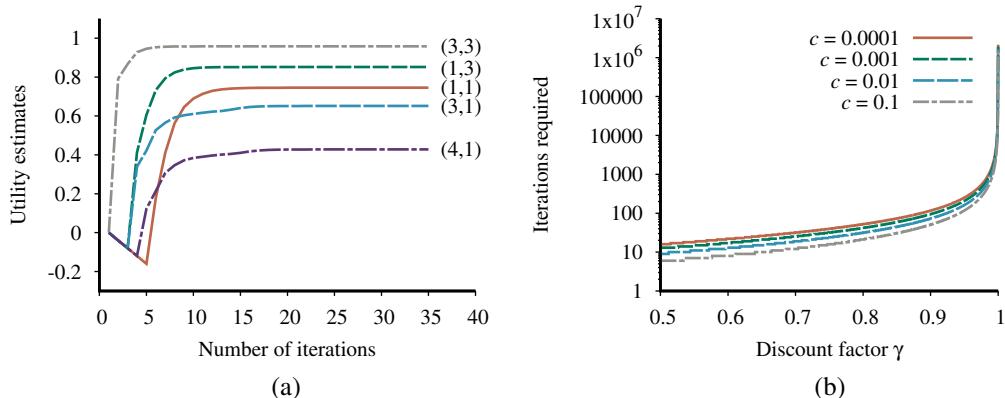

Let  $U_i(s)$  be the utility value for state  $s$  at the  $i$ th iteration. The iteration step, called a **Bellman update**, looks like this:

$$U_{i+1}(s) \leftarrow \max_{a \in A(s)} \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U_i(s')], \quad (16.10)$$

where the update is assumed to be applied simultaneously to all the states at each iteration. If we apply the Bellman update infinitely often, we are guaranteed to reach an equilibrium (see “convergence of value iteration” below), in which case the final utility values must be solutions to the Bellman equations. In fact, they are also the *unique* solutions, and the corresponding policy (obtained using Equation (16.4)) is optimal. The detailed algorithm, including a termination condition when the utilities are “close enough,” is shown in Figure 16.6. Notice that we make use of the *Q-VALUE* function defined on page 559.

We can apply value iteration to the  $4 \times 3$  world in Figure 16.1(a). Starting with initial values of zero, the utilities evolve as shown in Figure 16.7(a). Notice how the states at different distances from (4,3) accumulate negative reward until a path is found to (4,3), whereupon the utilities start to increase. We can think of the value iteration algorithm as *propagating information* through the state space by means of local updates.

Bellman update

**Figure 16.7** (a) Graph showing the evolution of the utilities of selected states using value iteration. (b) The number of value iterations required to guarantee an error of at most  $\epsilon = c \cdot R_{\max}$ , for different values of  $c$ , as a function of the discount factor  $\gamma$ .

### Convergence of value iteration

We said that value iteration eventually converges to a unique set of solutions of the Bellman equations. In this section, we explain why this happens. We introduce some useful mathematical ideas along the way, and we obtain some methods for assessing the error in the utility function returned when the algorithm is terminated early; this is useful because it means that we don't have to run forever. This section is quite technical.

Contraction

The basic concept used in showing that value iteration converges is the notion of a **contraction**. Roughly speaking, a contraction is a function of one argument that, when applied to two different inputs in turn, produces two output values that are “closer together,” by at least some constant factor, than the original inputs. For example, the function “divide by two” is a contraction, because, after we divide any two numbers by two, their difference is halved. Notice that the “divide by two” function has a fixed point, namely zero, that is unchanged by the application of the function. From this example, we can discern two important properties of contractions:

- A contraction has only one fixed point; if there were two fixed points they would not get closer together when the function was applied, so it would not be a contraction.
- When the function is applied to any argument, the value must get closer to the fixed point (because the fixed point does not move), so repeated application of a contraction always reaches the fixed point in the limit.

Now, suppose we view the Bellman update (Equation (16.10)) as an operator  $B$  that is applied simultaneously to update the utility of every state. Then the Bellman equation becomes  $U = BU$  and the Bellman update equation can be written as

$$U_{i+1} \leftarrow BU_i.$$

Max norm

Next, we need a way to measure distances between utility vectors. We will use the **max norm**, which measures the “length” of a vector by the absolute value of its biggest component:

$$\|U\| = \max_s |U(s)|.$$

With this definition, the “distance” between two vectors,  $\|U - U'\|$ , is the maximum difference between any two corresponding elements. The main result of this section is the following: Let  $U_i$  and  $U'_i$  be any two utility vectors. Then we have

$$\|BU_i - BU'_i\| \leq \gamma \|U_i - U'_i\|. \quad (16.11)$$

That is, *the Bellman update is a contraction by a factor of  $\gamma$  on the space of utility vectors.* (Exercise 16.VICT provides some guidance on proving this claim.) Hence, from the properties of contractions in general, it follows that value iteration always converges to a unique solution of the Bellman equations whenever  $\gamma < 1$ . 

We can also use the contraction property to analyze the *rate* of convergence to a solution. In particular, we can replace  $U'_i$  in Equation (16.11) with the *true* utilities  $U$ , for which  $BU = U$ . Then we obtain the inequality

$$\|BU_i - U\| \leq \gamma \|U_i - U\|.$$

If we view  $\|U_i - U\|$  as the *error* in the estimate  $U_i$ , we see that the error is reduced by a factor of at least  $\gamma$  on each iteration. Thus, value iteration converges exponentially fast. We can calculate the number of iterations required as follows: First, recall from Equation (16.1) that the utilities of all states are bounded by  $\pm R_{\max}/(1 - \gamma)$ . This means that the maximum initial error  $\|U_0 - U\| \leq 2R_{\max}/(1 - \gamma)$ . Suppose we run for  $N$  iterations to reach an error of at most  $\epsilon$ . Then, because the error is reduced by at least  $\gamma$  each time, we require  $\gamma^N \cdot 2R_{\max}/(1 - \gamma) \leq \epsilon$ . Taking logs, we find that

$$N = \lceil \log(2R_{\max}/\epsilon(1 - \gamma)) / \log(1/\gamma) \rceil$$

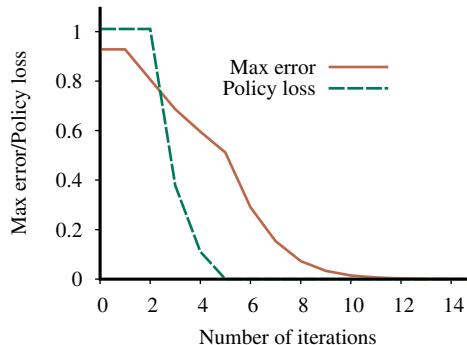

iterations suffice. Figure 16.7(b) shows how  $N$  varies with  $\gamma$ , for different values of the ratio  $\epsilon/R_{\max}$ . The good news is that, because of the exponentially fast convergence,  $N$  does not depend much on the ratio  $\epsilon/R_{\max}$ . The bad news is that  $N$  grows rapidly as  $\gamma$  becomes close to 1. We can get fast convergence if we make  $\gamma$  small, but this effectively gives the agent a short horizon and could miss the long-term effects of the agent’s actions.

The error bound in the preceding paragraph gives some idea of the factors influencing the run time of the algorithm, but is sometimes overly conservative as a method of deciding when to stop the iteration. For the latter purpose, we can use a bound relating the error to the size of the Bellman update on any given iteration. From the contraction property (Equation (16.11)), it can be shown that if the update is small (i.e., no state’s utility changes by much), then the error, compared with the true utility function, also is small. More precisely,

$$\text{if } \|U_{i+1} - U_i\| < \epsilon(1 - \gamma)/\gamma \text{ then } \|U_{i+1} - U\| < \epsilon. \quad (16.12)$$

This is the termination condition used in the VALUE-ITERATION algorithm of Figure 16.6.

So far, we have analyzed the error in the utility function returned by the value iteration algorithm. *What the agent really cares about, however, is how well it will do if it makes its decisions on the basis of this utility function.* Suppose that after  $i$  iterations of value iteration, the agent has an estimate  $U_i$  of the true utility  $U$  and obtains the maximum expected utility (MEU) policy  $\pi_i$  based on one-step look-ahead using  $U_i$  (as in Equation (16.4)). Will the resulting behavior be nearly as good as the optimal behavior? This is a crucial question for any real agent, and it turns out that the answer is yes.  $U^{\pi_i}(s)$  is the utility obtained if  $\pi_i$  is executed starting in  $s$ , and the **policy loss**  $\|U^{\pi_i} - U\|$  is the most the agent can lose by 

**Figure 16.8** The maximum error  $\|U_i - U\|$  of the utility estimates and the policy loss  $\|U^{\pi_i} - U\|$ , as a function of the number of iterations of value iteration on the  $4 \times 3$  world.

executing  $\pi_i$  instead of the optimal policy  $\pi^*$ . The policy loss of  $\pi_i$  is connected to the error in  $U_i$  by the following inequality:

$$\text{if } \|U_i - U\| < \epsilon \text{ then } \|U^{\pi_i} - U\| < 2\epsilon. \quad (16.13)$$

In practice, it often occurs that  $\pi_i$  becomes optimal long before  $U_i$  has converged. Figure 16.8 shows how the maximum error in  $U_i$  and the policy loss approach zero as the value iteration process proceeds for the  $4 \times 3$  environment with  $\gamma=0.9$ . The policy  $\pi_5$  is optimal when  $i=5$ , even though the maximum error in  $U_i$  is still 0.51.

Now we have everything we need to use value iteration in practice. We know that it converges to the correct utilities, we can bound the error in the utility estimates if we stop after a finite number of iterations, and we can bound the policy loss that results from executing the corresponding MEU policy. As a final note, all of the results in this section depend on discounting with  $\gamma < 1$ . If  $\gamma=1$  and the environment contains terminal states, then a similar set of convergence results and error bounds can be derived.

### 16.2.2 Policy iteration

In the previous section, we observed that it is possible to get an optimal policy even when the utility function estimate is inaccurate. If one action is clearly better than all others, then the exact magnitude of the utilities on the states involved need not be precise. This insight suggests an alternative way to find optimal policies. The **policy iteration** algorithm alternates the following two steps, beginning from some initial policy  $\pi_0$ :

Policy iteration

Policy evaluation

Policy improvement

- **Policy evaluation:** given a policy  $\pi_i$ , calculate  $U_i = U^{\pi_i}$ , the utility of each state if  $\pi_i$  were to be executed.
- **Policy improvement:** Calculate a new MEU policy  $\pi_{i+1}$ , using one-step look-ahead based on  $U_i$  (as in Equation (16.4)).

The algorithm terminates when the policy improvement step yields no change in the utilities. At this point, we know that the utility function  $U_i$  is a fixed point of the Bellman update, so it is a solution to the Bellman equations, and  $\pi_i$  must be an optimal policy. Because there are only finitely many policies for a finite state space, and each iteration can be shown to yield a

---

```

function POLICY-ITERATION(mdp) returns a policy
  inputs: mdp, an MDP with states S, actions A(s), transition model  $P(s' | s, a)$ 
  local variables: U, a vector of utilities for states in S, initially zero
     $\pi$ , a policy vector indexed by state, initially random

  repeat
     $U \leftarrow \text{POLICY-EVALUATION}(\pi, U, mdp)$ 
    unchanged?  $\leftarrow$  true
    for each state s in S do
       $a^* \leftarrow \underset{a \in A(s)}{\operatorname{argmax}} \text{Q-VALUE}(mdp, s, a, U)$ 
      if  $\text{Q-VALUE}(mdp, s, a^*, U) > \text{Q-VALUE}(mdp, s, \pi[s], U)$  then
         $\pi[s] \leftarrow a^*$ ; unchanged?  $\leftarrow$  false
    until unchanged?
  return  $\pi$ 

```

**Figure 16.9** The policy iteration algorithm for calculating an optimal policy.

---

better policy, policy iteration must terminate. The algorithm is shown in Figure 16.9. As with value iteration, we use the Q-VALUE function defined on page 559.

How do we implement POLICY-EVALUATION? It turns out that doing so is simpler than solving the standard Bellman equations (which is what value iteration does), because the action in each state is fixed by the policy. At the *i*th iteration, the policy  $\pi_i$  specifies the action  $\pi_i(s)$  in state *s*. This means that we have a simplified version of the Bellman equation (16.5) relating the utility of *s* (under  $\pi_i$ ) to the utilities of its neighbors:

$$U_i(s) = \sum_{s'} P(s' | s, \pi_i(s)) [R(s, \pi_i(s), s') + \gamma U_i(s')]. \quad (16.14)$$

For example, suppose  $\pi_i$  is the policy shown in Figure 16.2(a). Then we have  $\pi_i(1, 1) = Up$ ,  $\pi_i(1, 2) = Up$ , and so on, and the simplified Bellman equations are

$$\begin{aligned} U_i(1, 1) &= 0.8[-0.04 + U_i(1, 2)] + 0.1[-0.04 + U_i(2, 1)] + 0.1[-0.04 + U_i(1, 1)], \\ U_i(1, 2) &= 0.8[-0.04 + U_i(1, 3)] + 0.2[-0.04 + U_i(1, 2)], \end{aligned}$$

and so on for all the states. The important point is that these equations are *linear*, because the “max” operator has been removed. For *n* states, we have *n* linear equations with *n* unknowns, which can be solved exactly in time  $O(n^3)$  by standard linear algebra methods. If the transition model is sparse—that is, if each state transitions only to a small number of other states—then the solution process can be faster still.

For small state spaces, policy evaluation using exact solution methods is often the most efficient approach. For large state spaces,  $O(n^3)$  time might be prohibitive. Fortunately, it is not necessary to do *exact* policy evaluation. Instead, we can perform some number of simplified value iteration steps (simplified because the policy is fixed) to give a reasonably good approximation of the utilities. The simplified Bellman update for this process is

$$U_{i+1}(s) \leftarrow \sum_{s'} P(s' | s, \pi_i(s)) [R(s, \pi_i(s), s') + \gamma U_i(s')],$$

**Modified policy iteration**

**Asynchronous policy iteration**

and this is repeated several times to efficiently produce the next utility estimate. The resulting algorithm is called **modified policy iteration**.

The algorithms we have described so far require updating the utility or policy for all states at once. It turns out that this is not strictly necessary. In fact, on each iteration, we can pick *any subset* of states and apply *either* kind of updating (policy improvement or simplified value iteration) to that subset. This very general algorithm is called **asynchronous policy iteration**. Given certain conditions on the initial policy and initial utility function, asynchronous policy iteration is guaranteed to converge to an optimal policy. The freedom to choose any states to work on means that we can design much more efficient heuristic algorithms—for example, algorithms that concentrate on updating the values of states that are likely to be reached by a good policy. There's no sense planning for the results of an action you will never do.

### 16.2.3 Linear programming

**Linear programming** or LP, which was mentioned briefly in Chapter 4 (page 139), is a general approach for formulating constrained optimization problems, and there are many industrial-strength LP solvers available. Given that the Bellman equations involve a lot of sums and maxes, it is perhaps not surprising that solving an MDP can be reduced to solving a suitably formulated linear program.

The basic idea of the formulation is to consider as variables in the LP the utilities  $U(s)$  of each state  $s$ , noting that the utilities for an optimal policy are the highest utilities attainable that are consistent with the Bellman equations. In LP language, that means we seek to minimize  $U(s)$  for all  $s$  subject to the inequalities

$$U(s) \geq \sum_{s'} P(s' | s, a) [R(s, a, s') + \gamma U(s')]$$

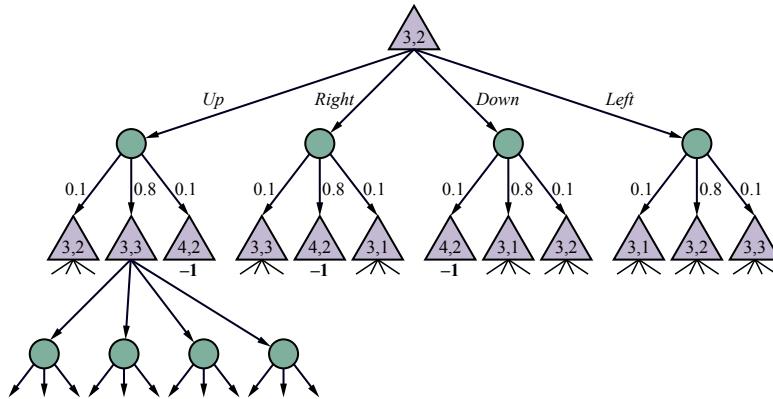

for every state  $s$  and every action  $a$ .

This creates a connection from dynamic programming to linear programming, for which algorithms and complexity issues have been studied in great depth. For example, from the fact that linear programming is solvable in polynomial time, one can show that MDPs can be solved in time polynomial in the number of states and actions and the number of bits required to specify the model. In practice, it turns out that LP solvers are seldom as efficient as dynamic programming for solving MDPs. Moreover, polynomial time may sound good, but the number of states is often very large. Finally, it's worth remembering that even the simplest and most uninformed of the search algorithms in Chapter 3 runs in linear time in the number of states and actions.

### 16.2.4 Online algorithms for MDPs

Value iteration and policy iteration are *offline* algorithms: like the A\* algorithm in Chapter 3, they generate an optimal solution for the problem, which can then be executed by a simple agent. For sufficiently large MDPs, such as the Tetris MDP with  $10^{62}$  states, exact offline solution, even by a polynomial-time algorithm, is not possible. Several techniques have been developed for approximate offline solution of MDPs; these are covered in the notes at the end of the chapter and in Chapter 23 (Reinforcement Learning).

Here we will consider online algorithms, analogous to those used for game playing in Chapter 6, where the agent does a significant amount of computation at each decision point rather than operating primarily with precomputed information.

**Figure 16.10** Part of an expectimax tree for the  $4 \times 3$  MDP rooted at (3,2). The triangular nodes are max modes and the circular nodes are chance nodes.

The most straightforward approach is actually a simplification of the EXPECTIMINIMAX algorithm for game trees with chance nodes: the EXPECTIMAX algorithm builds a tree of alternating max and chance nodes, as illustrated in Figure 16.10. (There is a slight difference from standard EXPECTIMINIMAX in that there are rewards on nonterminal as well as terminal transitions.) An evaluation function can be applied to the nonterminal leaves of the tree, or they can be given a default value. A decision can be extracted from the search tree by backing up the utility values from the leaves, taking an average at the chance nodes and taking the maximum at the decision nodes.

For problems in which the discount factor  $\gamma$  is not too close to 1, the  $\epsilon$ -horizon is a useful concept. Let  $\epsilon$  be a desired bound on the absolute error in the utilities computed from an expectimax tree of bounded depth, compared to the exact utilities in the MDP. Then the  $\epsilon$ -horizon is the tree depth  $H$  such that the sum of rewards beyond any leaf at that depth is less than  $\epsilon$ —roughly speaking, anything that happens after  $H$  is irrelevant because it's so far in the future. Because the sum of rewards beyond  $H$  is bounded by  $\gamma^H R_{\max} / (1 - \gamma)$ , a depth of  $H = \lceil \log_\gamma \epsilon / (1 - \gamma) / R_{\max} \rceil$  suffices. So, building a tree to this depth gives near-optimal decisions. For example, with  $\gamma = 0.5$ ,  $\epsilon = 0.1$ , and  $R_{\max} = 1$ , we find  $H = 5$ , which seems reasonable. On the other hand, if  $\gamma = 0.9$ ,  $H = 44$ , which seems less reasonable!

In addition to limiting the depth, it is also possible to avoid the potentially enormous branching factor at the chance nodes. (For example, if all the conditional probabilities in a DBN transition model are nonzero, the transition probabilities, which are given by the product of the conditional probabilities, are also nonzero, meaning that every state has *some* probability of transitioning to every other state.)

As noted in Section 13.4, expectations with respect to a probability distribution  $P$  can be approximated by generating  $N$  samples from  $P$  and using the sample mean. In mathematical form, we have

$$\sum_x P(x) f(x) \approx \frac{1}{N} \sum_{i=1}^N f(x_i).$$

So, if the branching factor is very large, meaning that there are very many possible  $x$  values, a good approximation to the value of the chance node can be obtained by sampling a bounded

**Figure 16.11** Performance of UCT as a function of the number of playouts per move for the  $4 \times 3$  world using a random playout policy, averaged over 1000 runs per data point.

number of outcomes from the action. Typically, the samples will focus on the *most likely* outcomes because those are most likely to be generated.

If you look closely at the tree in Figure 16.10, you will notice something: it isn't really a tree. For example, the root  $(3,2)$  is also a leaf, so one ought to consider this as a graph, and one ought to constrain the value of the leaf  $(3,2)$  to be the same as the value of the root  $(3,2)$ , since they are the same state. In fact, this line of thinking quickly brings us back to the Bellman equations that relate the values of states to the values of neighboring states. The explored states actually constitute a sub-MDP of the original MDP, and this sub-MDP can be solved using any of the algorithms in this chapter to yield a decision for the current state. (Frontier states are typically given a fixed estimated value.)

This general approach is called **real-time dynamic programming (RTDP)** and is quite analogous to LRTA\* in Chapter 4. Algorithms of this kind can be quite effective in moderate-sized domains such as grid worlds; in larger domains such as Tetris, there are two issues. First, the state space is such that any manageable set of explored states contains very few repeated states, so one might as well use a simple expectimax tree. Second, a simple heuristic for frontier nodes may not be enough to guide the agent, particularly if rewards are sparse.

One possible fix is to apply reinforcement learning to generate a much more accurate heuristic (see Chapter 23). Another approach is to look further ahead in the MDP using the Monte Carlo approach of Section 6.4. In fact, the UCT algorithm from Figure 6.10 was developed originally for MDPs rather than games. The changes required to solve MDPs rather than games are minimal: they arise primarily from the fact that the opponent (nature) is stochastic and from the need to keep track of rewards rather than just wins and losses.

When applied to the  $4 \times 3$  world, the performance of UCT is not especially impressive. As Figure 16.11 shows, it takes 160 playouts on average to reach a total reward of 0.4, whereas an optimal policy has an expected total reward of 0.7453 from the initial state (see Figure 16.3). One reason UCT can have difficulty is that it builds a tree rather than a graph and uses (an approximation to) expectimax rather than dynamic programming. The  $4 \times 3$  world is very “loopy”: although there are only 9 nonterminal states, UCT's playouts often continue for more than 50 actions.

UCT seems better suited for Tetris, where the playouts go far enough into the future to give the agent a sense of whether a potentially risky move will work out in the end or cause a massive pile-up. Exercise 16.UCTT explores the application of UCT to Tetris. One particularly interesting question is how much a simple simulation policy can help—for example, one that avoids creating overhangs and puts pieces as low as possible.

## 16.3 Bandit Problems

---

In Las Vegas, a *one-armed bandit* is a slot machine. A gambler can insert a coin, pull the lever, and collect the winnings (if any). An **n-armed bandit** has  $n$  levers. Behind each lever is a fixed but unknown probability distribution of winnings; each pull samples from that unknown distribution.

The gambler must choose which lever to play on each successive coin—the one that has paid off best, or maybe one that has not been tried yet? This is an example of the ubiquitous tradeoff between **exploitation** of the current best action to obtain rewards and **exploration** of previously unknown states and actions to gain information, which can in some cases be converted into a better policy and better long-term rewards. In the real world, one constantly has to decide between continuing in a comfortable existence, versus striking out into the unknown in the hopes of a better life.

The *n*-armed bandit problem is a formal model for real problems in many vitally important areas, such as deciding which of  $n$  possible new treatments to try to cure a disease, which of  $n$  possible investments to put part of your savings into, which of  $n$  possible research projects to fund, or which of  $n$  possible advertisements to show when the user visits a particular web page.

Early work on the problem began in the U.S. during World War II; it proved so recalcitrant that Allied scientists proposed that “the problem be dropped over Germany, as the ultimate instrument of intellectual sabotage” (Whittle, 1979).

It turns out that the scientists, both during and after the war, were trying to prove “obviously true” facts about bandit problems that are, in fact, false. (As Bradt *et al.* (1956) put it, “There are many nice properties which optimal strategies do not possess.”) For example, it was generally assumed that an optimal policy would eventually settle on the best arm in the long run; in fact, there is a finite probability that an optimal policy settles on a suboptimal arm. We now have a solid theoretical understanding of bandit problems as well as useful algorithms for solving them.

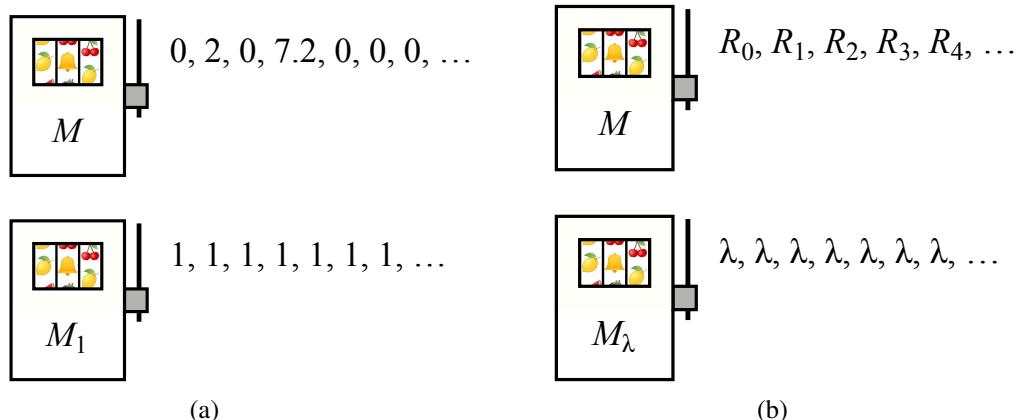

There are several different definitions of **bandit problems**; one of the cleanest and most general is as follows:

- Each arm  $M_i$  is a **Markov reward process** or MRP, that is, an MDP with only one possible action  $a_i$ . It has states  $S_i$ , transition model  $P_i(s' | s, a_i)$ , and reward  $R_i(s, a_i, s')$ . The arm defines a distribution over sequences of rewards  $R_{i,0}, R_{i,1}, R_{i,2}, \dots$ , where each  $R_{i,t}$  is a random variable.
- The overall bandit problem is an MDP: the state space is given by the Cartesian product  $S = S_1 \times \dots \times S_n$ ; the actions are  $a_1, \dots, a_n$ ; the transition model updates the state of whichever arm  $M_i$  is selected, according to its specific transition model, leaving the other arms unchanged; and the discount factor is  $\gamma$ .

N-armed bandit

Bandit problems

Markov reward process

**Figure 16.12** (a) A simple deterministic bandit problem with two arms. The arms can be pulled in any order, and each yields the sequence of rewards shown. (b) A more general case of the bandit in (a), where the first arm gives an arbitrary sequence of rewards and the second arm gives a fixed reward  $\lambda$ .

This definition is very general, covering a wide range of cases. The key property is that the arms are independent, coupled only by the fact that the agent can work on only one arm at a time. It's possible to define a still more general version in which fractional efforts can be applied to all arms simultaneously, but the total effort across all arms is bounded; the basic results described here carry over to this case.

We will see shortly how to formulate a typical bandit problem within this framework, but let's warm up with the simple special case of deterministic reward sequences. Let  $\gamma=0.5$ , and suppose that there are two arms labeled  $M$  and  $M_1$ . Pulling  $M$  multiple times yields the sequence of rewards  $0, 2, 0, 7.2, 0, 0, \dots$ , while pulling  $M_1$  yields  $1, 1, 1, \dots$  (Figure 16.12(a)). If, at the beginning, one had to commit to one arm or the other and stick with it, the choice would be made by computing the utility (total discounted reward) for each arm:

$$U(M_1) = \sum_{t=0}^{\infty} 0.5^t = 2.0.$$

One might think the best choice is to go with  $M_1$ , but a moment's more thought shows that starting with  $M$  and then switching to  $M_1$  after the fourth reward gives the sequence  $S=0, 2, 0, 7, 2, 1, 1, 1, \dots$ , for which

$$U(S) = (1.0 \times 0) + (0.5 \times 2) + (0.5^2 \times 0) + (0.5^3 \times 7.2) + \sum_{t=4}^{\infty} 0.5^t = 2.025.$$

Hence the strategy  $S$  that switches from  $M$  to  $M_1$  at the right time is better than either arm individually. In fact,  $S$  is optimal for this problem: all other switching times give less reward.

Let's generalize this case slightly, so that now the first arm  $M$  yields an arbitrary sequence  $R_0, R_1, R_2, \dots$  (which may be known or unknown) and the second arm  $M_\lambda$  yields  $\lambda, \lambda, \lambda, \dots$  for some known fixed constant  $\lambda$  (see Figure 16.12(b)). This is called a **one-armed bandit** in the literature, because it is formally equivalent to the case where there is one arm  $M$  that produces rewards  $R_0, R_1, R_2, \dots$  and costs  $\lambda$  for each pull. (Pulling arm  $M$  is equivalent to not

pulling  $M_\lambda$ , so it gives up a reward of  $\lambda$  each time.) With just one arm, the only choice is to whether to pull again or to stop. If you pull the first arm  $T$  times (i.e., at times  $0, 1, \dots, T - 1$ ) we say that the **stopping time** is  $T$ .

Going back to our version with  $M$  and  $M_\lambda$ , let's assume that after  $T$  pulls of the first arm, an optimal strategy eventually pulls the second arm for the first time. Since no information is gained from this move (we already know the payoff will be  $\lambda$ ), at time  $T + 1$  we will be in the same situation and thus an optimal strategy must make the same choice.

Equivalently, we can say that an optimal strategy is to run arm  $M$  up to time  $T$  and then switch to  $M_\lambda$  for the rest of time. It's possible that  $T = 0$  if the strategy chooses  $M_\lambda$  immediately, or  $T = \infty$  if the strategy never chooses  $M_\lambda$ , or somewhere in between. Now let's consider the value of  $\lambda$  such that an optimal strategy is *exactly indifferent* between (a) running  $M$  up to the best possible stopping time and then switching to  $M_\lambda$  forever, and (b) choosing  $M_\lambda$  immediately. At the tipping point we have

$$\max_{T>0} E \left[ \left( \sum_{t=0}^{T-1} \gamma^t R_t \right) + \sum_{t=T}^{\infty} \gamma^t \lambda \right] = \sum_{t=0}^{\infty} \gamma^t \lambda,$$

which simplifies to

$$\lambda = \max_{T>0} \frac{E \left( \sum_{t=0}^{T-1} \gamma^t R_t \right)}{E \left( \sum_{t=0}^{T-1} \gamma^t \right)}. \quad (16.15)$$

This equation defines a kind of “value” for  $M$  in terms of its ability to deliver a stream of timely rewards; the numerator of the fraction represents a utility while the denominator can be thought of as a “discounted time,” so the value describes the maximum obtainable utility per unit of discounted time. (It's important to remember that  $T$  in the equation is a stopping time, which is governed by a rule for stopping rather than being a simple integer; it reduces to a simple integer only when  $M$  is a deterministic reward sequence.) The value defined in Equation (16.15) is called the **Gittins index** of  $M$ .

The remarkable thing about the Gittins index is that it provides a very simple optimal policy for any bandit problem: *pull the arm that has the highest Gittins index, then update the Gittins indices*. Furthermore, because the index of arm  $M_i$  depends only on the properties of that arm, an optimal decision on the first iteration can be calculated in  $O(n)$  time, where  $n$  is the number of arms. And because the Gittins indices of the arms that are not selected remain unchanged, each decision after the first one can be calculated in  $O(1)$  time.

### 16.3.1 Calculating the Gittins index

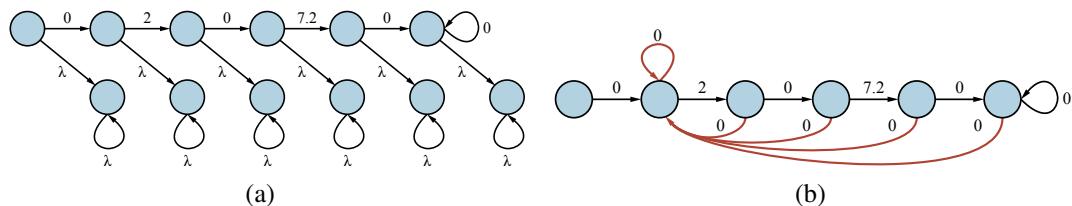

To get more of a feel for the index, let's calculate the value of the numerator, denominator, and ratio in Equation (16.15) for different possible stopping times on the deterministic reward sequence  $0, 2, 0, 7.2, 0, 0, 0, \dots$ :

$T$	1	2	3	4	5	6
$R_t$	0	2	0	7.2	0	0
$\sum \gamma^t R_t$	0.0	1.0	1.0	1.9	1.9	1.9
$\sum \gamma^t$	1.0	1.5	1.75	1.875	1.9375	1.9687
ratio	0.0	0.6667	0.5714	1.0133	0.9806	0.9651

Clearly, the ratio will decrease from here on, because the numerator remains constant while the denominator continues to increase. Thus, the Gittins index for this arm is 1.0133, the

Stopping time

Gittins index

**Figure 16.13** (a) The reward sequence  $M = 0, 2, 0, 7.2, 0, 0, 0, \dots$  augmented with a choice to switch permanently to a constant arm  $M_\lambda$  at each point. (b) An MDP whose optimal value is exactly equivalent to the optimal value for (a), at the point where the optimal policy is indifferent between  $M$  and  $M_\lambda$ .

maximum value attained by the ratio. In combination with a fixed arm  $M_\lambda$  with  $0 < \lambda \leq 1.0133$ , the optimal policy collects the first four rewards from  $M$  and then switches to  $M_\lambda$ . For  $\lambda > 1.0133$ , the optimal policy always chooses  $M_\lambda$ .

To calculate the Gittins index for a general arm  $M$  with current state  $s$ , we simply make the following observation: at the tipping point where an optimal policy is indifferent between choosing arm  $M$  and choosing the fixed arm  $M_\lambda$ , the value of choosing  $M$  is the same as the value of choosing an infinite sequence of  $\lambda$ -rewards.

Suppose we augment  $M$  so that at each state in  $M$ , the agent has two choices: either continue with  $M$  as before, or quit and receive an infinite sequence of  $\lambda$ -rewards (see Figure 16.13(a)). This turns  $M$  into an MDP, whose optimal policy is just the optimal stopping rule for  $M$ . Hence the value of an optimal policy in this new MDP is equal to the value of an infinite sequence of  $\lambda$ -rewards, that is,  $\lambda/(1-\gamma)$ . So we can just solve this MDP... but, unfortunately, we don't know the value of  $\lambda$  to put into the MDP, as this is precisely what we are trying to calculate. But we *do* know that, at the tipping point, an optimal policy is indifferent between  $M$  and  $M_\lambda$ , so we could replace the choice to get an infinite sequence of  $\lambda$ -rewards with the choice to go back and restart  $M$  from its initial state  $s$ . (More precisely, we add a new action in every state that has the same rewards and outcomes as the action available in  $s$ ; see Exercise 16.KATV.) This new MDP  $M^s$ , called a **restart MDP**, is illustrated in Figure 16.13(b).

We have the general result that the Gittins index for an arm  $M$  in state  $s$  is equal to  $1 - \gamma$  times the value of an optimal policy for the restart MDP  $M^s$ . This MDP can be solved by any of the algorithms in Section 16.2. Value iteration applied to  $M^s$  in Figure 16.13(b) gives a value of 2.0266 for the start state, so we have  $\lambda = 2.0266 \cdot (1 - \gamma) = 1.0133$  as before.

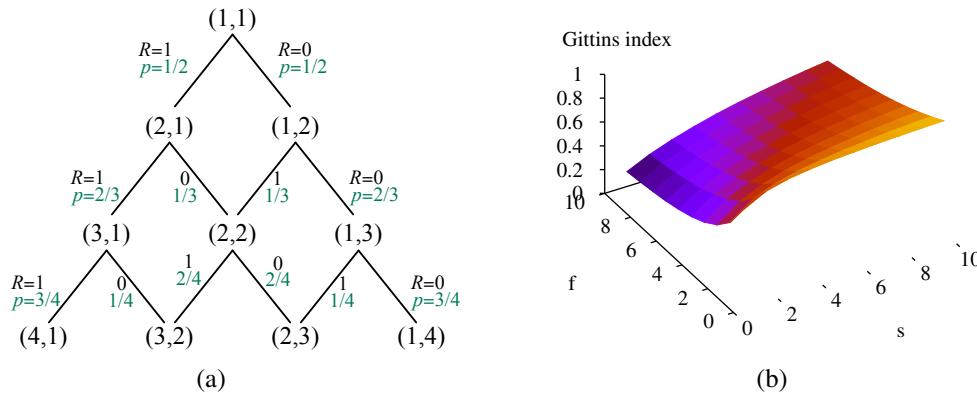

[Restart MDP](#)

### 16.3.2 The Bernoulli bandit

[Bernoulli bandit](#)

Perhaps the simplest and best-known instance of a bandit problem is the **Bernoulli bandit**, where each arm  $M_i$  produces a reward of 0 or 1 with a fixed but unknown probability  $\mu_i$ . The state of arm  $M_i$  is defined by  $s_i$  and  $f_i$ , the counts of successes (1s) and failures (0s) so far for that arm; the transition probability predicts the next outcome to be 1 with probability  $(s_i)/(s_i + f_i)$  and 0 with probability  $(f_i)/(s_i + f_i)$ . The counts are initialized to 1 so that the initial probabilities are 1/2 rather than 0/0.<sup>4</sup> The Markov reward process is shown in Figure 16.14(a).

<sup>4</sup> The probabilities are those of a Bayesian updating process with a Beta(1,1) prior (see Section 21.2.5).

**Figure 16.14** (a) States, rewards, and transition probabilities for the Bernoulli bandit. (b) Gittins indices for the states of the Bernoulli bandit process.

We cannot quite apply the transformation of the preceding section to calculate the Gittins index of the Bernoulli arm because it has infinitely many states. We can, however, obtain a very accurate approximation by solving the truncated MDP with states up to  $s_i + f_i = 100$  and  $\gamma = 0.9$ . The results are shown in Figure 16.14(b). The results are intuitively reasonable: we see that, generally speaking, arms with higher payoff probabilities are preferred, but there is also an **exploration bonus** associated with arms that have only been tried a few times. For example, the index for the state  $(3,2)$  is higher than the index for the state  $(7,4)$  (0.7057 vs. 0.6922), even though the estimated value at  $(3,2)$  is lower (0.6 vs. 0.6364).

Exploration bonus

### 16.3.3 Approximately optimal bandit policies

Calculating Gittins indices for more realistic problems is rarely easy. Fortunately, the general properties observed in the preceding section—namely, the desirability of some combination of estimated value and uncertainty—lend themselves to the creation of simple policies that turn out to be “nearly as good” as optimal policies.

The first class of methods uses the **upper confidence bound** or UCB heuristic, previously introduced for Monte Carlo tree search (Figure 6.11 on page 209). The basic idea is to use the samples from each arm to establish a **confidence interval** for the value of the arm, that is, a range within which the value can be estimated to lie with high confidence; then choose the arm with the highest upper bound on its confidence interval. The upper bound is the current mean value estimate  $\hat{\mu}_i$  plus some multiple of the standard deviation of the uncertainty in the value. The standard deviation is proportional to  $\sqrt{1/N_i}$ , where  $N_i$  is the number of times arm  $M_i$  has been sampled. So we have an approximate index value for arm  $M_i$  given by

$$UCB(M_i) = \hat{\mu}_i + g(N)/\sqrt{N_i},$$

where  $g(N)$  is an appropriately chosen function of  $N$ , the total number of samples drawn from all arms. A UCB policy simply picks the arm with the highest UCB value. Notice that the UCB value is not strictly an index because it depends on  $N$ , the total number of samples drawn across all arms, and not just on the arm itself.

The precise definition of  $g$  determines the **regret** relative to the clairvoyant policy, which simply picks the best arm and yields average reward  $\mu^*$ . A famous result due to Lai and

Upper confidence bound

Robbins (1985) shows that, for the undiscounted case, no possible algorithm can have regret that grows more slowly than  $O(\log N)$ . Several different choices of  $g$  lead to a UCB policy that matches this growth; for example, we can use  $g(N) = (2 \log(1 + N \log^2 N))^{1/2}$ .

#### Thompson sampling

A second method, **Thompson sampling** (Thompson, 1933), chooses an arm randomly according to the probability that the arm is in fact optimal, given the samples so far. Suppose that  $P_i(\mu_i)$  is the current probability distribution for the true value of arm  $M_i$ . Then a simple way to implement Thompson sampling is to generate one sample from each  $P_i$  and then pick the best sample. This algorithm also has a regret that grows as  $O(\log N)$ .

#### 16.3.4 Non-indexable variants

Bandit problems were motivated in part by the task of testing new medical treatments on seriously ill patients. For this task, the goal of maximizing the total number of successes over time clearly makes sense: each successful test means a life saved, each failure a life lost.

If we change the assumptions slightly, however, a different problem emerges. Suppose that, instead of determining the best medical treatment for each new human patient, we are instead testing different drugs on samples of bacteria with the goal of deciding which drug is best. We will then put that drug into production and forgo the others. In this scenario there is no additional cost if the bacteria dies—there is a fixed cost for each test, but we don't have to minimize test failures; rather we are just trying to make a good decision as fast as possible.

#### Selection problem

The task of choosing the best option under these conditions is called a **selection problem**. Selection problems are ubiquitous in industrial and personnel contexts. One often must decide which supplier to use for a process; or which candidate employees to hire. Selection problems are superficially similar to the bandit problem but have different mathematical properties. In particular, *no index function exists for selection problems*. The proof of this fact requires showing any scenario where the optimal policy switches its preferences for two arms  $M_1$  and  $M_2$  when a third arm  $M_3$  is added (see Exercise 16.SELC).

Chapter 6 introduced the concept of **metalevel** decision problems such as deciding what computations to make during a game-tree search prior to making a move. A metalevel decision of this kind is also a selection problem rather than a bandit problem. Clearly, a node expansion or evaluation *costs* the same amount of time whether it produces a high or a low output value. It is perhaps surprising, then, that the Monte Carlo tree search algorithm (see page 209) has been so successful, given that it tries to solve selection problems with the UCB heuristic, which was designed for bandit problems. Generally speaking, one expects optimal bandit algorithms to explore much less than optimal selection algorithms, because the bandit algorithm assumes that a failed trial costs real money.

#### Bandit superprocess BSP

An important generalization of the bandit process is the **bandit superprocess** or **BSP**, in which each arm is a full Markov decision process in its own right, rather than being a Markov reward process with only one possible action. All other properties remain the same: the arms are independent, only one (or a bounded number) can be worked on at a time, and there is a single discount factor.

#### Multitasking

Examples of BSPs include daily life, where one can attend to one task at a time, even though several tasks may need attention; project management with multiple projects; teaching with multiple pupils needing individual guidance; and so on. The ordinary term for this is **multitasking**. It is so ubiquitous as to be barely noticeable: when formulating a real-world decision problem, decision analysts rarely ask if their client has other, unrelated problems.

One might reason as follows: “If there are  $n$  disjoint MDPs then it is obvious that an optimal policy overall is built from the optimal solutions of the individual MDPs. Given its optimal policy  $\pi_i$ , each MDP becomes a Markov reward process where there is only one action  $\pi_i(s)$  in each state  $s$ . So we have reduced the  $n$ -armed bandit superprocess to an  $n$ -armed bandit process.” For example, if a real-estate developer has one construction crew and several shopping centers to build, it seems to be just common sense that one should devise the optimal construction plan for each shopping center and then solve the bandit problem to decide where to send the crew each day.

While this sounds highly plausible, it is incorrect. In fact, the globally optimal policy for a BSP may include actions that are locally suboptimal from the point of view of the constituent MDP in which they are taken. The reason for this is that the availability of other MDPs in which to act changes the balance between short-term and long-term rewards in a component MDP. In fact, it tends to lead to greedier behavior in each MDP (seeking short-term rewards) because aiming for long-term reward in one MDP would delay rewards in all the other MDPs.

For example, suppose the locally optimal construction schedule for one shopping center has the first shop available for rent by week 15, whereas a suboptimal schedule costs more but has the first shop available by week 5. If there are four shopping centers to build, it might be better to use the locally suboptimal schedule in each so that rents start coming in from weeks 5, 10, 15, and 20, rather than weeks 15, 30, 45, and 60. In other words, what would be only a 10-week delay for a single MDP turns into a 40-week delay for the fourth MDP. In general, the globally and locally optimal policies necessarily coincide only when the discount factor is 1; in that case, there is no cost to delaying rewards in any MDP.

The next question is how to solve BSPs. Obviously, the globally optimal solution for a BSP could be computed by converting it into a global MDP on the Cartesian-product state space. The number of states would be exponential in the number of arms of the BSP, so this would be horrendously impractical.

Instead, we can take advantage of the loose nature of the interaction between the arms. This interaction arises only from the agent’s limited ability to attend to the arms simultaneously. To some extent, the interaction can be modeled by the notion of **opportunity cost**: how much utility is given up per time step by not devoting that time step to another arm. The higher the opportunity cost, the more necessary it is to generate early rewards in a given arm. In some cases, an optimal policy in a given arm is unaffected by the opportunity cost. (Trivially, this is true in a Markov reward process because there is only one policy.) In that case, an optimal policy can be applied, converting that arm into a Markov reward process.

Such an optimal policy, if it exists, is called a **dominating policy**. It turns out that by adding actions to states, it is always possible to create a relaxed version of an MDP (see Section 3.6.2) so that it has a dominating policy, which thus gives an upper bound on the value of acting in the arm. A lower bound can be computed by solving each arm separately (which may yield a suboptimal policy overall) and then computing the Gittins indices. If the lower bound for acting in one arm is higher than the upper bounds for all other actions, then the problem is solved; if not, then a combination of look-ahead search and recomputation of bounds is guaranteed to eventually identify an optimal policy for the BSP. With this approach, relatively large BSPs ( $10^{40}$  states or more) can be solved in a few seconds.

Opportunity cost

Dominating policy

## 16.4 Partially Observable MDPs

Partially observable  
MDP

The description of Markov decision processes in Section 16.1 assumed that the environment was **fully observable**. With this assumption, the agent always knows which state it is in. This, combined with the Markov assumption for the transition model, means that the optimal policy depends only on the current state.

When the environment is only **partially observable**, the situation is, one might say, much less clear. The agent does not necessarily know which state it is in, so it cannot execute the action  $\pi(s)$  recommended for that state. Furthermore, the utility of a state  $s$  and the optimal action in  $s$  depend not just on  $s$ , but also on *how much the agent knows* when it is in  $s$ . For these reasons, **partially observable MDPs** (or **POMDPs**—pronounced “pom-dee-pees”) are usually viewed as much more difficult than ordinary MDPs. We cannot avoid POMDPs, however, because the real world is one.

### 16.4.1 Definition of POMDPs

To get a handle on POMDPs, we must first define them properly. A POMDP has the same elements as an MDP—the transition model  $P(s'|s,a)$ , actions  $A(s)$ , and reward function  $R(s,a,s')$ —but, like the partially observable search problems of Section 4.4, it also has a **sensor model**  $P(e|s)$ . Here, as in Chapter 14, the sensor model specifies the probability of perceiving evidence  $e$  in state  $s$ .<sup>5</sup> For example, we can convert the  $4 \times 3$  world of Figure 16.1 into a POMDP by adding a noisy or partial sensor instead of assuming that the agent knows its location exactly. The noisy four-bit sensor from page 494 could be used, which reports the presence or absence of a wall in each compass direction with accuracy  $1 - \epsilon$ .

As with MDPs, we can obtain compact representations for large POMDPs by using dynamic decision networks (see Section 16.1.4). We add sensor variables  $E_t$ , assuming that the state variables  $X_t$  may not be directly observable. The POMDP sensor model is then given by  $P(E_t|X_t)$ . For example, we might add sensor variables to the DDN in Figure 16.4 such as *BatteryMeter* <sub>$t$</sub>  to estimate the actual charge  $Battery_t$ , and *Speedometer* <sub>$t$</sub>  to estimate the magnitude of the velocity vector  $\dot{X}_t$ . A sonar sensor *Walls* <sub>$t$</sub>  might give estimated distances to the nearest wall in each of the four cardinal directions relative to the robot’s current orientation; these values depends on the current position and orientation  $X_t$ .

In Chapters 4 and 11, we studied nondeterministic and partially observable planning problems and identified the **belief state**—the set of actual states the agent might be in—as a key concept for describing and calculating solutions. In POMDPs, the belief state  $b$  becomes a *probability distribution* over all possible states, just as in Chapter 14. For example, the initial belief state for the  $4 \times 3$  POMDP could be the uniform distribution over the nine nonterminal states along with 0s for the terminal states, that is,  $\langle \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, \frac{1}{9}, 0, 0 \rangle$ .

We use the notation  $b(s)$  to refer to the probability assigned to the actual state  $s$  by belief state  $b$ . The agent can calculate its current belief state as the conditional probability distribution over the actual states given the sequence of percepts and actions so far. This is essentially the **filtering** task described in Chapter 14. The basic recursive filtering equation (14.5 on page 485) shows how to calculate the new belief state from the previous belief state and the new evidence. For POMDPs, we also have an action to consider, but the result is essentially the same. If  $b$  was the previous belief state, and the agent does action  $a$  and then

<sup>5</sup> The sensor model can also depend on the action and outcome state, but this change is not fundamental.

perceives evidence  $e$ , then the new belief state is obtained by calculating the probability of now being in state  $s'$ , for each  $s'$ , with the following formula:

$$b'(s') = \alpha P(e|s') \sum_s P(s'|s, a) b(s),$$

where  $\alpha$  is a normalizing constant that makes the belief state sum to 1. By analogy with the update operator for filtering (page 485), we can write this as

$$b' = \alpha \text{FORWARD}(b, a, e). \quad (16.16)$$

In the  $4 \times 3$  POMDP, suppose the agent moves *Left* and its sensor reports one adjacent wall; then it's quite likely (although not guaranteed, because both the motion and the sensor are noisy) that the agent is now in (3,1). Exercise 16.POMD asks you to calculate the exact probability values for the new belief state.

The fundamental insight required to understand POMDPs is this: *the optimal action depends only on the agent's current belief state*. That is, an optimal policy can be described by a mapping  $\pi^*(b)$  from belief states to actions. It does *not* depend on the *actual* state the agent is in. This is a good thing, because the agent does not know its actual state; all it knows is the belief state. Hence, the decision cycle of a POMDP agent can be broken down into the following three steps:

1. Given the current belief state  $b$ , execute the action  $a = \pi^*(b)$ .
2. Observe the percept  $e$ .
3. Set the current belief state to  $\text{FORWARD}(b, a, e)$  and repeat.

We can think of POMDPs as requiring a search in belief-state space, just like the methods for sensorless and contingency problems in Chapter 4. The main difference is that the POMDP belief-state space is *continuous*, because a POMDP belief state is a probability distribution. For example, a belief state for the  $4 \times 3$  world is a point in an 11-dimensional continuous space. An action changes the belief state, not just the physical state, because it affects the percept that is received. Hence, the action is evaluated at least in part according to the information the agent acquires as a result. POMDPs therefore include the value of information (Section 15.6) as one component of the decision problem.

Let's look more carefully at the outcome of actions. In particular, let's calculate the probability that an agent in belief state  $b$  reaches belief state  $b'$  after executing action  $a$ . Now, if we knew the action *and the subsequent percept*, then Equation (16.16) would provide a *deterministic* update to the belief state:  $b' = \text{FORWARD}(b, a, e)$ . Of course, the subsequent percept is not yet known, so the agent might arrive in one of several possible belief states  $b'$ , depending on the percept that is received. The probability of perceiving  $e$ , given that  $a$  was performed starting in belief state  $b$ , is given by summing over all the actual states  $s'$  that the agent might reach:

$$\begin{aligned} P(e|a, b) &= \sum_{s'} P(e|a, s', b) P(s'|a, b) \\ &= \sum_{s'} P(e|s') P(s'|a, b) \\ &= \sum_{s'} P(e|s') \sum_s P(s'|s, a) b(s). \end{aligned}$$

Let us write the probability of reaching  $b'$  from  $b$ , given action  $a$ , as  $P(b' | b, a)$ . This probability can be calculated as follows:

$$\begin{aligned} P(b' | b, a) &= \sum_e P(b' | e, a, b)P(e | a, b) \\ &= \sum_e P(b' | e, a, b) \sum_{s'} P(e | s') \sum_s P(s' | s, a) b(s), \end{aligned} \quad (16.17)$$

where  $P(b' | e, a, b)$  is 1 if  $b' = \text{FORWARD}(b, a, e)$  and 0 otherwise.

Equation (16.17) can be viewed as defining a transition model for the belief-state space. We can also define a reward function for belief-state transitions, which is derived from the expected reward of the real state transitions that might be occurring. Here, we use the simple form  $\rho(b, a)$ , the expected reward if the agent does  $a$  in belief state  $b$ :

$$\rho(b, a) = \sum_s b(s) \sum_{s'} P(s' | s, a) R(s, a, s').$$

Together,  $P(b' | b, a)$  and  $\rho(b, a)$  define an *observable* MDP on the space of belief states. Furthermore, it can be shown that an optimal policy for this MDP,  $\pi^*(b)$ , is also an optimal policy for the original POMDP. In other words, *solving a POMDP on a physical state space can be reduced to solving an MDP on the corresponding belief-state space*. This fact is perhaps less surprising if we remember that the belief state is always observable to the agent, by definition.

## 16.5 Algorithms for Solving POMDPs

We have shown how to reduce POMDPs to MDPs, but the MDPs we obtain have a continuous (and usually high-dimensional) state space. This means we will have to redesign the dynamic programming algorithms from Sections 16.2.1 and 16.2.2, which assumed a finite state space and a finite number of actions. Here we describe a value iteration algorithm designed specifically for POMDPs, followed by an online decision-making algorithm similar to those developed for games in Chapter 6.

### 16.5.1 Value iteration for POMDPs

Section 16.2.1 described a value iteration algorithm that computed one utility value for each state. With infinitely many belief states, we need to be more creative. Consider an optimal policy  $\pi^*$  and its application in a specific belief state  $b$ : the policy generates an action, then, for each subsequent percept, the belief state is updated and a new action is generated, and so on. For this specific  $b$ , therefore, the policy is exactly equivalent to a **conditional plan**, as defined in Chapter 4 for nondeterministic and partially observable problems. Instead of thinking about policies, let us think about conditional plans and how the expected utility of executing a fixed conditional plan varies with the initial belief state. We make two observations:

1. Let the utility of executing a *fixed* conditional plan  $p$  starting in physical state  $s$  be  $\alpha_p(s)$ . Then the expected utility of executing  $p$  in belief state  $b$  is just  $\sum_s b(s)\alpha_p(s)$ , or  $b \cdot \alpha_p$  if we think of them both as vectors. Hence, the expected utility of a fixed conditional plan varies *linearly* with  $b$ ; that is, it corresponds to a hyperplane in belief space.
2. At any given belief state  $b$ , an optimal policy will choose to execute the conditional plan with highest expected utility; and the expected utility of  $b$  under an optimal policy is just

**Figure 16.15** (a) Utility of two one-step plans as a function of the initial belief state  $b(B)$  for the two-state world, with the corresponding utility function shown in bold. (b) Utilities for 8 distinct two-step plans. (c) Utilities for four undominated two-step plans. (d) Utility function for optimal eight-step plans.

the utility of that conditional plan:  $U(b) = U^{\pi^*}(b) = \max_p b \cdot \alpha_p$ . If an optimal policy  $\pi^*$  chooses to execute  $p$  starting at  $b$ , then it is reasonable to expect that it might choose to execute  $p$  in belief states that are very close to  $b$ ; in fact, if we bound the depth of the conditional plans, then there are only finitely many such plans and the continuous space of belief states will generally be divided into *regions*, each corresponding to a particular conditional plan that is optimal in that region.

From these two observations, we see that the utility function  $U(b)$  on belief states, being the maximum of a collection of hyperplanes, will be *piecewise linear* and *convex*.

To illustrate this, we use a simple two-state world. The states are labeled  $A$  and  $B$  and there are two actions: *Stay* stays put with probability 0.9 and *Go* switches to the other state with probability 0.9. The rewards are  $R(\cdot, \cdot, A) = 0$  and  $R(\cdot, \cdot, B) = 1$ ; that is, any transition ending in  $A$  has reward zero and any transition ending in  $B$  has reward 1. For now we will assume the discount factor  $\gamma = 1$ . The sensor reports the correct state with probability 0.6. Obviously, the agent should *Stay* when it's in state  $B$  and *Go* when it's in state  $A$ . The problem is that it doesn't know where it is!

The advantage of a two-state world is that the belief space can be visualized in one dimension, because the two probabilities  $b(A)$  and  $b(B)$  sum to 1. In Figure 16.15(a), the  $x$ -axis

represents the belief state, defined by  $b(B)$ , the probability of being in state  $B$ . Now let us consider the one-step plans  $[Stay]$  and  $[Go]$ , each of which receives the reward for one transition as follows:

$$\begin{aligned}\alpha_{[Stay]}(A) &= 0.9R(A, Stay, A) + 0.1R(A, Stay, B) = 0.1 \\ \alpha_{[Stay]}(B) &= 0.1R(B, Stay, A) + 0.9R(B, Stay, B) = 0.9 \\ \alpha_{[Go]}(A) &= 0.1R(A, Go, A) + 0.9R(A, Go, B) = 0.9 \\ \alpha_{[Go]}(B) &= 0.9R(B, Go, A) + 0.1R(B, Go, B) = 0.1\end{aligned}$$

The hyperplanes (lines, in this case) for  $b \cdot \alpha_{[Stay]}$  and  $b \cdot \alpha_{[Go]}$  are shown in Figure 16.15(a) and their maximum is shown in bold. The bold line therefore represents the utility function for the finite-horizon problem that allows just one action, and in each “piece” of the piecewise linear utility function an optimal action is the first action of the corresponding conditional plan. In this case, the optimal one-step policy is to *Stay* when  $b(B) > 0.5$  and *Go* otherwise.

Once we have utilities  $\alpha_p(s)$  for all the conditional plans  $p$  of depth 1 in each physical state  $s$ , we can compute the utilities for conditional plans of depth 2 by considering each possible first action, each possible subsequent percept, and then each way of choosing a depth-1 plan to execute for each percept:

```
[Stay; if Percept=A then Stay else Stay]
[Stay; if Percept=A then Stay else Go]
[Go; if Percept=A then Stay else Stay]
```

...

There are eight distinct depth-2 plans in all, and their utilities are shown in Figure 16.15(b). Notice that four of the plans, shown as dashed lines, are suboptimal across the entire belief space—we say these plans are **dominated**, and they need not be considered further. There are four undominated plans, each of which is optimal in a specific region, as shown in Figure 16.15(c). The regions partition the belief-state space.

We repeat the process for depth 3, and so on. In general, let  $p$  be a depth- $d$  conditional plan whose initial action is  $a$  and whose depth- $(d-1)$  subplan for percept  $e$  is  $p.e$ ; then

$$\alpha_p(s) = \sum_{s'} P(s' | s, a)[R(s, a, s') + \gamma \sum_e P(e | s') \alpha_{p.e}(s')]. \quad (16.18)$$

This recursion naturally gives us a value iteration algorithm, which is given in Figure 16.16. The structure of the algorithm and its error analysis are similar to those of the basic value iteration algorithm in Figure 16.6 on page 563; the main difference is that instead of computing one utility number for each state, POMDP-VALUE-ITERATION maintains a collection of undominated plans with their utility hyperplanes.

The algorithm’s complexity depends primarily on how many plans get generated. Given  $|A|$  actions and  $|E|$  possible observations, there are  $|A|^{|O(|E|^{d-1})|}$  distinct depth- $d$  plans. Even for the lowly two-state world with  $d=8$ , that’s  $2^{255}$  plans. The elimination of dominated plans is essential for reducing this doubly exponential growth: the number of undominated plans with  $d=8$  is just 144. The utility function for these 144 plans is shown in Figure 16.15(d).

Notice that the intermediate belief states have lower value than state  $A$  and state  $B$ , because in the intermediate states the agent lacks the information needed to choose a good action. This is why information has value in the sense defined in Section 15.6 and optimal policies in POMDPs often include information-gathering actions.

Dominated plan

---

```

function POMDP-VALUE-ITERATION(pomdp,  $\epsilon$ ) returns a utility function
  inputs: pomdp, a POMDP with states  $S$ , actions  $A(s)$ , transition model  $P(s' | s, a)$ ,
    sensor model  $P(e | s)$ , rewards  $R(s, a, s')$ , discount  $\gamma$ 
     $\epsilon$ , the maximum error allowed in the utility of any state
  local variables:  $U, U'$ , sets of plans  $p$  with associated utility vectors  $\alpha_p$ 
   $U' \leftarrow$  a set containing all one-step plans  $[a]$ , with  $\alpha_{[a]}(s) = \sum_{s'} P(s' | s, a) R(s, a, s')$ 
  repeat
     $U \leftarrow U'$ 
     $U' \leftarrow$  the set of all plans consisting of an action and, for each possible next percept,
      a plan in  $U$  with utility vectors computed according to Equation (16.18)
     $U' \leftarrow \text{REMOVE-DOMINATED-PLANS}(U')$ 
  until MAX-DIFFERENCE( $U, U'$ )  $\leq \epsilon(1 - \gamma)/\gamma$ 
  return  $U$ 

```

**Figure 16.16** A high-level sketch of the value iteration algorithm for POMDPs. The REMOVE-DOMINATED-PLANS step and MAX-DIFFERENCE test are typically implemented as linear programs.

---

Given such a utility function, an executable policy can be extracted by looking at which hyperplane is optimal at any given belief state  $b$  and executing the first action of the corresponding plan. In Figure 16.15(d), the corresponding optimal policy is still the same as for depth-1 plans: *Stay* when  $b(B) > 0.5$  and *Go* otherwise.

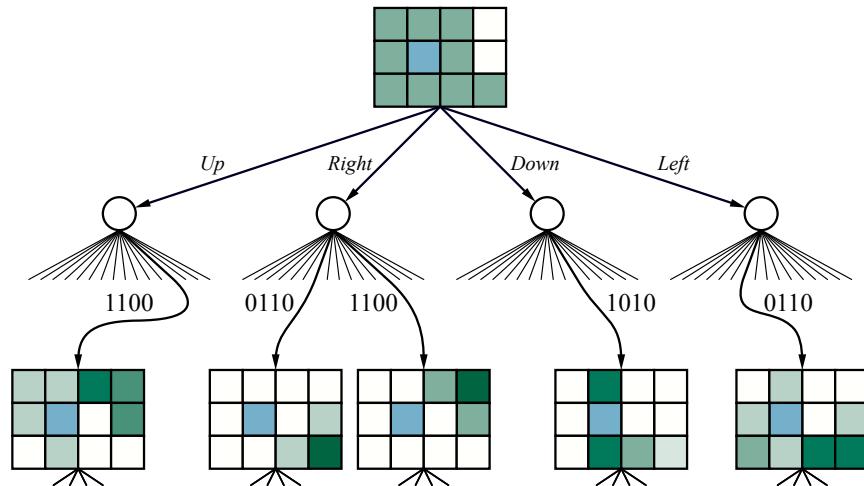

In practice, the value iteration algorithm in Figure 16.16 is hopelessly inefficient for larger problems—even the  $4 \times 3$  POMDP is too hard. The main reason is that given  $n$  undominated conditional plans at level  $d$ , the algorithm constructs  $|A| \cdot n^{|E|}$  conditional plans at level  $d + 1$  before eliminating the dominated ones. With the four-bit sensor,  $|E|$  is 16, and  $n$  can be in the hundreds, so this is hopeless.

Since this algorithm was developed in the 1970s, there have been several advances, including more efficient forms of value iteration and various kinds of policy iteration algorithms. Some of these are discussed in the notes at the end of the chapter. For general POMDPs, however, finding optimal policies is very difficult (PSPACE-hard, in fact—that is, very hard indeed). The next section describes a different, approximate method for solving POMDPs, one based on look-ahead search.

### 16.5.2 Online algorithms for POMDPs

The basic design for an online POMDP agent is straightforward: it starts with some prior belief state; it chooses an action based on some deliberation process centered on its current belief state; after acting, it receives an observation and updates its belief state using a filtering algorithm; and the process repeats.

One obvious choice for the deliberation process is the expectimax algorithm from Section 16.2.4, except with belief states rather than physical states as the decision nodes in the tree. The chance nodes in the POMDP tree have branches labeled by possible observations and leading to the next belief state, with transition probabilities given by Equation (16.17). A fragment of the belief-state expectimax tree for the  $4 \times 3$  POMDP is shown in Figure 16.17.

**Figure 16.17** Part of an expectimax tree for the  $4 \times 3$  POMDP with a uniform initial belief state. The belief states are depicted with shading proportional to the probability of being in each location.

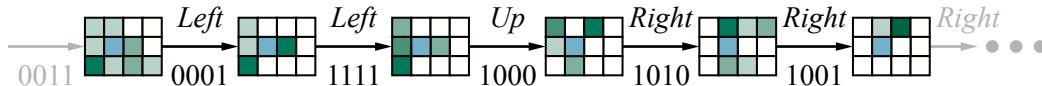

The time complexity of an exhaustive search to depth  $d$  is  $O(|A|^d \cdot |\mathbf{E}|^d)$ , where  $|A|$  is the number of available actions and  $|\mathbf{E}|$  is the number of possible percepts. (Notice that this is far less than the number of possible depth- $d$  conditional plans generated by value iteration.) As in the observable case, sampling at the chance nodes is a good way to cut down the branching factor without losing too much accuracy in the final decision. Thus, the complexity of approximate online decision making in POMDPs may not be drastically worse than that in MDPs.

For very large state spaces, exact filtering is infeasible, so the agent will need to run an approximate filtering algorithm such as particle filtering (see page 510). Then the belief states in the expectimax tree become collections of particles rather than exact probability distributions. For problems with long horizons, we may also need to run the kind of long-range playouts used in the UCT algorithm (Figure 6.11). The combination of particle filtering and UCT applied to POMDPs goes under the name of partially observable Monte Carlo planning or **POMCP**. With a DDN representation for the model, the POMCP algorithm is, at least in principle, applicable to very large and realistic POMDPs. Details of the algorithm are explored in Exercise 16.POMC. POMCP is capable of generating competent behavior in the  $4 \times 3$  POMDP. A short (and somewhat fortunate) example is shown in Figure 16.18.

POMCP

POMDP agents based on dynamic decision networks and online decision making have a number of advantages compared with other, simpler agent designs presented in earlier chapters. In particular, they handle partially observable, stochastic environments and can easily revise their “plans” to handle unexpected evidence. With appropriate sensor models, they can handle sensor failure and can plan to gather information. They exhibit “graceful degradation” under time pressure and in complex environments, using various approximation techniques.

So what is missing? The principal obstacle to real-world deployment of such agents is the inability to generate successful behavior over long time-scales. Random or near-random playouts have no hope of gaining any positive reward on, say, the task of laying the table

**Figure 16.18** A sequence of percepts, belief states, and actions in the  $4 \times 3$  POMDP with a wall-sensing error of  $\epsilon=0.2$ . Notice how the early *Left* moves are safe—they are very unlikely to fall into  $(4, 2)$ —and coerce the agent’s location into a small number of possible locations. After moving *Up*, the agent thinks it is probably in  $(3, 3)$ , but possibly in  $(1, 3)$ . Fortunately, moving *Right* is a good idea in both cases, so it moves *Right*, finds out that it had been in  $(1, 3)$  and is now in  $(2, 3)$ , and then continues moving *Right* and reaches the goal.

for dinner, which might take tens of millions of motor-control actions. It seems necessary to borrow some of the hierarchical planning ideas described in Section 11.4. At the time of writing, there are not yet satisfactory and efficient ways to apply these ideas in stochastic, partially observable environments.

## Summary

This chapter shows how to use knowledge about the world to make decisions even when the outcomes of an action are uncertain and the rewards for acting might not be reaped until many actions have passed. The main points are as follows:

- Sequential decision problems in stochastic environments, also called **Markov decision processes**, or MDPs, are defined by a **transition model** specifying the probabilistic outcomes of actions and a **reward function** specifying the reward in each state.
- The utility of a state sequence is the sum of all the rewards over the sequence, possibly discounted over time. The solution of an MDP is a **policy** that associates a decision with every state that the agent might reach. An optimal policy maximizes the utility of the state sequences encountered when it is executed.
- The utility of a state is the expected sum of rewards when an optimal policy is executed from that state. The **value iteration** algorithm iteratively solves a set of equations relating the utility of each state to those of its neighbors.
- **Policy iteration** alternates between calculating the utilities of states under the current policy and improving the current policy with respect to the current utilities.
- Partially observable MDPs, or POMDPs, are much more difficult to solve than are MDPs. They can be solved by conversion to an MDP in the continuous space of belief states; both value iteration and policy iteration algorithms have been devised. Optimal behavior in POMDPs includes information gathering to reduce uncertainty and therefore make better decisions in the future.
- A decision-theoretic agent can be constructed for POMDP environments. The agent uses a **dynamic decision network** to represent the transition and sensor models, to update its belief state, and to project forward possible action sequences.

We shall return MDPs and POMDPs in Chapter 23, which covers **reinforcement learning** methods that allow an agent to improve its behavior from experience.

## Bibliographical and Historical Notes

---

Richard Bellman developed the ideas underlying the modern approach to sequential decision problems while working at the RAND Corporation beginning in 1949. According to his autobiography (Bellman, 1984), he coined the term “dynamic programming” to hide from a research-phobic Secretary of Defense, Charles Wilson, the fact that his group was doing mathematics. (This cannot be strictly true, because his first paper using the term (Bellman, 1952) appeared before Wilson became Secretary of Defense in 1953.) Bellman’s book, *Dynamic Programming* (1957), gave the new field a solid foundation and introduced the value iteration algorithm.

Shapley (1953b) actually described the value iteration algorithm independently of Bellman, but his results were not widely appreciated in the operations research community, perhaps because they were presented in the more general context of Markov games. Although the original formulations included discounting, its analysis in terms of stationary preferences was suggested by Koopmans (1972). The shaping theorem is due to Ng *et al.* (1999).

Ron Howard’s Ph.D. thesis (1960) introduced policy iteration and the idea of average reward for solving infinite-horizon problems. Several additional results were introduced by Bellman and Dreyfus (1962). The use of contraction mappings in analyzing dynamic programming algorithms is due to Denardo (1967). Modified policy iteration is due to van Nunen (1976) and Puterman and Shin (1978). Asynchronous policy iteration was analyzed by Williams and Baird (1993), who also proved the policy loss bound in Equation (16.13). The general family of **prioritized sweeping** algorithms aims to speed up convergence to optimal policies by heuristically ordering the value and policy update calculations (Moore and Atkeson, 1993; Andre *et al.*, 1998; Wingate and Seppi, 2005).

The formulation of MDP-solving as a linear program is due to de Ghellinck (1960), Manne (1960), and D’Épenoux (1963). Although linear programming has traditionally been considered inferior to dynamic programming as an exact solution method for MDPs, de Farias and Roy (2003) show that it is possible to use linear programming and a linear representation of the utility function to obtain provably good approximate solutions to very large MDPs. Papadimitriou and Tsitsiklis (1987) and Littman *et al.* (1995) provide general results on the computational complexity of MDPs. Yinyu Ye (2011) analyzes the relationship between policy iteration and the simplex method for linear programming and proves that for fixed  $\gamma$ , the runtime of policy iteration is polynomial in the number of states and actions.

Seminal work by Sutton (1988) and Watkins (1989) on reinforcement learning methods for solving MDPs played a significant role in introducing MDPs into the AI community. (Earlier work by Werbos (1977) contained many similar ideas, but was not taken up to the same extent.) AI researchers have pushed MDPs in the direction of more expressive representations that can accommodate much larger problems than the traditional atomic representations based on transition matrices.

The basic ideas for an agent architecture using dynamic decision networks were proposed by Dean and Kanazawa (1989a). Tatman and Shachter (1990) showed how to apply dynamic programming algorithms to DDN models. Several authors made the connection between MDPs and AI planning problems, developing probabilistic forms of the compact STRIPS representation for transition models (Wellman, 1990b; Koenig, 1991). The book *Planning and Control* by Dean and Wellman (1991) explores the connection in great depth.

Later work on **factored MDPs** (Boutilier *et al.*, 2000; Koller and Parr, 2000; Guestrin *et al.*, 2003b) uses structured representations of the value function as well as the transition model, with provable improvements in complexity. **Relational MDPs** (Boutilier *et al.*, 2001; Guestrin *et al.*, 2003a) go one step further, using structured representations to handle domains with many related objects. Open-universe MDPs and POMDPs (Srivastava *et al.*, 2014b) also allow for uncertainty over the existence and identity of objects and actions.

Many authors have developed approximate online algorithms for decision making in MDPs, often borrowing explicitly from earlier AI approaches to real-time search and game-playing (Werbos, 1992; Dean *et al.*, 1993; Tash and Russell, 1994). The work of Barto *et al.* (1995) on RTDP (real-time dynamic programming) provided a general framework for understanding such algorithms and their connection to reinforcement learning and heuristic search. The analysis of depth-bounded expectimax with sampling at chance nodes is due to Kearns *et al.* (2002). The UCT algorithm described in the chapter is due to Kocsis and Szepesvari (2006) and borrows from earlier work on random playouts for estimating the values of states (Abramson, 1990; Brügmann, 1993; Chang *et al.*, 2005).

Bandit problems were introduced by Thompson (1933) but came to prominence after World War II through the work of Herbert Robbins (1952). Bradt *et al.* (1956) proved the first results concerning stopping rules for one-armed bandits, which led eventually to the breakthrough results of John Gittins (Gittins and Jones, 1974; Gittins, 1989). Katehakis and Veinott (1987) suggested the restart MDP as a method of computing Gittins indices. The text by Berry and Fristedt (1985) covers many variations on the basic problem, while the pellucid online text by Ferguson (2001) connects bandit problems with stopping problems.

Lai and Robbins (1985) initiated the study of the asymptotic regret of optimal bandit policies. The UCB heuristic was introduced and analyzed by Auer *et al.* (2002). Bandit superprocesses (BSPs) were first studied by Nash (1973) but have remained largely unknown in AI. Hadfield-Menell and Russell (2015) describe an efficient branch-and-bound algorithm capable of solving relatively large BSPs. Selection problems were introduced by Bechhofer (1954). Hay *et al.* (2012) developed a formal framework for metareasoning problems, showing that simple instances mapped to selection rather than bandit problems. They also proved the satisfying result that expected computation cost of the optimal computational strategy is never higher than the expected gain in decision quality—although there are cases where the optimal policy may, with some probability, keep computing long past the point where any possible gain has been used up.

The observation that a partially observable MDP can be transformed into a regular MDP over belief states is due to Astrom (1965) and Aoki (1965). The first complete algorithm for the exact solution of POMDPs—essentially the value iteration algorithm presented in this chapter—was proposed by Edward Sondik (1971) in his Ph.D. thesis. (A later journal paper by Smallwood and Sondik (1973) contains some errors, but is more accessible.) Lovejoy (1991) surveyed the first twenty-five years of POMDP research, reaching somewhat pessimistic conclusions about the feasibility of solving large problems.

The first significant contribution within AI was the Witness algorithm (Cassandra *et al.*, 1994; Kaelbling *et al.*, 1998), an improved version of POMDP value iteration. Other algorithms soon followed, including an approach due to Hansen (1998) that constructs a policy incrementally in the form of a finite-state automaton whose states define the possible belief states of the agent.

Factored MDP

Relational MDP

More recent work in AI has focused on **point-based** value iteration methods that, at each iteration, generate conditional plans and  $\alpha$ -vectors for a finite set of belief states rather than for the entire belief space. Lovejoy (1991) proposed such an algorithm for a fixed grid of points, an approach taken also by Bonet (2002). An influential paper by Pineau *et al.* (2003) suggested generating reachable points by simulating trajectories in a somewhat greedy fashion; Spaan and Vlassis (2005) observe that one need generate plans for only a small, randomly selected subset of points to improve on the plans from the previous iteration for all points in the set. Shani *et al.* (2013) survey these and other developments in point-based algorithms, which have led to good solutions for problems with thousands of states. Because POMDPs are PSPACE-hard (Papadimitriou and Tsitsiklis, 1987), further progress on offline solution methods may require taking advantage of various kinds of structure in value functions arising from a factored representation of the model.

The online approach for POMDPs—using look-ahead search to select an action for the current belief state—was first examined by Satia and Lave (1973). The use of sampling at chance nodes was explored analytically by Kearns *et al.* (2000) and Ng and Jordan (2000). The POMCP algorithm is due to Silver and Veness (2011).

With the development of reasonably effective approximation algorithms for POMDPs, their use as models for real-world problems has increased, particularly in education (Rafferty *et al.*, 2016), dialog systems (Young *et al.*, 2013), robotics (Hsiao *et al.*, 2007; Huynh and Roy, 2009), and self-driving cars (Forbes *et al.*, 1995; Bai *et al.*, 2015). An important large-scale application is the Airborne Collision Avoidance System X (ACAS X), which keeps airplanes and drones from colliding midair. The system uses POMDPs with neural networks to do function approximation. ACAS X significantly improves safety compared to the legacy TCAS system, which was built in the 1970s using expert system technology (Kochenderfer, 2015; Julian *et al.*, 2018).

Complex decision making has also been studied by economists and psychologists. They find that decision makers are not always rational, and may not be operating exactly as described by the models in this chapter. For example, when given a choice, a majority of people prefer \$100 today over a guarantee of \$200 in two years, but those same people prefer \$200 in eight years over \$100 in six years. One way to interpret this result is that people are not using additive exponentially discounted rewards; perhaps they are using **hyperbolic rewards** (the hyperbolic function dips more steeply in the near term than does the exponential decay function). This and other possible interpretations are discussed by Rubinstein (2003).

#### Hyperbolic reward

The texts by Bertsekas (1987) and Puterman (1994) provide rigorous introductions to sequential decision problems and dynamic programming. Bertsekas and Tsitsiklis (1996) include coverage of reinforcement learning. Sutton and Barto (2018) cover similar ground but in a more accessible style. Sigaud and Buffet (2010), Mausam and Kolobov (2012) and Kochenderfer (2015) cover sequential decision making from an AI perspective. Krishnamurthy (2016) provides thorough coverage of POMDPs.

# CHAPTER 17

## MULTIAGENT DECISION MAKING

*In which we examine what to do when more than one agent inhabits the environment.*

### 17.1 Properties of Multiagent Environments

So far, we have largely assumed that only one agent has been doing the sensing, planning, and acting. But this represents a huge simplifying assumption, which fails to capture many real-world AI settings. In this chapter, therefore, we will consider the issues that arise when an agent must make decisions in environments that contain multiple actors. Such environments are called **multiagent systems**, and agents in such a system face a **multiagent planning problem**. However, as we will see, the precise nature of the multiagent planning problem—and the techniques that are appropriate for solving it—will depend on the relationships among the agents in the environment.

Multiagent systems  
Multiagent planning problem

#### 17.1.1 One decision maker

The first possibility is that while the environment contains multiple *actors*, it contains only one *decision maker*. In such a case, the decision maker develops plans for the other agents, and tells them what to do. The assumption that agents will simply do what they are told is called the **benevolent agent assumption**. However, even in this setting, plans involving multiple actors will require actors to *synchronize* their actions. Actors *A* and *B* will have to act at the same time for joint actions (such as singing a duet), at different times for mutually exclusive actions (such as recharging batteries when there is only one plug), and sequentially when one establishes a precondition for the other (such as *A* washing the dishes and then *B* drying them).

Benevolent agent assumption

One special case is where we have a single decision maker with multiple effectors that can operate concurrently—for example, a human who can walk and talk at the same time. Such an agent needs to do **multieffector planning** to manage each effector while handling positive and negative interactions among the effectors. When the effectors are physically decoupled into detached units—as in a fleet of delivery robots in a factory—multieffector planning becomes **multibody planning**.

Multieffector planning

A multibody problem is still a “standard” single-agent problem as long as the relevant sensor information collected by each body can be pooled—either centrally or within each body—to form a common estimate of the world state that then informs the execution of the overall plan; in this case, the multiple bodies can be thought of as acting as a single body. When communication constraints make this impossible, we have what is sometimes called a **decentralized planning** problem; this is perhaps a misnomer, because the planning phase is centralized but the execution phase is at least partially decoupled. In this case,

Decentralized planning

subplan constructed for each body may need to include explicit communicative actions with other bodies. For example, multiple reconnaissance robots covering a wide area may often be out of radio contact with each other and should share their findings during times when communication is feasible.

### 17.1.2 Multiple decision makers

The second possibility is that the other actors in the environment are also decision makers: they each have preferences and choose and execute their own plan. We call them **counterparts**. In this case, we can distinguish two further possibilities.

Counterparts

Common goal

Coordination problem

Game theory

Strategic decision making

Agent design

Mechanism design

- The first is that, although there are multiple decision makers, they are all pursuing a **common goal**. This is roughly the situation of workers in a company, in which different decision makers are pursuing, one hopes, the same goals on behalf of the company. The main problem faced by the decision makers in this setting is the **coordination problem**: they need to ensure that they are all pulling in the same direction, and not accidentally fouling up each other's plans.
- The second possibility is that the decision makers each have their own personal preferences, which they each will pursue to the best of their abilities. It could be that the preferences are diametrically opposed, as is the case in zero-sum games such as chess (see Chapter 6). But most multiagent encounters are more complicated than that, with more complex preferences.

When there are multiple decision makers, each pursuing their own preferences, an agent must take into account the preferences of other agents, as well as the fact that these other agents are *also* taking into account the preferences of other agents, and so on. This brings us into the realm of **game theory**: the theory of strategic decision making. It is this *strategic* aspect of reasoning—players each taking into account how other players may act—that distinguishes game theory from decision theory. In the same way that decision theory provides the theoretical foundation for decision making in single-agent AI, game theory provides the theoretical foundation for decision making in multiagent systems.

The use of the word “game” here is also not ideal: a natural inference is that game theory is mainly concerned with recreational pursuits, or artificial scenarios. Nothing could be further from the truth. Game theory is the theory of **strategic decision making**. It is used in decision making situations including the auctioning of oil drilling rights and wireless frequency spectrum rights, bankruptcy proceedings, product development and pricing decisions, and national defense—situations involving billions of dollars and many lives. Game theory in AI can be used in two main ways:

1. **Agent design:** Game theory can be used by an agent to analyze its possible decisions and compute the expected utility for each of these (under the assumption that other agents are acting rationally, according to game theory). In this way, game-theoretic techniques can determine the best strategy against a rational player and the expected return for each player.
2. **Mechanism design:** When an environment is inhabited by many agents, it might be possible to define the rules of the environment (i.e., the game that the agents must play) so that the collective good of all agents is maximized when each agent adopts the game-theoretic solution that maximizes its own utility. For example, game theory can

help design the protocols for a collection of Internet traffic routers so that each router has an incentive to act in such a way that global throughput is maximized. Mechanism design can also be used to construct intelligent multiagent systems that solve complex problems in a distributed fashion.

Game theory provides a range of different models, each with its own set of underlying assumptions; it is important to choose the right model for each setting. The most important distinction is whether we should consider it a cooperative game or not:

- In a **cooperative game**, it is possible to have a binding agreement between agents, thereby enabling robust cooperation. In the human world, legal contracts and social norms help establish such binding agreements. In the world of computer programs, it may be possible to inspect source code to make sure it will follow an agreement. We use cooperative game theory to analyze this situation. Cooperative game
- If binding agreements are not possible, we have a **non-cooperative game**. Although this term suggests that the game is inherently competitive, and that cooperation is not possible, that need not be the case: non-cooperative simply means that there is no central agreement that binds all agents and guarantees cooperation. But it could well be that agents independently decide to cooperate, because it is in their own best interests. We use non-cooperative game theory to analyze this situation. Non-cooperative game

Some environments will combine multiple different dimensions. For example, a package delivery company may do centralized, offline planning for the routes of its trucks and planes each day, but leave some aspects open for autonomous decisions by drivers and pilots who can respond individually to traffic and weather situations. Also, the goals of the company and its employees are brought into alignment, to some extent, by the payment of **incentives** Incentive (salaries and bonuses)—a sure sign that this is a true multiagent system.

### 17.1.3 Multiagent planning

For the time being, we will treat the multieffector, multibody, and multiagent settings in the same way, labeling them generically as **multiactor** settings, using the generic term **actor** to cover effectors, bodies, and agents. The goal of this section is to work out how to define transition models, correct plans, and efficient planning algorithms for the multiactor setting. A correct plan is one that, if executed by the actors, achieves the goal. (In the true multiagent setting, of course, the agents may not agree to execute any particular plan, but at least they will know what plans *would* work if they *did* agree to execute them.) Multiactor  
Actor

A key difficulty in attempting to come up with a satisfactory model of multiagent action is that we must somehow deal with the thorny issue of **concurrency**, by which we simply mean that the plans of each agent may be executed simultaneously. If we are to reason about the execution of multiactor plans, then we will first need a model of multiactor plans that embodies a satisfactory model of concurrent action. Concurrency

In addition, multiactor action raises a whole set of issues that are not a concern in single-agent planning. In particular, *agents must take into account the way in which their own actions interact with the actions of other agents*. For example, an agent will need to consider whether the actions performed by other agents might clobber the preconditions of its own actions, whether the resources it makes use of while executing its policy are sharable, or may

be depleted by other agents; whether actions are mutually exclusive; and a helpfully inclined agent could consider how its actions might facilitate the actions of others.

To answer these questions we need a model of concurrent action within which we can properly formulate them. Models of concurrent action have been a major focus of research in the mainstream computer science community for decades, but no definitive, universally accepted model has prevailed. Nevertheless, the following three approaches have become widely established.

#### Interleaved execution

The first approach is to consider the **interleaved execution** of the actions in respective plans. For example, suppose we have two agents,  $A$  and  $B$ , with plans as follows:

$$\begin{aligned} A &: [a_1, a_2] \\ B &: [b_1, b_2]. \end{aligned}$$

The key idea of the interleaved execution model is that the only thing we can be certain about in the execution of the two agents' plans is that the order of actions in the respective plans will be preserved. If we further assume that actions are atomic, then there are six different ways in which the two plans above might be executed concurrently:

$$\begin{aligned} &[a_1, a_2, b_1, b_2] \\ &[b_1, b_2, a_1, a_2] \\ &[a_1, b_1, a_2, b_2] \\ &[b_1, a_1, b_2, a_2] \\ &[a_1, b_1, b_2, a_2] \\ &[b_1, a_1, a_2, b_2] \end{aligned}$$

- ▶ For a plan to be correct in the interleaved execution model, *it must be correct with respect to all possible interleavings of the plans*. The interleaved execution model has been widely adopted within the concurrency community, because it is a reasonable model of the way multiple threads take turns running on a single CPU. However, it does not model the case where two actions actually happen at the same time. Furthermore, the number of interleaved sequences will grow exponentially with the number of agents and actions: as a consequence, checking the correctness of a plan, which is computationally straightforward in single-agent settings, is computationally difficult with the interleaved execution model.

#### True concurrency

The second approach is **true concurrency**, in which we do not attempt to create a full serialized ordering of the actions, but leave them *partially ordered*: we know that  $a_1$  will occur before  $a_2$ , but with respect to the ordering of  $a_1$  and  $b_1$ , for example, we can say nothing; one may occur before the other, or they could occur concurrently. We can always “flatten” a partial-order model of concurrent plans into an interleaved model, but in doing so, we lose the partial-order information. While partial-order models are arguably more satisfying than interleaved models as a theoretical account of concurrent action, they have not been as widely adopted in practice.

#### Synchronization

The third approach is to assume perfect **synchronization**: there is a global clock that each agent has access to, each action takes the same amount of time, and actions at each point in the joint plan are simultaneous. Thus, the actions of each agent are executed synchronously, in lockstep with each other (it may be that some agents execute a no-op action when they are waiting for other actions to complete). Synchronous execution is not a very complete model of concurrency in the real world, but it has a simple semantics, and for this reason, it is the model we will work with here.

---

```

Actors(A, B)
Init(At(A, LeftBaseline)  $\wedge$  At(B, RightNet)  $\wedge$ 
Approaching(Ball, RightBaseline)  $\wedge$  Partner(A, B)  $\wedge$  Partner(B, A))
Goal(Returned(Ball)  $\wedge$  (At(x, RightNet)  $\vee$  At(x, LeftNet)))
Action(Hit(actor, Ball),
    PRECOND:Approaching(Ball, loc)  $\wedge$  At(actor, loc)
    EFFECT:Returned(Ball))
Action(Go(actor, to),
    PRECOND:At(actor, loc)  $\wedge$  to  $\neq$  loc,
    EFFECT:At(actor, to)  $\wedge$   $\neg$  At(actor, loc))

```

**Figure 17.1** The doubles tennis problem. Two actors,  $A$  and  $B$ , are playing together and can be in one of four locations: *LeftBaseline*, *RightBaseline*, *LeftNet*, and *RightNet*. The ball can be returned only if a player is in the right place. The *NoOp* action is a dummy, which has no effect. Note that each action must include the actor as an argument.

---

We begin with the transition model; for the single-agent deterministic case, this is the function  $\text{RESULT}(s, a)$ , which gives the state that results from performing the action  $a$  when the environment is in state  $s$ . In the single-agent setting, there might be  $b$  different choices for the action;  $b$  can be quite large, especially for first-order representations with many objects to act on, but action schemas provide a concise representation nonetheless.

In the multiactor setting with  $n$  actors, the single action  $a$  is replaced by a **joint action**  $\langle a_1, \dots, a_n \rangle$ , where  $a_i$  is the action taken by the  $i$ th actor. Immediately, we see two problems: first, we have to describe the transition model for  $b^n$  different joint actions; second, we have a joint planning problem with a branching factor of  $b^n$ .

Having put the actors together into a multiactor system with a huge branching factor, the principal focus of research on multiactor planning has been to *decouple* the actors to the extent possible, so that (ideally) the complexity of the problem grows linearly with  $n$  rather than exponentially with  $b^n$ .

If the actors have no interaction with one another—for example,  $n$  actors each playing a game of solitaire—then we can simply solve  $n$  separate problems. If the actors are **loosely coupled**, can we attain something close to this exponential improvement? This is, of course, a central question in many areas of AI. We have seen successful solution methods for loosely coupled systems in the context of CSPs, where “tree like” constraint graphs yielded efficient solution methods (see page 186), as well as in the context of disjoint pattern databases (page 119) and additive heuristics for planning (page 374).

The standard approach to loosely coupled problems is to pretend the problems are completely decoupled and then fix up the interactions. For the transition model, this means writing action schemas as if the actors acted independently.

Let’s see how this works for a game of doubles tennis. Here, we have two human tennis players who form a doubles team with the common goal of winning the match against an opponent team. Let’s suppose that at one point in the game, the team has the goal of returning the ball that has been hit to them and ensuring that at least one of them is covering the net. Figure 17.1 shows the initial conditions, goal, and action schemas for this problem. It is easy to see that we can get from the initial conditions to the goal with a two-step **joint plan** that

Joint action

Loosely coupled

Joint plan

specifies what each player has to do:  $A$  should move over to the right baseline and hit the ball, while  $B$  should just stay put at the net:

PLAN 1:       $A : [Go(A, RightBaseline), Hit(A, Ball)]$   
 $B : [NoOp(B), NoOp(B)]$ .

Problems arise, however, when a plan dictates that both agents hit the ball at the same time. In the real world, this won't work, but the action schema for *Hit* says that the ball will be returned successfully. The difficulty is that preconditions constrain the state in which an action by itself can be executed successfully, but do not constrain other concurrent actions that might mess it up.

Concurrent action constraint

We solve this problem by augmenting action schemas with one new feature: a **concurrent action constraint** stating which actions must or must not be executed concurrently. For example, the *Hit* action could be described as follows:

*Action(Hit(actor, Ball)),*  
**CONCURRENT:**  $\forall b \ b \neq actor \Rightarrow \neg Hit(b, Ball)$   
**PRECOND:**  $Approaching(Ball, loc) \wedge At(actor, loc)$   
**EFFECT:**  $Returned(Ball)$ .

In other words, the *Hit* action has its stated effect only if no other *Hit* action by another agent occurs at the same time. (In the SATPLAN approach, this would be handled by a partial **action exclusion axiom**.) For some actions, the desired effect is achieved *only* when another action occurs concurrently. For example, two agents are needed to carry a cooler full of beverages to the tennis court:

*Action(Carry(actor, cooler, here, there)),*  
**CONCURRENT:**  $\exists b \ b \neq actor \wedge Carry(b, cooler, here, there)$   
**PRECOND:**  $At(actor, here) \wedge At(cooler, here) \wedge Cooler(cooler)$   
**EFFECT:**  $At(actor, there) \wedge At(cooler, there) \wedge \neg At(actor, here) \wedge \neg At(cooler, here)$ .

With these kinds of action schemas, any of the planning algorithms described in Chapter 11 can be adapted with only minor modifications to generate multiactor plans. To the extent that the coupling among subplans is loose—meaning that concurrency constraints come into play only rarely during plan search—one would expect the various heuristics derived for single-agent planning to also be effective in the multiactor context.

### 17.1.4 Planning with multiple agents: Cooperation and coordination

Now let us consider a true multiagent setting in which each agent makes its own plan. To start with, let us assume that the goals and knowledge base are shared. One might think that this reduces to the multibody case—each agent simply computes the joint solution and executes its own part of that solution. Alas, the “the” in “the joint solution” is misleading. Here is a second plan that also achieves the goal:

PLAN 2:       $A : [Go(A, LeftNet), NoOp(A)]$   
 $B : [Go(B, RightBaseline), Hit(B, Ball)]$ .

If both agents can agree on either plan 1 or plan 2, the goal will be achieved. But if  $A$  chooses plan 2 and  $B$  chooses plan 1, then nobody will return the ball. Conversely, if  $A$  chooses 1 and  $B$  chooses 2, then they will both try to hit the ball and that too will fail. The agents know this, but how can they coordinate to make sure they agree on the plan?

One option is to adopt a **convention** before engaging in joint activity. A convention is any constraint on the selection of joint plans. For example, the convention “stick to your side of the court” would rule out plan 1, causing both partners to select plan 2. Drivers on a road face the problem of not colliding with each other; this is (partially) solved by adopting the convention “stay on the right-hand side of the road” in most countries; the alternative, “stay on the left-hand side,” works equally well as long as all agents in an environment agree. Similar considerations apply to the development of human language, where the important thing is not which language each individual should speak, but the fact that a community all speaks the same language. When conventions are widespread, they are called **social laws**.

Convention

Social law

In the absence of a convention, agents can use **communication** to achieve common knowledge of a feasible joint plan. For example, a tennis player could shout “Mine!” or “Yours!” to indicate a preferred joint plan. Communication does not necessarily involve a verbal exchange. For example, one player can communicate a preferred joint plan to the other simply by executing the first part of it. If agent *A* heads for the net, then agent *B* is obliged to go back to the baseline to hit the ball, because plan 2 is the only joint plan that begins with *A*’s heading for the net. This approach to coordination, sometimes called **plan recognition**, works when a single action (or short sequence of actions) by one agent is enough for the other to determine a joint plan unambiguously.

Plan recognition

## 17.2 Non-Cooperative Game Theory

We will now introduce the key concepts and analytical techniques of game theory—the theory that underpins decision making in multiagent environments. Our tour will start with non-cooperative game theory.

### 17.2.1 Games with a single move: Normal form games

The first game model we will look at is one in which all players take action simultaneously and the result of the game is based on the profile of actions that are selected in this way. (Actually, it is not crucial that the actions take place at the same time; what matters is that no player has knowledge of the other players’ choices.) These games are called **normal form games**. A normal form game is defined by three components:

Normal form game

Player

- **Players** or agents who will be making decisions. Two-player games have received the most attention, although  $n$ -player games for  $n > 2$  are also common. We give players capitalized names, like *Ali* and *Bo* or *O* and *E*.
- **Actions** that the players can choose. We will give actions lowercase names, like *one* or *testify*. The players may or may not have the same set of actions available.
- A **payoff function** that gives the utility to each player for each combination of actions by all the players. For two-player games, the payoff function for a player can be represented by a matrix in which there is a row for each possible action of one player, and a column for each possible choice of the other player: a chosen row and a chosen column define a matrix cell, which is labeled with the payoff for the relevant player. In the two-player case, it is conventional to combine the two matrices into a single **payoff matrix**, in which each cell is labeled with payoffs for both players.

Payoff function

Payoff matrix

To illustrate these ideas, let’s look at an example game, called **two-finger Morra**. In this game, two players, *O* and *E*, simultaneously display one or two fingers. Let the total number

of fingers displayed be  $f$ . If  $f$  is odd,  $O$  collects  $f$  dollars from  $E$ ; and if  $f$  is even,  $E$  collects  $f$  dollars from  $O$ .<sup>1</sup> The payoff matrix for two-finger Morra is as follows:

	$O: \text{one}$	$O: \text{two}$
$E: \text{one}$	$E = +2, O = -2$	$E = -3, O = +3$
$E: \text{two}$	$E = -3, O = +3$	$E = +4, O = -4$

Row player

Column player

Solution concept

Strategy

Pure strategy

Mixed strategy

Strategy profile

Prisoner's dilemma

We say that  $E$  is the **row player** and  $O$  is the **column player**. So, for example, the lower-right corner shows that when player  $O$  chooses action *two* and  $E$  also chooses *two*, the payoff is  $+4$  for  $E$  and  $-4$  for  $O$ .

Before analyzing two-finger Morra, it is worth considering why game-theoretic ideas are needed at all: why can't we tackle the challenge facing (say) player  $E$  using the apparatus of decision theory and utility maximization that we've been using elsewhere in the book? To see why something else is needed, let's suppose  $E$  is trying to find the best action to perform. The alternatives are *one* or *two*. If  $E$  chooses *one*, then the payoff will be either  $+2$  or  $-3$ . Which payoff  $E$  will *actually* receive, however, will depend on the choice made by  $O$ : the most that  $E$  can do, as the row player, is to force the outcome of the game to be in a particular row. Similarly,  $O$  chooses only the column.

To choose optimally between these possibilities,  $E$  must take into account how  $O$  will act as a rational decision maker. But  $O$ , in turn, should take into account the fact that  $E$  is a rational decision maker. Thus, decision making in multiagent settings is quite different in character to decision making in single-agent settings, because the players need to take each other's reasoning into account. The role of **solution concepts** in game theory is to try to make this kind of reasoning precise.

The term **strategy** is used in game theory to denote what we have previously called a *policy*. A **pure strategy** is a deterministic policy; for a single-move game, a pure strategy is just a single action. As we will see below, for many games an agent can do better with a **mixed strategy**, which is a randomized policy that selects actions according to a probability distribution. The mixed strategy that chooses action  $a$  with probability  $p$  and action  $b$  otherwise is written  $[p:a;(1-p):b]$ . For example, a mixed strategy for two-finger Morra might be  $[0.5:\text{one}; 0.5:\text{two}]$ . A **strategy profile** is an assignment of a strategy to each player; given the strategy profile, the game's **outcome** is a numeric value for each player—if players use mixed strategies, then we must use expected utility.

So, how should agents decide act in games like Morra? Game theory provides a range of solution concepts that attempt to define rational action with respect to an agent's beliefs about the other agent's beliefs. Unfortunately, there is no one perfect solution concept: it is problematic to define what “rational” means when each agent chooses only part of the strategy profile that determines the outcome.

We introduce our first solution concept through what is probably the most famous game in the game theory canon—the **prisoner's dilemma**. This game is motivated by the following story: Two alleged burglars, Ali and Bo, are caught red-handed near the scene of a burglary and are interrogated separately. A prosecutor offers each a deal: if you testify against your partner as the leader of a burglary ring, you'll go free for being the cooperative one, while

<sup>1</sup> Morra is a recreational version of an **inspection game**. In such games, an inspector chooses a day to inspect a facility (such as a restaurant or a biological weapons plant), and the facility operator chooses a day to hide all the nasty stuff. The inspector wins if the days are different, and the facility operator wins if they are the same.

your partner will serve 10 years in prison. However, if you both testify against each other, you'll both get 5 years. Ali and Bo also know that if both refuse to testify they will serve only 1 year each for the lesser charge of possessing stolen property. Now Ali and Bo face the so-called prisoner's dilemma: should they testify or refuse? Being rational agents, Ali and Bo each want to maximize their own expected utility, which means minimizing the number of years in prison—each is indifferent about the welfare of the other player. The prisoner's dilemma is captured in the following payoff matrix:

	<i>Ali:testify</i>	<i>Ali:refuse</i>
<i>Bo:testify</i>	$A = -5, B = -5$	$A = -10, B = 0$
<i>Bo:refuse</i>	$A = 0, B = -10$	$A = -1, B = -1$

Now, put yourself in Ali's place. She can analyze the payoff matrix as follows:

- Suppose Bo plays *testify*. Then I get 5 years if I testify and 10 years if I don't, so in that case testifying is better.
- On the other hand, if Bo plays *refuse*, then I go free if I testify and I get 1 year if I refuse, so testifying is also better in that case.
- So *no matter what Bo chooses to do*, it would be better for me to testify.

Ali has discovered that *testify* is a **dominant strategy** for the game. We say that a strategy  $s$  for player  $p$  **strongly dominates** strategy  $s'$  if the outcome for  $s$  is better for  $p$  than the outcome for  $s'$ , for every choice of strategies by the other player(s). Strategy  $s$  **weakly dominates**  $s'$  if  $s$  is better than  $s'$  on at least one strategy profile and no worse on any other. A dominant strategy is a strategy that dominates all others. A common assumption in game theory is that *a rational player will always choose a dominant strategy and avoid a dominated strategy*. Being rational—or at least not wishing to be thought irrational—Ali chooses the dominant strategy.

It is not hard to see that Bo's reasoning will be identical: he will also conclude that *testify* is a dominant strategy for him, and will choose to play it. The solution of the game, according to dominant strategy analysis, will be that both players choose *testify*, and as a consequence both will serve 5 years in prison.

In a situation like this, where all players choose a dominant strategy, then the outcome that results is said to be a **dominant strategy equilibrium**. It is an “equilibrium” because no player has any incentive to deviate from their part of it: by definition, if they did so, they could not do better, and may do worse. In this sense, dominant strategy equilibrium is a very strong solution concept.

Going back to the prisoner's dilemma, we can see that the *dilemma* is that the dominant strategy equilibrium outcome in which both players *testify* is worse for both players than the outcome they would get if they both refused to testify. The (*refuse, refuse*) outcome would give both players just one year in prison, which would be better for *both* of them than the 5 years that each would serve if they chose the dominant strategy equilibrium.

Is there any way for Ali and Bo to arrive at the (*refuse, refuse*) outcome? It is certainly an *allowable* option for both of them to refuse to testify, but it is hard to see how rational agents could make this choice, given the way the game is set up. Remember, this is a non-cooperative game: they aren't allowed to talk to each other, so they cannot make a binding agreement to *refuse*.

Dominant strategy

Strong domination

Weak domination

Dominant strategy equilibrium

It is, however, possible to get to the *(refuse, refuse)* solution if we change the game. We could change it to a cooperative game where the agents are allowed to form a binding agreement. Or we could change to a **repeated game** in which the players know that they will meet again—we will see how this works below. Alternatively, the players might have moral beliefs that encourage cooperation and fairness. But that would mean they have different utility functions, and again, they would be playing a different game.

#### Best response

The presence of a dominant strategy for a particular player greatly simplifies the decision making process for that player. Once Ali has realized that testifying is a dominant strategy, she doesn't need to invest any effort in trying to figure out what Bo will do, because she knows that *no matter what Bo does*, testifying would be her **best response**. However, most games have neither dominant strategies nor dominant strategy equilibria. It is rare that a single strategy is the best response to all possible counterpart strategies.

#### Nash equilibrium

The next solution concept we consider is weaker than dominant strategy equilibrium, but it is much more widely applicable. It is called **Nash equilibrium**, and is named for John Forbes Nash, Jr. (1928–2015), who studied it in his 1950 Ph.D. thesis—work for which he was awarded a Nobel Prize in 1994.

A strategy profile is a Nash equilibrium if no player could unilaterally change their strategy and as a consequence receive a higher payoff, under the assumption that the other players stayed with their strategy choices. Thus, in a Nash equilibrium, every player is simultaneously playing a best response to the choices of their counterparts. A Nash equilibrium represents a stable point in a game: stable in the sense that there is no rational incentive for any player to deviate. However, Nash equilibria are *local* stable points: as we will see, a game may contain multiple Nash equilibria.

Since a dominant strategy is a best response to *all* counterpart strategies, it follows that any dominant strategy equilibrium must also be a Nash equilibrium (Exercise 17.EQIB). In the prisoner's dilemma, therefore, there is a unique dominant strategy equilibrium, which is also the unique Nash equilibrium.

The following example game demonstrates, first, that sometimes games have no dominant strategies, and second, that some games have multiple Nash equilibria.

	<i>Ali:l</i>	<i>Ali:r</i>
<i>Bo:t</i>	$A = 10, B = 10$	$A = 0, B = 0$
<i>Bo:b</i>	$A = 0, B = 0$	$A = 1, B = 1$

It is easy to verify that there are no dominant strategies in this game, for either player, and hence no dominant strategy equilibrium. However, the strategy profiles  $(t, l)$  and  $(b, r)$  are both Nash equilibria. Now, clearly it is in the interests of both agents to aim for the *same* Nash equilibrium—either  $(t, l)$  or  $(b, r)$ —but since we are in the domain of *non-cooperative* game theory, players must make their choices independently, without any knowledge of the choices of the others, and without any way of making an agreement with them. This is an example of a **coordination problem**: the players want to coordinate their actions globally, so that they both choose actions leading to the same equilibrium, but must do so using only local decision making.

#### Focal point

A number of approaches to resolving coordination problems have been proposed. One idea is that of **focal points**. A focal point in a game is an outcome that in some way stands out to players as being an “obvious” outcome upon which to coordinate their choices. This

is of course not a precise definition—what it means will depend on the game at hand. In the example above, though, there is one obvious focal point: the outcome  $(t, l)$  would give both players substantially higher utility than they would obtain if they coordinated on  $(b, r)$ . From the point of view of game theory, both outcomes are Nash equilibria—but it would be a perverse player indeed who expected to coordinate on  $(b, r)$ .

Some games have no Nash equilibria in pure strategies, as the following game, called **matching pennies**, illustrates. In this game, Ali and Bo simultaneously choose one side of a coin, either heads or tails: if they make the same choices, then Bo gives Ali \$1, while if they make different choices, then Ali gives Bo \$1:

Matching pennies

	<i>Ali:heads</i>	<i>Ali:tails</i>
<i>Bo:heads</i>	$A = 1, B = -1$	$A = -1, B = 1$
<i>Bo:tails</i>	$A = -1, B = 1$	$A = 1, B = -1$

We invite the reader to check that the game contains no dominant strategies, and that no outcome is a Nash equilibrium in pure strategies: in every outcome, one player regrets their choice, and would rather have chosen differently, given the choice of the other player.

To find a Nash equilibrium, the trick is to use mixed strategies—to allow players to randomize over their choices. Nash proved that *every game has at least one Nash equilibrium in mixed strategies*. This explains why Nash equilibrium is such an important solution concept: other solution concepts, such as dominant strategy equilibrium, are not guaranteed to exist for every game, but we always get a solution if we look for Nash equilibria with mixed strategies.

In the case of matching pennies, we have a Nash equilibrium in mixed strategies if both players choose *heads* and *tails* with equal probability. To see that this outcome is indeed a Nash equilibrium, suppose one of the players chose an outcome with a probability other than 0.5. Then the other player would be able to exploit that, putting all their weight behind a particular strategy. For example, suppose Bo played *heads* with probability 0.6 (and so *tails* with probability 0.4). Then Ali would do best to play *heads* with certainty. It is then easy to see that Bo playing *heads* with probability 0.6 could not form part of any Nash equilibrium.

### 17.2.2 Social welfare

The main perspective in game theory is that of players within the game, trying to obtain the best outcomes for themselves that they can. However, it is sometimes instructive to adopt a different perspective. Suppose you were a benevolent, omniscient entity looking down on the game, and you were able to *choose* the outcome. Being benevolent, you want to choose the best overall outcome—the outcome that would be best for *society as a whole*, so to speak. How should you choose? What criteria might you apply? This is where the notion of **social welfare** comes in.

Social welfare

Probably the most important and least contentious social welfare criterion is that you should avoid outcomes that *waste* utility. This requirement is captured in the concept of **Pareto optimality**, which is named for the Italian economist Vilfredo Pareto (1848–1923). An outcome is Pareto optimal if there is no other outcome that would make one player better off without making someone else worse off. If you choose an outcome that is not Pareto optimal, then it wastes utility in the sense that you could have given more utility to at least one agent, without taking any from other agents.

Pareto optimality

**Utilitarian social welfare** is a measure of how good an outcome is in the aggregate. The utilitarian social welfare of an outcome is simply the sum of utilities given to players by that

Utilitarian social welfare

outcome. There are two key difficulties with utilitarian social welfare. The first is that it considers the sum but not the *distribution* of utilities among players, so it could lead to a very unequal distribution if that happens to maximize the sum. The second difficulty is that it assumes a *common scale* for utilities. Many economists argue that this is impossible to establish because utility (unlikely money) is a subjective quantity. If we're trying to decide how to divide up a batch of cookies, should we give them all to the utility monster who says, "I love cookies a thousand times more than anyone else?" That would maximize the total self-reported utility, but doesn't seem right.

Egalitarian social welfare

Gini coefficient

The question of how utility is distributed among players is addressed by research in **egalitarian social welfare**. For example, one proposal suggests that we should maximize the expected utility of the worst-off member of society—a maximin approach. Other metrics are possible, including the **Gini coefficient**, which summarizes how evenly utility is spread among the players. The main difficulties with such proposals is that they may sacrifice a great deal of total welfare for small distributional gains, and, like plain utilitarianism, they are still at the mercy of the utility monster.

Applying these concepts to the prisoner's dilemma game, introduced above, explains why it is called a dilemma. Recall that  $(\text{testify}, \text{testify})$  is a dominant strategy equilibrium, and the only Nash equilibrium. However, this is the only outcome that is *not* Pareto optimal. The outcome  $(\text{refuse}, \text{refuse})$  maximizes both utilitarian and egalitarian social welfare. The dilemma in the prisoner's dilemma thus arises because a very strong solution concept (dominant strategy equilibrium) leads to an outcome that essentially fails every test of what counts as a reasonable outcome from the point of view of the "society." Yet there is no clear way for the individual players to arrive at a better solution.

### Computing equilibria

Let's now consider the key computational questions associated with the concepts discussed above. First we will consider pure strategies, where randomization is not permitted.

If players have only a finite number of possible choices, then exhaustive search can be used to find equilibria: iterate through each possible strategy profile, and check whether any player has a beneficial deviation from that profile; if not, then it is a Nash equilibrium in pure strategies. Dominant strategies and dominant strategy equilibria can be computed by similar algorithms. Unfortunately, the number of possible strategy profiles for  $n$  players each with  $m$  possible actions, is  $m^n$ , i.e., infeasibly large for an exhaustive search.

Myopic best response

An alternative approach, which works well in some games, is **myopic best response** (also known as **iterated best response**): start by choosing a strategy profile at random; then, if some player is not playing their optimal choice given the choices of others, flip their choice to an optimal one, and repeat the process. The process will converge if it leads to a strategy profile in which every player is making an optimal choice, given the choices of the others—a Nash equilibrium, in other words. For some games, myopic best response does not converge, but for some important classes of games, it is guaranteed to converge.

Computing mixed-strategy equilibria is algorithmically much more intricate. To keep things simple, we will focus on methods for zero-sum games and comment briefly on their extension to other games at the end of this section.

Zero-sum game

In 1928, von Neumann developed a method for finding the *optimal* mixed strategy for two-player, **zero-sum games**—games in which the payoffs always add up to zero (or a con-

stant, as explained on page 193). Clearly, Morra is such a game. For two-player, zero-sum games, we know that the payoffs are equal and opposite, so we need consider the payoffs of only one player, who will be the maximizer (just as in Chapter 6). For Morra, we pick the even player  $E$  to be the maximizer, so we can define the payoff matrix by the values  $U_E(e, o)$ —the payoff to  $E$  if  $E$  does  $e$  and  $O$  does  $o$ . (For convenience we call player  $E$  “her” and  $O$  “him.”) Von Neumann’s method is called the **maximin** technique, and it works as follows:

Maximin

- Suppose we change the rules as follows: first  $E$  picks her strategy and reveals it to  $O$ . Then  $O$  picks his strategy, with knowledge of  $E$ ’s strategy. Finally, we evaluate the expected payoff of the game based on the chosen strategies. This gives us a turn-taking game to which we can apply the standard **minimax** algorithm from Chapter 6. Let’s suppose this gives an outcome  $U_{E,O}$ . Clearly, this game favors  $O$ , so the true utility  $U$  of the original game (from  $E$ ’s point of view) is *at least*  $U_{E,O}$ . For example, if we just look at pure strategies, the minimax game tree has a root value of  $-3$  (see Figure 17.2(a)), so we know that  $U \geq -3$ .
- Now suppose we change the rules to force  $O$  to reveal his strategy first, followed by  $E$ . Then the minimax value of this game is  $U_{O,E}$ , and because this game favors  $E$  we know that  $U$  is *at most*  $U_{O,E}$ . With pure strategies, the value is  $+2$  (see Figure 17.2(b)), so we know  $U \leq +2$ .

Combining these two arguments, we see that the true utility  $U$  of the solution to the original game must satisfy

$$U_{E,O} \leq U \leq U_{O,E} \quad \text{or in this case,} \quad -3 \leq U \leq 2.$$

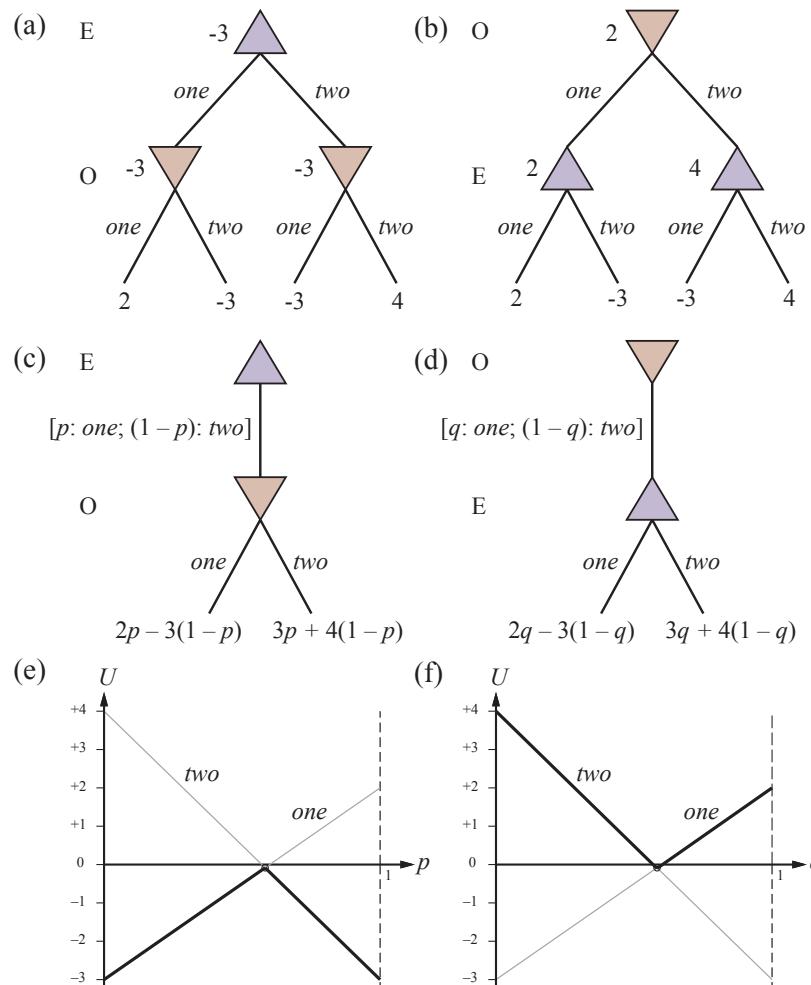

To pinpoint the value of  $U$ , we need to turn our analysis to mixed strategies. First, observe the following: *once the first player has revealed a strategy, the second player might as well choose a pure strategy*. The reason is simple: if the second player plays a mixed strategy,  $[p:\text{one};(1-p):\text{two}]$ , its expected utility is a linear combination  $(p \cdot U_{\text{one}} + (1-p) \cdot U_{\text{two}})$  of the utilities of the pure strategies,  $U_{\text{one}}$  and  $U_{\text{two}}$ . This linear combination can never be better than the better of  $U_{\text{one}}$  and  $U_{\text{two}}$ , so the second player can just choose the better one.

With this observation in mind, the minimax trees can be thought of as having infinitely many branches at the root, corresponding to the infinitely many mixed strategies the first player can choose. Each of these leads to a node with two branches corresponding to the pure strategies for the second player. We can depict these infinite trees finitely by having one “parameterized” choice at the root:

- If  $E$  chooses first, the situation is as shown in Figure 17.2(c).  $E$  chooses the strategy  $[p:\text{one};(1-p):\text{two}]$  at the root, and then  $O$  chooses a pure strategy (and hence a move) given the value of  $p$ . If  $O$  chooses *one*, the expected payoff (to  $E$ ) is  $2p - 3(1-p) = 5p - 3$ ; if  $O$  chooses *two*, the expected payoff is  $-3p + 4(1-p) = 4 - 7p$ . We can draw these two payoffs as straight lines on a graph, where  $p$  ranges from 0 to 1 on the  $x$ -axis, as shown in Figure 17.2(e).  $O$ , the minimizer, will always choose the lower of the two lines, as shown by the heavy lines in the figure. Therefore, the best that  $E$  can do at the root is to choose  $p$  to be at the intersection point, which is where

$$5p - 3 = 4 - 7p \quad \Rightarrow \quad p = 7/12.$$

The utility for  $E$  at this point is  $U_{E,O} = -1/12$ .

**Figure 17.2** (a) and (b): Minimax game trees for two-finger Morra if the players take turns playing pure strategies. (c) and (d): Parameterized game trees where the first player plays a mixed strategy. The payoffs depend on the probability parameter ( $p$  or  $q$ ) in the mixed strategy. (e) and (f): For any particular value of the probability parameter, the second player will choose the “better” of the two actions, so the value of the first player’s mixed strategy is given by the heavy lines. The first player will choose the probability parameter for the mixed strategy at the intersection point.

- If  $O$  moves first, the situation is as shown in Figure 17.2(d).  $O$  chooses the strategy  $[q:one; (1-q):two]$  at the root, and then  $E$  chooses a move given the value of  $q$ . The payoffs are  $2q - 3(1-q) = 5q - 3$  and  $-3q + 4(1-q) = 4 - 7q$ .<sup>2</sup> Again, Figure 17.2(f) shows that the best  $O$  can do at the root is to choose the intersection point:

$$5q - 3 = 4 - 7q \quad \Rightarrow \quad q = 7/12.$$

The utility for  $E$  at this point is  $U_{O,E} = -1/12$ .

<sup>2</sup> It is a coincidence that these equations are the same as those for  $p$ ; the coincidence arises because  $U_E(one,two) = U_E(two,one) = -3$ . This also explains why the optimal strategy is the same for both players.

Now we know that the true utility of the original game lies between  $-1/12$  and  $-1/12$ ; that is, it is exactly  $-1/12$ ! (The conclusion is that it is better to be *O* than *E* if you are playing this game.) Furthermore, the true utility is attained by the mixed strategy  $[7/12:one;5/12:two]$ , which should be played by both players. This strategy is called the **maximin equilibrium** of the game, and is a Nash equilibrium. Note that each component strategy in an equilibrium mixed strategy has the same expected utility. In this case, both *one* and *two* have the same expected utility,  $-1/12$ , as the mixed strategy itself.

Our result for two-finger Morra is an example of the general result by von Neumann: *every two-player zero-sum game has a maximin equilibrium when you allow mixed strategies.* Furthermore, every Nash equilibrium in a zero-sum game is a maximin for both players. A player who adopts the maximin strategy has two guarantees: First, no other strategy can do better against an opponent who plays well (although some other strategies might be better at exploiting an opponent who makes irrational mistakes). Second, the player continues to do just as well even if the strategy is revealed to the opponent.

The general algorithm for finding maximin equilibria in zero-sum games is somewhat more involved than Figures 17.2(e) and (f) might suggest. When there are  $n$  possible actions, a mixed strategy is a point in  $n$ -dimensional space and the lines become hyperplanes. It's also possible for some pure strategies for the second player to be dominated by others, so that they are not optimal against *any* strategy for the first player. After removing all such strategies (which might have to be done repeatedly), the optimal choice at the root is the highest (or lowest) intersection point of the remaining hyperplanes.

Finding this choice is an example of a **linear programming** problem: maximizing an objective function subject to linear constraints. Such problems can be solved by standard techniques in time polynomial in the number of actions (and in the number of bits used to specify the reward function, if you want to get technical).

The question remains, what should a rational agent actually *do* in playing a single game of Morra? The rational agent will have derived the fact that  $[7/12:one;5/12:two]$  is the maximin equilibrium strategy, and will assume that this is mutual knowledge with a rational opponent. The agent could use a 12-sided die or a random number generator to pick randomly according to this mixed strategy, in which case the expected payoff would be  $-1/12$  for *E*. Or the agent could just decide to play *one*, or *two*. In either case, the expected payoff remains  $-1/12$  for *E*. Curiously, unilaterally choosing a particular action does not harm one's expected payoff, but allowing the other agent to know that one has made such a unilateral decision *does* affect the expected payoff, because then the opponent can adjust strategy accordingly.

Finding equilibria in non-zero-sum games is somewhat more complicated. The general approach has two steps: (1) Enumerate all possible subsets of actions that might form mixed strategies. For example, first try all strategy profiles where each player uses a single action, then those where each player uses either one or two actions, and so on. This is exponential in the number of actions, and so only applies to relatively small games. (2) For each strategy profile enumerated in (1), check to see if it is an equilibrium. This is done by solving a set of equations and inequalities that are similar to the ones used in the zero-sum case. For two players these equations are linear and can be solved with basic linear programming techniques, but for three or more players they are nonlinear and may be very difficult to solve.

Maximin equilibrium

Repeated game  
Stage game

### 17.2.3 Repeated games

So far, we have looked only at games that last a single move. The simplest kind of multiple-move game is the **repeated game** (also called an **iterated game**), in which players repeatedly play rounds of a single-move game, called the **stage game**. A strategy in a repeated game specifies an action choice for each player at each time step for every possible history of previous choices of players.

First, let's look at the case where the stage game is repeated a fixed, finite, and mutually known number of rounds—all of these conditions are required for the following analysis to work. Let's suppose Ali and Bo are playing a repeated version of the prisoner's dilemma, and that both they know that they must play exactly 100 rounds of the game. On each round, they will be asked whether to *testify* or *refuse*, and will receive a payoff for that round according to the rules of the prisoner's dilemma that we saw above.

At the end of 100 rounds, we find the overall payoff for each player by summing that player's payoffs in the 100 rounds. What strategies should Ali and Bo choose to play this game? Consider the following argument. They both know that the 100th round will not be a repeated game—that is, its outcome can have no effect on future rounds. So, on the 100th round, they are in effect playing a single prisoner's dilemma game.

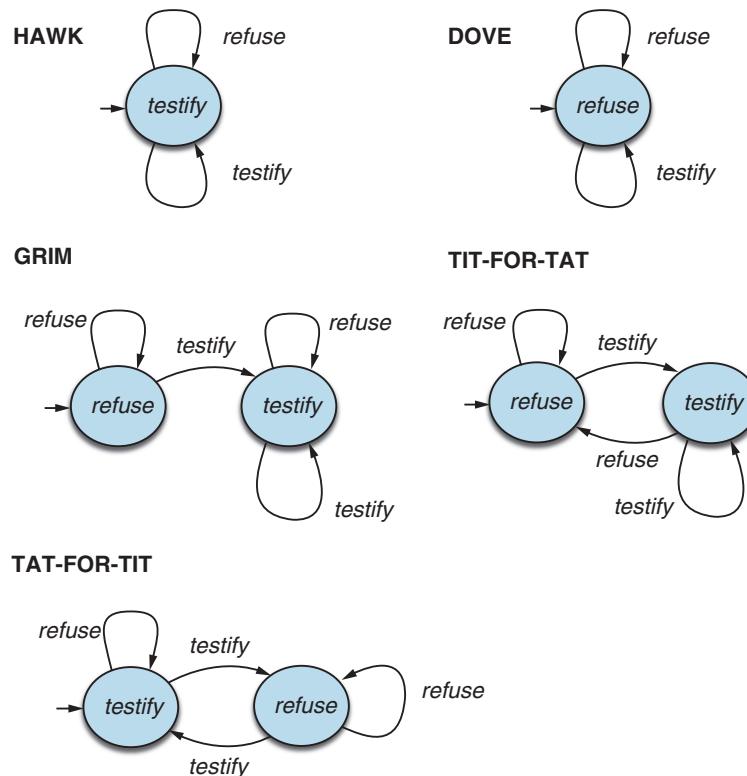

As we saw above, the outcome of the 100th round will be  $(\text{testify}, \text{testify})$ , the dominant equilibrium strategy for both players. But once the 100th round is determined, the 99th round can have no effect on subsequent rounds, so it too will yield  $(\text{testify}, \text{testify})$ . By this inductive argument, both players will choose *testify* on every round, earning a total jail sentence of 500 years each. This type of reasoning is known as **backward induction**, and plays a fundamental role in game theory.

However, if we drop one of the three conditions—fixed, finite, or mutually known—then the inductive argument doesn't hold. Suppose that the game is repeated an *infinite* number of times. Mathematically, a strategy for a player in an infinitely repeated game is a function that maps every possible finite history of the game to a choice in the stage game for that player in the corresponding round. Thus, a strategy looks at what happened previously in the game, and decides what choice to make in the current round. But we can't store an infinite table in a finite computer. We need a *finite* model of strategies for games that will be played an *infinite* number of rounds. For this reason, it is standard to represent strategies for infinitely repeated games as finite state machines (FSMs) with output.

Backward induction

Tit-for-Tat

Figure 17.3 illustrates a number of FSM strategies for the iterated prisoner's dilemma. Consider the **Tit-for-Tat** strategy. Each oval is a state of the machine, and inside the oval is the choice that would be made by the strategy if the machine was in that state. From each state, we have one outgoing edge for every possible choice of the counterpart agent: we follow the outgoing edge corresponding to the choice made by the other to find the next state of the machine. Finally, one state is labeled with an incoming arrow, indicating that it is the initial state. Thus, with TIT-FOR-TAT, the machine starts in the *refuse* state; if the counterpart agent plays *refuse*, then it stays in the *refuse* state, while if the counterpart plays *testify* it transitions to the *testify* state. It will remain in the *testify* state as long its counterpart plays *testify*, but if ever its counterpart plays *refuse*, it will transition back to the *refuse* state. In sum, TIT-FOR-TAT will start by choosing *refuse*, and will then simply copy whatever its counterpart did on the previous round.

**Figure 17.3** Some common, colorfully named finite-state machine strategies for the infinitely repeated prisoner's dilemma.

The HAWK and DOVE strategies are simpler: HAWK simply plays *testify* on every round, while DOVE simply plays *refuse* on every round. The GRIM strategy is somewhat similar to TIT-FOR-TAT, but with one important difference: if ever its counterpart plays *testify*, then it essentially turns into HAWK: it plays *testify* forever. While TIT-FOR-TAT is forgiving, in the sense that it will respond to a subsequent *refuse* by reciprocating the same, with GRIM there is no way back. Just playing *testify* once will result in punishment (playing *testify*) that goes on forever. (Can you see what TAT-FOR-TIT does?)

The next issue with infinitely repeated games is how to measure the utility of an infinite sequence of payoffs. Here, we will focus on the **limit of means** approach—essentially, this means taking the average of utilities received over the infinite sequence. With this approach, given an infinite sequence of payoffs  $(U_0, U_1, U_2, \dots)$ , we define the utility of the sequence to the corresponding player to be:

$$\lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^T U_t.$$

This value cannot be guaranteed to converge for arbitrary sequences of utilities, but it *is* guaranteed to do so for the utility sequences that are generated if we use FSM strategies. To see this, observe that if FSM strategies play against each other, then *eventually, the FSMs will reenter a configuration that they were in previously, at which point they will start to repeat*

Limit of means

*themselves.* More precisely, any utility sequence generated by FSM strategies will consist of a finite (possibly empty) non-repeating sequence, followed by a nonempty finite sequence that repeats infinitely often. To compute the average utility received by a player over that infinite sequence, we simply have to compute the average over the finite repeating sequence.

In what follows, we will assume that players in an infinitely repeated game simply choose a finite state machine to play the game on their behalf. We don't impose any constraints on these machines: they can be as big and elaborate as players want. When all players have chosen a finite state machine to play on their behalf, then we can compute the payoffs for each player using the limit of means approach as described above. In this way, an infinitely repeated game reduces to a normal form game, albeit one with infinitely many possible strategies for each player.

Let's see what happens when we play the infinitely repeated prisoner's dilemma using some strategies from Figure 17.3. First, suppose Ali and Bo both pick DOVE.

0      1      2      3      4      5      ...

Ali: DOVE *refuse refuse refuse refuse refuse refuse* ... utility = -1

Bo: DOVE *refuse refuse refuse refuse refuse refuse* ... utility = -1

It is not hard to see that this strategy pair does not form a Nash equilibrium: either player would have done better to alter their choice to HAWK. So, suppose Ali switches to HAWK:

0      1      2      3      4      5      ...

Ali: HAWK *testify testify testify testify testify testify* ... utility = 0

Bo: DOVE *refuse refuse refuse refuse refuse refuse* ... utility = -10

This is the worst possible outcome for Bo; and this strategy pair is again not a Nash equilibrium. Bo would have done better by also choosing HAWK:

0      1      2      3      4      5      ...

Ali: HAWK *testify testify testify testify testify testify* ... utility = -5

Bo: HAWK *testify testify testify testify testify testify* ... utility = -5

This strategy pair *does* form a Nash equilibrium, but not a very interesting one—it takes us more or less back to where we started in the one-shot version of the game, with both players testifying against each other. It illustrates a key property of infinitely repeated games: *Nash equilibria of the stage game will be sustained as equilibria in an infinitely repeated version of the game.*

However, our story is not over yet. Suppose that Bo switched to GRIM:

0      1      2      3      4      5      ...

Ali: HAWK *testify testify testify testify testify testify* ... utility = -5

Bo: GRIM *refuse testify testify testify testify testify* ... utility = -5

Here, Bo does no worse than playing HAWK: on the first round, Ali plays *testify* while Bo plays *refuse*, but this triggers Bo into testifying forever after: the loss of utility on the first round disappears in the limit. Overall, the two players get the same utility as if they had both played HAWK. But here is the thing: these strategies do not form a Nash equilibrium because this time, Ali has a beneficial deviation—to GRIM. If both players choose GRIM, then this is what happens:

0      1      2      3      4      5      ...

Ali: GRIM *refuse refuse refuse refuse refuse refuse* ... utility = -1

Bo: GRIM *refuse refuse refuse refuse refuse refuse* ... utility = -1

The outcomes and payoffs are the same as if both players had chosen DOVE, but unlike that case, GRIM playing against GRIM forms a Nash equilibrium, and Ali and Bo are able to rationally achieve an outcome that is impossible in the one-shot version of the game.

To see that these strategies form a Nash equilibrium, suppose for the sake of contradiction that they do not. Then one player—assume without loss of generality that it is Ali—has a beneficial deviation, in the form of an FSM strategy that would yield a higher payoff than GRIM. Now, at some point this strategy would have to do something different from GRIM—otherwise it would obtain the same utility. So, at some point it must play *testify*. But then Bo’s GRIM strategy would flip to punishment mode, by permanently testifying in response. At that point, Ali would be doomed to receive a payoff of no more than  $-5$ : worse than the  $-1$  she would have received by choosing GRIM. Thus, both players choosing GRIM forms a Nash equilibrium in the infinitely repeated prisoner’s dilemma, giving a rationally sustained outcome that is impossible in the one-shot version of the game.

This is an instance of a general class of results called the **Nash folk theorems**, which characterize the outcomes that can be sustained by Nash equilibria in infinitely repeated games. Let’s say a player’s *security value* is the best payoff that the player could guarantee to obtain. Then the general form of the Nash folk theorems is roughly that *every outcome in which every player receives at least their security value can be sustained as a Nash equilibrium in an infinitely repeated game*. GRIM strategies are the key to the folk theorems: the mutual threat of punishment if any agent fails to play their part in the desired outcome keeps players in line. But it works as a deterrent only if the other player believes you have adopted this strategy—or at least that you might have adopted it.

We can also get different solutions by changing the agents, rather than changing the rules of engagement. Suppose the agents are finite state machines with  $n$  states and they are playing a game with  $m > n$  total steps. The agents are thus incapable of representing the number of remaining steps, and must treat it as an unknown. Therefore, they cannot do the backward induction, and are free to arrive at the more favorable (*refuse, refuse*) equilibrium in the iterated Prisoner’s Dilemma. In this case, ignorance *is* bliss—or rather, having your opponent believe that you are ignorant is bliss. Your success in these repeated games depends to a significant extent on the other player’s *perception* of you as a bully or a simpleton, and not on your actual characteristics.

#### 17.2.4 Sequential games: The extensive form

In the general case, a game consists of a sequence of turns that need not be all the same. Such games are best represented by a game tree, which game theorists call the **extensive form**. The tree includes all the same information we saw in Section 6.1: an initial state  $S_0$ , a function  $\text{PLAYER}(s)$  that tells which player has the move, a function  $\text{ACTIONS}(s)$  enumerating the possible actions, a function  $\text{RESULT}(s, a)$  that defines the transition to a new state, and a partial function  $\text{UTILITY}(s, p)$ , which is defined only on terminal states, to give the payoff for each player. Stochastic games can be captured by introducing a distinguished player, *Chance*, that can take random actions. *Chance*’s “strategy” is part of the definition of the game, specified as a probability distribution over actions (the other players get to choose their own strategy). To represent games with nondeterministic actions, such as billiards, we break the action into two pieces: the player’s action itself has a deterministic result, and then *Chance* has a turn to react to the action in its own capricious way.

[Extensive form](#)

## Perfect information

For the moment, we will make one simplifying assumption: we assume players have **perfect information**. Roughly, perfect information means that, when the game calls upon them to make a decision, they know precisely where they are in the game tree: they have no uncertainty about what has happened previously in the game. This is, of course, the situation in games like chess or Go, but not in games like poker or Kriegspiel. In the following section, we will show how the extensive form can be used to capture **imperfect information** in games, but for the moment, we will assume perfect information.

A strategy in an extensive-form game of perfect information is a function for a player that for every one of its decision states  $s$  dictates which action in  $\text{ACTIONS}(s)$  the player should choose to execute. When each player has selected a strategy, then the resulting strategy profile will trace a path in the game tree from the initial state  $S_0$  to a terminal state, and the **UTILITY** function defines the utilities that each player will then receive.

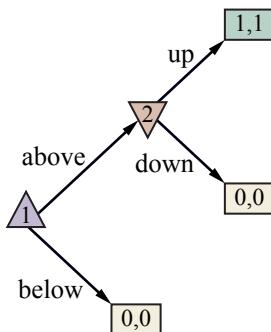

Given this setup, we can directly apply the apparatus of Nash equilibria that we introduced above to analyze extensive-form games. To compute Nash equilibria, we can use a straightforward generalization of the minimax search technique that we saw in Chapter 6. In the literature on extensive-form games, the technique is called backward induction—we already saw backward induction informally used to analyze the finitely repeated prisoner’s dilemma. Backward induction uses dynamic programming, working backwards from terminal states back to the initial state, progressively labeling each state with a payoff profile (an assignment of payoffs to players) that would be obtained if the game was played optimally from that point on.

In more detail, for each nonterminal state  $s$ , if all the children of  $s$  have been labeled with a payoff profile, then label  $s$  with a payoff profile from the child state that maximizes the payoff of the player making the decision at state  $s$ . (If there is a tie, then choose arbitrarily; if we have chance nodes, then compute expected utility.) The backward induction algorithm is guaranteed to terminate, and moreover runs in time polynomial in the size of the game tree.

As the algorithm does its work, it traces out strategies for each player. As it turns out, these strategies are Nash equilibrium strategies, and the payoff profile labeling the initial state is a payoff profile that would be obtained by playing Nash equilibrium strategies. Thus, Nash equilibrium strategies for extensive-form games can be computed in polynomial time using backward induction; and since the algorithm is guaranteed to label the initial state with a payoff profile, it follows that every extensive-form game has at least one Nash equilibrium in pure strategies.

These are attractive results, but there are several caveats. Game trees very quickly get very large, so polynomial running time should be understood in that context. But more problematically, Nash equilibrium itself has some limitations when it is applied to extensive-form games. Consider the game in Figure 17.4. Player 1 has two moves available: *above* or *below*. If she moves *below*, then both players receive a payoff of 0 (regardless of the move selected by player 2). If she moves *above*, then player 2 is presented with a choice of moving *up* or *down*: if she moves *down*, then both players receive a payoff of 0, while if she moves *up*, then they both receive 1.

Backward induction immediately tells us that  $(\text{above}, \text{up})$  is a Nash equilibrium, resulting in both players receiving a payoff of 1. However,  $(\text{below}, \text{down})$  is also a Nash equilibrium, which would result in both players receiving a payoff of 0. Player 2 is threatening player 1, by indicating that if called upon to make a decision she will choose *down*, resulting in a payoff

**Figure 17.4** An extensive-form game with a counterintuitive Nash equilibrium.

of 0 for player 1; in this case, player 1 has no better alternative than choosing *below*. The problem is that player 2's threat (to play *down*) is not a **credible threat**, because if player 2 is actually called upon to make the choice, then she will choose *up*.

A refinement of Nash equilibrium called **subgame perfect Nash equilibrium** deals with this problem. To define it, we need the idea of a **subgame**. Every decision state in a game tree (including the initial state) defines a subgame—the game in Figure 17.4 therefore contains two subgames, one rooted at player 1's decision state, one rooted at player 2's decision state. A profile of strategies then forms a subgame perfect Nash equilibrium in a game *G* if it is a Nash equilibrium in every subgame of *G*. Applying this definition to the game of Figure 17.4, we find that *(above, up)* is subgame perfect, but *(below, down)* is not, because choosing *down* is not a Nash equilibrium of the subgame rooted at player 2's decision state.

Although we needed some new terminology to define subgame perfect Nash equilibrium, we don't need any new algorithms. The strategies computed through backward induction will be subgame perfect Nash equilibria, and it follows that every extensive-form game of perfect information has a subgame perfect Nash equilibrium, which can be computed in time polynomial in the size of the game tree.

### Chance and simultaneous moves

To represent stochastic games, such as backgammon, in extensive form, we add a player called *Chance*, whose choices are determined by a probability distribution.

To represent simultaneous moves, as in the prisoner's dilemma or two-finger Morra, we impose an arbitrary order on the players, but we have the option of asserting that the earlier player's actions are not observable to the subsequent players: e.g., Ali must choose *refuse* or *testify* first, then Bo chooses, but Bo does not know what choice Ali made at that time (we can also represent the fact that the move is revealed later). However, we assume the players always remember all their own previous actions; this assumption is called **perfect recall**.

### Capturing imperfect information

A key feature of extensive form that sets it apart from the game trees that we saw in Chapter 6 is that it can capture partial observability. Game theorists use the term **imperfect information** to describe situations where players are uncertain about the actual state of the game.

Credible threat

Subgame perfect  
Nash equilibrium  
Subgame

Imperfect  
information

Unfortunately, backward induction does not work with games of imperfect information, and in general, they are considerably more complex to solve than games of perfect information.

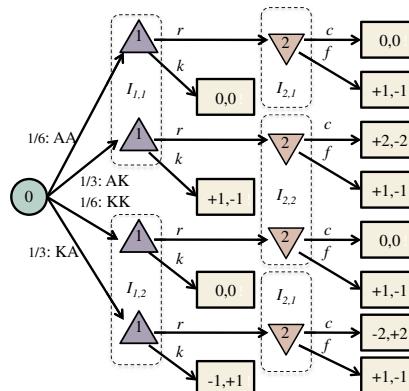

## Information set

We saw in Section 6.6 that a player in a partially observable game such as Kriegspiel can create a game tree over the space of **belief states**. With that tree, we saw that in some cases a player can find a sequence of moves (a strategy) that leads to a forced checkmate regardless of what actual state we started in, and regardless of what strategy the opponent uses. However, the techniques of Chapter 6 could not tell a player what to do when there is no guaranteed checkmate. If the player's best strategy depends on the opponent's strategy and vice versa, then minimax (or alpha–beta) by itself cannot find a solution. The extensive form *does* allow us to find solutions because it represents the belief states (game theorists call them **information sets**) of *all* players at once. From that representation we can find equilibrium solutions, just as we did with normal-form games.

As a simple example of a sequential game, place two agents in the  $4 \times 3$  world of Figure 16.1 and have them move simultaneously until one agent reaches an exit square and gets the payoff for that square. If we specify that no movement occurs when the two agents try to move into the same square simultaneously (a common problem at many traffic intersections), then certain pure strategies can get stuck forever. Thus, agents need a mixed strategy to perform well in this game: randomly choose between moving ahead and staying put. This is exactly what is done to resolve packet collisions in Ethernet networks.

Next we'll consider a very simple variant of poker. The deck has only four cards, two aces and two kings. One card is dealt to each player. The first player then has the option to *raise* the stakes of the game from 1 point to 2, or to *check*. If player 1 checks, the game is over. If player 1 raises, then player 2 has the option to *call*, accepting that the game is worth 2 points, or *fold*, conceding the 1 point. If the game does not end with a fold, then the payoff depends on the cards: it is zero for both players if they have the same card; otherwise the player with the king pays the stakes to the player with the ace.

The extensive-form tree for this game is shown in Figure 17.5. Player 0 is *Chance*; players 1 and 2 are depicted by triangles. Each action is depicted as an arrow with a label,

**Figure 17.5** Extensive form of a simplified version of poker with two players and only four cards. The moves are r (raise), f (fold), c (call), and k (check).

corresponding to a *raise*, *check*, *call*, or *fold*, or, for *Chance*, the four possible deals (“AK” means that player 1 gets an ace and player 2 a king). Terminal states are rectangles labeled by their payoff to player 1 and player 2. Information sets are shown as labeled dashed boxes; for example,  $I_{1,1}$  is the information set where it is player 1’s turn, and he knows he has an ace (but does not know what player 2 has). In information set  $I_{2,1}$ , it is player 2’s turn and she knows that she has an ace and that player 1 has raised, but does not know what card player 1 has. (Due to the limits of two-dimensional paper, this information set is shown as two boxes rather than one.)

One way to solve an extensive game is to convert it to a normal-form game. Recall that the normal form is a matrix, each row of which is labeled with a pure strategy for player 1, and each column by a pure strategy for player 2. In an extensive game a pure strategy for player  $i$  corresponds to an action for each information set involving that player. So in Figure 17.5, one pure strategy for player 1 is “raise when in  $I_{1,1}$  (that is, when I have an ace), and check when in  $I_{1,2}$  (when I have a king).” In the payoff matrix below, this strategy is called *rk*. Similarly, strategy *cf* for player 2 means “call when I have an ace and fold when I have a king.” Since this is a zero-sum game, the matrix below gives only the payoff for player 1; player 2 always has the opposite payoff:

	2:cc	2:cf	2:ff	2:fc
1:rr	0	-1/6	1	7/6
1:kr	-1/3	-1/6	5/6	2/3
1:rk	1/3	<b>0</b>	1/6	1/2
1:kk	0	<b>0</b>	0	0

This game is so simple that it has two pure-strategy equilibria, shown in bold: *cf* for player 2 and *rk* or *kk* for player 1. But in general we can solve extensive games by converting to normal form and then finding a solution (usually a mixed strategy) using standard linear programming methods. That works in theory. But if a player has  $I$  information sets and  $a$  actions per set, then that player will have  $a^I$  pure strategies. In other words, the size of the normal-form matrix is exponential in the number of information sets, so in practice the approach works only for tiny game trees—a dozen states or so. A game like two-player Texas hold ‘em poker has about  $10^{18}$  states, making this approach completely infeasible.

What are the alternatives? In Chapter 6 we saw how alpha–beta search could handle games of perfect information with huge game trees by generating the tree incrementally, by pruning some branches, and by heuristically evaluating nonterminal nodes. But that approach does not work well for games with imperfect information, for two reasons: first, it is harder to prune, because we need to consider mixed strategies that combine multiple branches, not a pure strategy that always chooses the best branch. Second, it is harder to heuristically evaluate a nonterminal node, because we are dealing with information sets, not individual states.

Koller *et al.* (1996) came to the rescue with an alternative representation of extensive games, called the **sequence form**, that is only linear in the size of the tree, rather than exponential. Rather than represent strategies, it represents paths through the tree; the number of paths is equal to the number of terminal nodes. Standard linear programming methods can again be applied to this representation. The resulting system can solve poker variants with 25,000 states in a minute or two. This is an exponential speedup over the normal-form approach, but still falls far short of handling, say, two-player Texas hold ‘em, with  $10^{18}$  states.

Sequence form

If we can't handle  $10^{18}$  states, perhaps we can simplify the problem by changing the game to a simpler form. For example, if I hold an ace and am considering the possibility that the next card will give me a pair of aces, then I don't care about the suit of the next card; under the rules of poker any suit will do equally well. This suggests forming an **abstraction** of the game, one in which suits are ignored. The resulting game tree will be smaller by a factor of  $4! = 24$ . Suppose I can solve this smaller game; how will the solution to that game relate to the original game? If no player is considering going for a flush (the only hand where the suits matter), then the solution for the abstraction will also be a solution for the original game. However, if any player is contemplating a flush, then the abstraction will be only an approximate solution (but it is possible to compute bounds on the error).

There are many opportunities for abstraction. For example, at the point in a game where each player has two cards, if I hold a pair of queens, then the other players' hands could be abstracted into three classes: *better* (only a pair of kings or a pair of aces), *same* (pair of queens) or *worse* (everything else). However, this abstraction might be too coarse. A better abstraction would divide *worse* into, say, *medium pair* (nines through jacks), *low pair*, and *no pair*. These examples are abstractions of states; it is also possible to abstract actions. For example, instead of having a bet action for each integer from 1 to 1000, we could restrict the bets to  $10^0, 10^1, 10^2$  and  $10^3$ . Or we could cut out one of the rounds of betting altogether. We can also abstract over chance nodes, by considering only a subset of the possible deals. This is equivalent to the rollout technique used in Go programs. Putting all these abstractions together, we can reduce the  $10^{18}$  states of poker to  $10^7$  states, a size that can be solved with current techniques.

We saw in Chapter 6 how poker programs such as Libratus and DeepStack were able to defeat champion human players at heads up (two-player) Texas hold 'em poker. More recently, the program Pluribus was able to defeat human champions at six-player poker in two formats: five copies of the program at the table with one human, and one copy of the program with five humans. There is a huge leap in complexity here. With one opponent, there are  $\binom{50}{2} = 1225$  possibilities for the opponent's hidden cards. But with five opponents there are  $50 \text{choose } 10 \approx 10$  billion possibilities. Pluribus develops a baseline strategy entirely from self-play, then modifies the strategy during actual game play to react to a specific situation. Pluribus uses a combination of techniques, including Monte Carlo tree search, depth-limited search, and abstraction.

The extensive form is a versatile representation: it can handle partially observable, multiagent, stochastic, sequential, real-time environments—most of the hard cases from the list of environment properties on page 61. However, there are two limitations to the extensive form in particular and game theory in general. First, it does not deal well with continuous states and actions (although there have been some extensions to the continuous case; for example, the theory of **Cournot competition** uses game theory to solve problems where two companies choose prices for their products from a continuous space). Second, game theory assumes the game is *known*. Parts of the game may be specified as unobservable to some of the players, but it must be known what parts are unobservable. In cases in which the players learn the unknown structure of the game over time, the model begins to break down. Let's examine each source of uncertainty, and whether each can be represented in game theory.

#### Cournot competition

**Actions:** There is no easy way to represent a game where the players have to discover what actions are available. Consider the game between computer virus writers and security

experts. Part of the problem is anticipating what action the virus writers will try next.

*Strategies:* Game theory is very good at representing the idea that the other players' strategies are initially unknown—as long as we assume all agents are rational. The theory does not say what to do when the other players are less than fully rational. The notion of a **Bayes–Nash equilibrium** partially addresses this point: it is an equilibrium with respect to a player's prior probability distribution over the other players' strategies—in other words, it expresses a player's beliefs about the other players' likely strategies.

Bayes–Nash equilibrium

*Chance:* If a game depends on the roll of a die, it is easy enough to model a chance node with uniform distribution over the outcomes. But what if it is possible that the die is unfair? We can represent that with another chance node, higher up in the tree, with two branches for “die is fair” and “die is unfair,” such that the corresponding nodes in each branch are in the same information set (that is, the players don't know if the die is fair or not). And what if we suspect the other opponent does know? Then we add *another* chance node, with one branch representing the case where the opponent does know, and one where the opponent doesn't.

*Utilities:* What if we don't know our opponent's utilities? Again, that can be modeled with a chance node, such that the other agent knows its own utilities in each branch, but we don't. But what if we don't know our *own* utilities? For example, how do I know if it is rational to order the chef's salad if I don't know how much I will like it? We can model that with yet another chance node specifying an unobservable “intrinsic quality” of the salad.

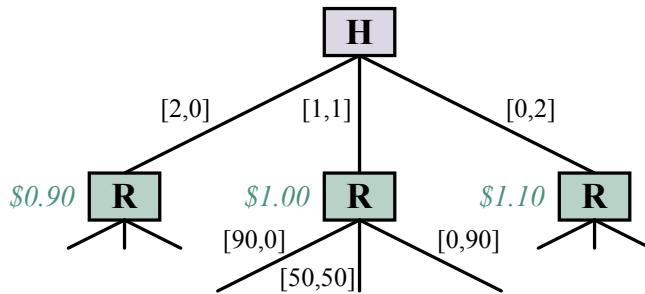

Thus, we see that game theory is good at representing most sources of uncertainty—but at the cost of doubling the size of the tree every time we add another node; a habit that quickly leads to intractably large trees. Because of these and other problems, game theory has been used primarily to *analyze* environments that are at equilibrium, rather than to *control* agents within an environment.

### 17.2.5 Uncertain payoffs and assistance games

In Chapter 1 (page 22), we noted the importance of designing AI systems that can operate under uncertainty about the true human objective. Chapter 15 (page 543) introduced a simple model for uncertainty about one's *own* preferences, using the example of durian-flavored ice cream. By the simple device of adding a new latent variable to the model to represent the unknown preferences, together with an appropriate sensor model (e.g., observing the taste of a small sample of the ice cream), uncertain preferences can be handled in a natural way.

Chapter 15 also studied the **off-switch problem**: we showed that a robot with uncertainty about human preferences will defer to the human and allow itself to be switched off. In that problem, Robbie the robot is uncertain about Harriet the human's preferences, but we model Harriet's decision (whether or not to switch Robbie off) as a simple, deterministic consequence of her own preferences for the action that Robbie proposes. Here, we generalize this idea into a full two-person game called an **assistance game**, in which both Harriet and Robbie are players. We assume that Harriet observes her own preferences  $\theta$  and acts in accordance with them, while Robbie has a prior probability  $P(\theta)$  over Harriet's preferences. The payoff is defined by  $\theta$  and is identical for both players: both Harriet and Robbie are maximizing Harriet's payoff. In this way, the assistance game provides a formal model of the idea of provably beneficial AI introduced in Chapter 1.

In addition to the deferential behavior exhibited by Robbie in the off-switch problem—which is a restricted kind of assistance game—other behaviors that emerge as equilibrium

**Figure 17.6** The paperclip game. Each branch is labeled  $[p, s]$  denoting the number of paperclips and staples manufactured on that branch. Harriet the human can choose to make two paperclips, two staples, or one of each. (The values in green italics are the values for Harriet if the game ended there, assuming  $\theta = 0.45$ .) Robbie the robot then has a choice to make 90 paperclips, 90 staples, or 50 of each.

strategies in general assistance games include actions on Harriet’s part that we would describe as teaching, rewarding, commanding, correcting, demonstrating, or explaining, as well as actions on Robbie’s part that we would describe as asking permission, learning from demonstrations, preference elicitation, and so on. The key point is that these behaviors need not be scripted: by solving the game, Harriet and Robbie work out for themselves how to convey preference information from Harriet to Robbie, so that Robbie can be more useful to Harriet. We need not stipulate in advance that Harriet is to “give rewards” or that Robbie is to “follow instructions,” although these may be reasonable interpretations of how they end up behaving.

#### Paperclip game

To illustrate assistance games, we’ll use the **paperclip game**. It’s a very simple game in which Harriet the human has an incentive to “signal” to Robbie the robot some information about her preferences. Robbie is able to interpret that signal because he can solve the game and therefore he can understand what would have to be true about Harriet’s preferences in order for her to signal in that way.

The steps of the game are depicted in Figure 17.6. It involves making paperclips and staples. Harriet’s preferences are expressed by a payoff function that depends on the number of paperclips and the number of staples produced, with a certain “exchange rate” between the two. Harriet’s preference parameter  $\theta$  denotes the relative value (in dollars) of a paperclip; for example, she might value paperclips at  $\theta = 0.45$  dollars, which means staples are worth  $1 - \theta = 0.55$  dollars. So, if  $p$  paperclips and  $s$  staples are produced, Harriet’s payoff will be  $p\theta + s(1 - \theta)$  dollars in all. Robbie’s prior is  $P(\theta) = \text{Uniform}(\theta; 0, 1)$ . In the game itself, Harriet goes first, and can choose to make two paperclips, two staples, or one of each. Then Robbie can choose to make 90 paperclips, 90 staples, or 50 of each.

Notice that if she were doing this by herself, Harriet would just make two staples, with a value of \$1.10. (See the annotations at the first level of the tree in Figure 17.6.) But Robbie is watching, and he learns from her choice. What exactly does he learn? Well, that depends on how Harriet makes her choice. How does Harriet make her choice? That depends on how Robbie is going to interpret it. We can resolve this circularity by finding a Nash equilibrium. In this case, it is unique and can be found by applying myopic best response: pick any strategy for Harriet; pick the best strategy for Robbie, given Harriet’s strategy; pick the best strategy

for Harriet, given Robbie's strategy; and so on. The process unfolds as follows:

1. Start with the greedy strategy for Harriet: make two paperclips if she prefers paperclips; make one of each if she is indifferent; make two staples if she prefers staples.
2. There are three possibilities Robbie has to consider, given this strategy for Harriet:
  - (a) If Robbie sees Harriet make two paperclips, he infers that she prefers paperclips, so he now believes the value of a paperclip is uniformly distributed between 0.5 and 1.0, with an average of 0.75. In that case, his best plan is to make 90 paperclips with an expected value of \$67.50 for Harriet.
  - (b) If Robbie sees Harriet make one of each, he infers that she values paperclips and staples at 0.50, so the best choice is to make 50 of each.
  - (c) If Robbie sees Harriet make two staples, then by the same argument as in (a), he should make 90 staples.
3. Given this strategy for Robbie, Harriet's best strategy is now somewhat different from the greedy strategy in step 1. If Robbie is going to respond to her making one of each by making 50 of each, then she is better off making one of each not just if she is exactly indifferent, but if she is anywhere close to indifferent. In fact, the optimal policy is now to make one of each if she values paperclips anywhere between about 0.446 and 0.554.
4. Given this new strategy for Harriet, Robbie's strategy remains unchanged. For example, if she chooses one of each, he infers that the value of a paperclip is uniformly distributed between 0.446 and 0.554, with an average of 0.50, so the best choice is to make 50 of each. Because Robbie's strategy is the same as in step 2, Harriet's best response will be the same as in step 3, and we have found the equilibrium.

With her strategy, Harriet is, in effect, teaching Robbie about her preferences using a simple code—a language, if you like—that emerges from the equilibrium analysis. Note also that Robbie never learns Harriet's preferences exactly, but he learns enough to act optimally on her behalf—i.e., he acts just as he would if he did know her preferences exactly. He is provably beneficial to Harriet under the assumptions stated, and under the assumption that Harriet is playing the game correctly.

Myopic best response works for this example and others like it, but not for more complex cases. It is possible to prove that provided there are no ties that cause coordination problems, finding an optimal strategy profile for an assistance game is reducible to solving a POMDP whose state space is the underlying state space of the game plus the human preference parameters  $\theta$ . POMDPs in general are very hard to solve (Section 16.5), but the POMDPs that represent assistance games have additional structure that enables more efficient algorithms.

Assistance games can be generalized to allow for multiple human participants, multiple robots, imperfectly rational humans, humans who don't know their own preferences, and so on. By providing a factored or structured action space, as opposed to the simple atomic actions in the paperclip game, the opportunities for communication can be greatly enhanced. Few of these variations have been explored so far, but we expect the key property of assistance games to remain true: the more intelligent the robot, the better the outcome for the human.

## 17.3 Cooperative Game Theory

Recall that cooperative games capture decision making scenarios in which agents can form binding agreements with one another to cooperate. They can then benefit from receiving extra value compared to what they would get by acting alone.

We start by introducing a model for a class of **cooperative games**. Formally, these games are called “cooperative games with transferable utility in characteristic function form.” The idea of the model is that when a group of agents cooperate, the group as a whole obtains some utility value, which can then be split among the group members. The model does not say what actions the agents will take, nor does the game structure itself specify how the value obtained will be split up (that will come later).

Characteristic function

Formally, we use the formula  $G = (N, v)$  to say that a cooperative game,  $G$ , is defined by a set of players  $N = \{1, \dots, n\}$  and a **characteristic function**,  $v$ , which for every subset of players  $C \subseteq N$  gives the value that the group of players could obtain, should they choose to work together.

Typically, we assume that the empty set of players achieves nothing ( $v(\{\}) = 0$ ), and that the function is nonnegative ( $v(C) \geq 0$  for all  $C$ ). In some games we make the further assumption that players achieve nothing by working alone:  $v(\{i\}) = 0$  for all  $i \in N$ .

Coalition

It is conventional to refer to a subset of players  $C$  as a **coalition**. In everyday use the term “coalition” implies a collection of people with some common cause (such as the Coalition to Stop Gun Violence), but we will refer to *any* subset of players as a coalition. The set of all players  $N$  is known as the **grand coalition**.

Grand coalition

Coalition structure

In our model, every player must choose to join exactly one coalition (which could be a coalition of just the single player alone). Thus, the coalitions form a **partition** of the set of players. We call the partition a **coalition structure**. Formally, a coalition structure over a set of players  $N$  is a set of coalitions  $\{C_1, \dots, C_k\}$  such that:

$$\begin{aligned} C_i &\neq \{\} \\ C_i &\subseteq N \\ C_i \cap C_j &= \{\} \text{ for all } i \neq j \in N \\ C_1 \cup \dots \cup C_k &= N. \end{aligned}$$

For example, if we have  $N = \{1, 2, 3\}$ , then there are seven possible coalitions:

$$\{1\}, \{2\}, \{3\}, \{1, 2\}, \{2, 3\}, \{3, 1\}, \text{ and } \{1, 2, 3\}$$

and five possible coalition structures:

$$\{\{1\}, \{2\}, \{3\}\}, \{\{1\}, \{2, 3\}\}, \{\{2\}, \{1, 3\}\}, \{\{3\}, \{1, 2\}\}, \text{ and } \{\{1, 2, 3\}\}.$$

Payoff vector

We use the notation  $\mathbf{CS}(N)$  to denote the set of all coalition structures over player set  $N$ , and  $CS(i)$  to denote the coalition that player  $i$  belongs to.

The **outcome** of a game is defined by the choices the players make, in deciding which coalitions to form, and in choosing how to divide up the  $v(C)$  value that each coalition receives. Formally, given a cooperative game defined by  $(N, v)$ , the outcome is a pair  $(CS, \mathbf{x})$  consisting of a coalition structure and a **payoff vector**  $\mathbf{x} = (x_1, \dots, x_n)$  where  $x_i$  is the value

that goes to player  $i$ . The payoff must satisfy the constraint that each coalition  $C$  splits up all of its value  $v(C)$  among its members:

$$\sum_{i \in C} x_i = v(C) \quad \text{for all } C \subseteq N$$

For example, given the game  $(\{1, 2, 3\}, v)$  where  $v(\{1\})=4$  and  $v(\{2, 3\})=10$ , a possible outcome is:

$$(\{\{1\}, \{2, 3\}\}, (4, 5, 5)).$$

That is, player 1 stays alone and accepts a value of 4, while players 2 and 3 team up to receive a value of 10, which they choose to split evenly.

Some cooperative games have the feature that when two coalitions merge together, they do no worse than if they had stayed apart. This property is called **superadditivity**. Formally, Superadditivity a game is superadditive if its characteristic function satisfies the following condition:

$$v(C \cup D) \geq v(C) + v(D) \quad \text{for all } C, D \subseteq N$$

If a game is superadditive, then the grand coalition receives a value that is at least as high as or higher than the total received by any other coalition structure. However, as we will see shortly, superadditive games do not always end up with a grand coalition, for much the same reason that the players do not always arrive at a collectively desirable Pareto-optimal outcome in the prisoner's dilemma.

### 17.3.2 Strategy in cooperative games

The basic assumption in cooperative game theory is that players will make strategic decisions about who they will cooperate with. Intuitively, players will not desire to work with unproductive players—they will naturally seek out players that collectively yield a high coalitional value. But these sought-after players will be doing their own strategic reasoning. Before we can describe this reasoning, we need some further definitions.

An **imputation** for a cooperative game  $(N, v)$  is a payoff vector that satisfies the following two conditions: Imputation

$$\begin{aligned} \sum_{i=1}^n x_i &= v(N) \\ x_i &\geq v(\{i\}) \text{ for all } i \in N. \end{aligned}$$

The first condition says that an imputation must distribute the total value of the grand coalition; the second condition, known as **individual rationality**, says that each player is at least as well off as if it had worked alone. Individual rationality

Given an imputation  $\mathbf{x} = (x_1, \dots, x_n)$  and a coalition  $C \subseteq N$ , we define  $x(C)$  to be the sum  $\sum_{i \in C} x_i$ —the total amount disbursed to  $C$  by the imputation  $\mathbf{x}$ .

Next, we define the **core** of a game  $(N, v)$  as the set of all imputations  $\mathbf{x}$  that satisfy the condition  $x(C) \geq v(C)$  for every possible coalition  $C \subset N$ . Thus, if an imputation  $\mathbf{x}$  is *not* in the core, then there exists some coalition  $C \subset N$  such that  $v(C) > x(C)$ . The players in  $C$  would refuse to join the grand coalition because they would be better off sticking with  $C$ . Core

The core of a game therefore consists of all the possible payoff vectors that no coalition could object to on the grounds that they could do better by not joining the grand coalition. Thus, if the core is empty, then the grand coalition cannot form, because no matter how the grand coalition divided its payoff, some smaller coalition would refuse to join. The main computational questions around the core relate to whether or not it is empty, and whether a particular payoff distribution is in the core.

The definition of the core naturally leads to a system of linear inequalities, as follows (the unknowns are variables  $x_1, \dots, x_n$ , and the values  $v(C)$  are constants):

$$\begin{aligned} x_i &\geq v(\{i\}) \quad \text{for all } i \in N \\ \sum_{i \in N} x_i &= v(N) \\ \sum_{i \in C} x_i &\geq v(C) \quad \text{for all } C \subseteq N \end{aligned}$$

Any solution to these inequalities will define an imputation in the core. We can formulate the inequalities as a linear program by using a dummy objective function (for example, maximizing  $\sum_{i \in N} x_i$ ), which will allow us to compute imputations in time polynomial in the number of inequalities. The difficulty is that this gives an exponential number of inequalities (one for each of the  $2^n$  possible coalitions). Thus, this approach yields an algorithm for checking non-emptiness of the core that runs in exponential time. Whether we can do better than this depends on the game being studied: for many classes of cooperative game, the problem of checking non-emptiness of the core is co-NP-complete. We give an example below.

Before proceeding, let's see an example of a superadditive game with an empty core. The game has three players  $N = \{1, 2, 3\}$ , and has a characteristic function defined as follows:

$$v(C) = \begin{cases} 1 & \text{if } |C| \geq 2 \\ 0 & \text{otherwise.} \end{cases}$$

Now consider any imputation  $(x_1, x_2, x_3)$  for this game. Since  $v(N) = 1$ , it must be the case that at least one player  $i$  has  $x_i > 0$ , and the other two get a total payoff less than 1. Those two could benefit by forming a coalition without player  $i$  and sharing the value 1 among themselves. But since this holds for all imputations, the core must be empty.

The core formalizes the idea of the grand coalition being *stable*, in the sense that no coalition can profitably defect from it. However, the core may contain imputations that are *unreasonable*, in the sense that one or more players might feel they were unfair. Suppose  $N = \{1, 2\}$ , and we have a characteristic function  $v$  defined as follows:

$$\begin{aligned} v(\{1\}) &= v(\{2\}) = 5 \\ v(\{1, 2\}) &= 20. \end{aligned}$$

Here, cooperation yields a surplus of 10 over what players could obtain working in isolation, and so intuitively, cooperation will make sense in this scenario. Now, it is easy to see that the imputation  $(6, 14)$  is in the core of this game: neither player can deviate to obtain a higher utility. But from the point of view of player 1, this might appear unreasonable, because it gives 9/10 of the surplus to player 2. Thus, the notion of the core tells us when a grand coalition can form, but it does not tell us how to distribute the payoff.

#### Shapley value

The **Shapley value** is an elegant proposal for how to divide the  $v(N)$  value among the players, given that the grand coalition  $N$  formed. Formulated by Nobel laureate Lloyd Shapley in the early 1950s, the Shapley value is intended to be a *fair* distribution scheme.

What does *fair* mean? It would be unfair to distribute  $v(N)$  based on the eye color of players, or their gender, or skin color. Students often suggest that the value  $v(N)$  should be divided equally, which seems like it might be fair, until we consider that this would give the same reward to players that contribute a lot and players that contribute nothing. Shapley's insight was to suggest that the only fair way to divide the value  $v(N)$  was to do so according to how much each player *contributed* to creating the value  $v(N)$ .

#### Marginal contribution

First we need to define the notion of a player's **marginal contribution**. The marginal

contribution that a player  $i$  makes to a coalition  $C$  is the value that  $i$  would add (or remove), should  $i$  join the coalition  $C$ . Formally, the marginal contribution that player  $i$  makes to  $C$  is denoted by  $mc_i(C)$ :

$$mc_i(C) = v(C \cup \{i\}) - v(C).$$

Now, a first attempt to define a payoff division scheme in line with Shapley's suggestion that players should be rewarded according to their contribution would be to pay each player  $i$  the value that they would add to the coalition containing all other players:

$$mc_i(N - \{i\}).$$

The problem is that this implicitly assumes that player  $i$  is the *last* player to enter the coalition. So, Shapley suggested, we need to consider all possible ways that the grand coalition could form, that is, all possible orderings of the players  $N$ , and consider the value that  $i$  adds to the preceding players in the ordering. Then, a player should be rewarded by being paid *the average marginal contribution that player  $i$  makes, over all possible orderings of the players, to the set of players preceding  $i$  in the ordering*.

We let  $\mathcal{P}$  denote all possible permutations (e.g., orderings) of the players  $N$ , and denote members of  $\mathcal{P}$  by  $p, p', \dots$  etc. Where  $p \in \mathcal{P}$  and  $i \in N$ , we denote by  $p_i$  the set of players that precede  $i$  in the ordering  $p$ . Then the Shapley value for a game  $G$  is the imputation  $\phi(G) = (\phi_1(G), \dots, \phi_n(G))$  defined as follows:

$$\phi_i(G) = \frac{1}{n!} \sum_{p \in \mathcal{P}} mc_i(p_i). \quad (17.1)$$

This should convince you that the Shapley value is a reasonable proposal. But the remarkable fact is that it is the *unique* solution to a set of axioms that characterizes a “fair” payoff distribution scheme. We'll need some more definitions before defining the axioms.

We define a **dummy player** as a player  $i$  that never adds any value to a coalition—that is,  $mc_i(C) = 0$  for all  $C \subseteq N - \{i\}$ . We will say that two players  $i$  and  $j$  are **symmetric players** if they always make *identical* contributions to coalitions—that is,  $mc_i(C) = mc_j(C)$  for all  $C \subseteq N - \{i, j\}$ . Finally, where  $G = (N, v)$  and  $G' = (N, v')$  are games with the same set of players, the game  $G + G'$  is the game with the same player set, and a characteristic function  $v''$  defined by  $v''(C) = v(C) + v'(C)$ .

Dummy player  
Symmetric players

Given these definitions, we can define the fairness axioms satisfied by the Shapley value:

- **Efficiency:**  $\sum_{i \in N} \phi_i(G) = v(N)$ . (All the value should be distributed.)
- **Dummy Player:** If  $i$  is a dummy player in  $G$  then  $\phi_i(G) = 0$ . (Players who never contribute anything should never receive anything.)
- **Symmetry:** If  $i$  and  $j$  are symmetric in  $G$  then  $\phi_i(G) = \phi_j(G)$ . (Players who make identical contributions should receive identical payoffs.)
- **Additivity:** The value is additive over games: For all games  $G = (N, v)$  and  $G' = (N, v')$ , and for all players  $i \in N$ , we have  $\phi_i(G + G') = \phi_i(G) + \phi_i(G')$ .

The additivity axiom is admittedly rather technical. If we accept it as a requirement, however, we can establish the following key property: *the Shapley value is the only way to distribute coalitional value so as to satisfy these fairness axioms.*

### 17.3.3 Computation in cooperative games

From a theoretical point of view, we now have a satisfactory solution. But from a computational point of view, we need to know how to *compactly represent* cooperative games, and how to *efficiently compute* solution concepts such as the core and the Shapley value.

The obvious representation for a characteristic function would be a table listing the value  $v(C)$  for all  $2^n$  coalitions. This is infeasible for large  $n$ . A number of approaches to compactly representing cooperative games have been developed, which can be distinguished by whether or not they are *complete*. A complete representation scheme is one that is capable of representing *any* cooperative game. The drawback with complete representation schemes is that there will always be some games that cannot be represented compactly. An alternative is to use a representation scheme that is guaranteed to be compact, but which is not complete.

#### Marginal contribution nets

Marginal contribution net

We now describe one representation scheme, called **marginal contribution nets** (MC-nets). We will use a slightly simplified version to facilitate presentation, and the simplification makes it incomplete—the full version of MC-nets is a complete representation.

The idea behind marginal contribution nets is to represent the characteristic function of a game  $(N, v)$  as a set of coalition-value rules, of the form:  $(C_i, x_i)$ , where  $C_i \subseteq N$  is a coalition and  $x_i$  is a number. To compute the value of a coalition  $C$ , we simply sum the values of all rules  $(C_i, x_i)$  such that  $C_i \subseteq C$ . Thus, given a set of rules  $R = \{(C_1, x_1), \dots, (C_k, x_k)\}$ , the corresponding characteristic function is:

$$v(C) = \sum \{x_i \mid (C_i, x_i) \in R \text{ and } C_i \subseteq C\}.$$

Suppose we have a rule set  $R$  containing the following three rules:

$$\{\{\{1, 2\}, 5\}, \{\{2\}, 2\}, \{\{3\}, 4\}\}.$$

Then, for example, we have:

- $v(\{1\}) = 0$  (because no rules apply),
- $v(\{3\}) = 4$  (third rule),
- $v(\{1, 3\}) = 4$  (third rule),
- $v(\{2, 3\}) = 6$  (second and third rules), and
- $v(\{1, 2, 3\}) = 11$  (first, second, and third rules).

With this representation we can compute the Shapley value in polynomial time. The key insight is that each rule can be understood as defining a game on its own, in which the players are symmetric. By appealing to Shapley's axioms of additivity and symmetry, therefore, the Shapley value  $\phi_i(R)$  of player  $i$  in the game associated with the rule set  $R$  is then simply:

$$\phi_i(R) = \sum_{(C, x) \in R} \begin{cases} \frac{x}{|C|} & \text{if } i \in C \\ 0 & \text{otherwise.} \end{cases}$$

The version of marginal contribution nets that we have presented here is not a *complete* representation scheme: there are games whose characteristic function cannot be represented using rule sets of the form described above. A richer type of marginal contribution networks allows for rules of the form  $(\phi, x)$ , where  $\phi$  is a propositional logic formula over the players  $N$ : a coalition  $C$  satisfies the condition  $\phi$  if it corresponds to a satisfying assignment for  $\phi$ .

**Figure 17.7** The coalition structure graph for  $N = \{1, 2, 3, 4\}$ . Level 1 has coalition structures containing a single coalition; level 2 has coalition structures containing two coalitions, and so on.

This scheme is a complete representation—in the worst case, we need a rule for every possible coalition. Moreover, the Shapley value can be computed in polynomial time with this scheme; the details are more involved than for the simple rules described above, although the basic principle is the same; see the notes at the end of the chapter for references.

### Coalition structures for maximum social welfare

We obtain a different perspective on cooperative games if we assume that the agents share a common purpose. For example, if we think of the agents as being workers in a company, then the strategic considerations relating to coalition formation that are addressed by the core, for example, are not relevant. Instead, we might want to organize the workforce (the agents) into teams so as to maximize their overall productivity. More generally, the task is to find a coalition that maximizes the *social welfare* of the system, defined as the sum of the values of the individual coalitions. We write the social welfare of a coalition structure  $CS$  as  $sw(CS)$ , with the following definition:

$$sw(CS) = \sum_{C \in CS} v(C).$$

Then a socially optimal coalition structure  $CS^*$  with respect to  $G$  maximizes this quantity. Finding a socially optimal coalition structure is a very natural computational problem, which has been studied beyond the multiagent systems community: it is sometimes called the **set partitioning problem**. Unfortunately, the problem is NP-hard, because the number of possible coalition structures grows exponentially in the number of players.

Set partitioning problem

Coalition structure graph

Finding the optimal coalition structure by naive exhaustive search is therefore infeasible in general. An influential approach to optimal coalition structure formation is based on the idea of searching a subspace of the **coalition structure graph**. The idea is best explained with reference to an example.

Suppose we have a game with four agents,  $N = \{1, 2, 3, 4\}$ . There are fifteen possible coalition structures for this set of agents. We can organize these into a coalition structure graph as shown in Figure 17.7, where the nodes at level  $\ell$  of the graph correspond to all the coalition structures with exactly  $\ell$  coalitions. An upward edge in the graph represents the division of a coalition in the lower node into two separate coalitions in the upper node.

For example, there is an edge from  $\{\{1\}, \{2, 3, 4\}\}$  to  $\{\{1\}, \{2\}, \{3, 4\}\}$  because this latter coalition structure is obtained from the former by dividing the coalition  $\{2, 3, 4\}$  into the coalitions  $\{2\}$  and  $\{3, 4\}$ .

The optimal coalition structure  $CS^*$  lies somewhere within the coalition structure graph, and so to find this, it seems we would have to evaluate every node in the graph. But consider the bottom two rows of the graph—levels 1 and 2. Every possible coalition (excluding the empty coalition) appears in these two levels. (Of course, not every possible coalition structure appears in these two levels.) Now, suppose we restrict our search for a possible coalition structure to *just* these two levels—we go no higher in the graph. Let  $CS'$  be the best coalition structure that we find in these two levels, and let  $CS^*$  be the best coalition structure overall. Let  $C^*$  be a coalition with the highest value of all possible coalitions:

$$C^* \in \arg \max_{C \subseteq N} v(C).$$

The value of the best coalition structure we find in the first two levels of the coalition structure graph must be at least as much as the value of the best possible coalition:  $sw(CS') \geq v(C^*)$ . This is because every possible coalition appears in at least one coalition structure in the first two levels of the graph. So assume the worst case, that is,  $sw(CS') = v(C^*)$ .
